Initiation and Use of Propranolol for Infantile Hemangioma: Report of a Consensus Conference

abstract

Infantile hemangiomas (IHs) are common neoplasms composed of proliferating endothelial-like cells. Despite the relative frequency of IH and the potential severity of complications, there are currently no uniform guidelines for treatment. Although propranolol has rapidly been adopted, there is significant uncertainty and divergence of opinion regarding safety monitoring, dose escalation, and its use in PHACE syndrome (PHACE = posterior fossa, hemangioma, arterial lesions, cardiac abnormalities, eye abnormalities; a cutaneous neurovascular syndrome characterized by large, segmental hemangiomas of the head and neck along with congenital anomalies of the brain, heart, eyes and/or chest wall). A consensus conference was held on December 9, 2011. The multidisciplinary team reviewed existing data on the pharmacologic properties of propranolol and all published reports pertaining to the use of propranolol in pediatric patients. Workgroups were assigned specific topics to propose protocols on the following subjects: contraindications, special populations, pretreatment evaluation, dose escalation, and monitoring. Consensus protocols were recorded during the meeting and refined after the meeting. When appropriate, protocol clarifications and revision were made and agreed upon by the group via teleconference. Because of the absence of high-quality clinical research data, evidence-based recommendations are not possible at present. However, the team agreed on a number of recommendations that arose from a review of existing evidence, including when to treat complicated IH; contraindications and pretreatment evaluation protocols; propranolol use in PHACE syndrome; formulation, target dose, and frequency of propranolol; initiation of propranolol in infants; cardiovascular monitoring; ongoing monitoring; and prevention of hypoglycemia. Where there was considerable controversy, the more conservative approach was selected. We acknowledge that the recommendations are conservative in nature and anticipate that they will be revised as more data are made available. Pediatrics 2013;131:128–140

PHACE—posterior fossa, hemangioma, arterial lesions, cardiac abnormalities, eye abnormalities

(Continued on last page)
Infantile hemangiomas (IHs) are common benign tumors composed of proliferating endothelial-like cells. The duration and rate of growth are variable; some infants will have hemangiomas that grow very little, whereas others grow rapidly and at an unpredictable rate. Although most are not worrisome, ∼12% of IHs are significantly complex, requiring referral to specialists for consideration of treatment. Complications of hemangiomas, for which systemic pharmacotherapy is typically initiated, include permanent disfigurement, ulceration, bleeding, visual compromise, airway obstruction, congestive heart failure and, rarely, death. Despite the relative frequency of IH and the potential severity of complications, uniform guidelines for treatment are lacking.

There are no US Food and Drug Administration (FDA)-approved agents for the treatment of IH, and treatment is currently based on expert opinion and observational studies. Prospective data addressing the efficacy and safety of any pharmacologic interventions for the treatment of IH have not been generated, and available data are confounded by the lack of a consensus on treatment criteria and objective outcome measures. Agents with reported activity in treating IH include corticosteroids, interferon α, vinca alkaloids, and, recently, propranolol.

Since the initial report of propranolol use for the treatment of IH in 2008, there has been a flurry of case reports and case series describing its efficacy and potential side effects. These publications were not subjected to the usual stringency of phase I/II/III clinical trials, and most were not prospective, randomized, or controlled. With clinical use, propranolol has been found to be rapidly effective for IH, well tolerated, and better than previous therapies at inducing regression. These observations, coupled with the immediate availability of the medication in a pediatric formulation, have led to a rapid and widespread adoption of propranolol for IH. Propranolol suspension is commercially available in the United States, but it does not currently have an FDA-approved indication for children. Cardiologists have historically used this medication in infants with the diagnosis of supraventricular tachycardia. In contrast to infants with supraventricular tachycardia, for whom initiation of propranolol typically occurs in an inpatient setting with extensive cardiac monitoring, the great majority of infants treated for IH are cardiac healthy and are treated in an outpatient setting. Guidelines for dose initiation, dose escalation, and toxicity monitoring were never generated for use with IH; therefore, each institution designed unique protocols. These protocols vary considerably; some centers hospitalize all children for initiation of treatment, whereas others do so only rarely. Some experts recommend intensive outpatient monitoring of patients, whereas others do little to no monitoring.

The distinct circumstances in which propranolol has become so widely used underscores the importance of bringing multiple specialties together to gain consensus regarding dose initiation, safety monitoring, dose escalation, and its use in specific situations (eg, PHACE syndrome). In this report, we review existing data on the pharmacologic properties of propranolol and all published reports pertaining to the use of propranolol in pediatric patients. With this review as the evidence base, a multidisciplinary, multiinstitutional expert panel met in December 2011 to develop a standardized, consensus-derived set of best practices for the use of propranolol in infants with IH. As more information accumulates, it is expected that this provisional set of best practices will change.

### REVIEW

#### Pharmacologic Properties of Propranolol

Propranolol is a synthetic, β-adrenergic receptor-blocking agent that is classified as nonselective because it blocks both β1- and β2-adrenergic receptors. Chronotropic, inotropic, and vasodilator responses decrease proportionately when propranolol blocks the β-receptor site, resulting in a decrease in heart rate (HR) and blood pressure (BP). Propranolol is highly lipophilic and undergoes first-pass metabolism by the liver with only ∼25% of oral propranolol reaching the systemic circulation. Multiple pathways in the cytochrome P450 system are involved in propranolol’s metabolism, making clinically important drug interactions a potential issue (Table 1).

Propranolol had previously been used in pediatric patients primarily for the treatment or prevention of cardiac arrhythmias, hypertension, outflow obstructions in congenital heart disease, and hypertrophic cardiomyopathy. Its antihypertensive effects result from decreased HR, decreased cardiac contractility, inhibition of renin release by the kidneys, and decreased sympathetic

**Propranolol Use for IH**

A comprehensive review of the literature was undertaken to understand the breadth of current clinical practice. A PubMed search cross-referenced with Google Scholar last performed on December 7, 2011, using the search terms “propranolol” and “hemangioma” yielded 177 articles. Of these, 115 articles were written in English and discussed use in humans. Thirty additional articles were excluded because they were nonapplicable or lacked sufficient clinical data. Eighty-five articles (including 1175 patients) were reviewed in detail.4,11,13,15,18,21,23,24,26

The majority of these publications included <5 patients, and nearly all were retrospective reports. There was only 1 prospective trial and 1 meta-analysis.58,80 Nearly half (35/85; 41%) of the publications included patients still undergoing treatment; therefore, adverse events may be underestimated. Although there was significant variability in the details provided by each article, the authors chose to be inclusive to understand the breadth of current clinical practice.

Response to therapy was discussed in 79 articles, and the definitions and measures of response varied widely, from “stabilization” to “complete response.” Fewer than 10 articles attempted to quantify the degree of involution.13,15,23,41,42,58 Positive response in all treated patients was reported in 86% of publications; the remaining 14% discussed at least some treatment failures. In total, 19 of 1175 published patients were reported as treatment failures, suggesting a 1.6% treatment failure rate. This rate may be underestimated because treatment failures may not be as commonly reported.

**Adverse Events of Propranolol in the Pediatric Population**

Although propranolol has been well studied in adults, observations of its use in infants and children, nearly 40 years in duration, have been mainly anecdotal. There are no FDA-approved indications for propranolol in pediatric patients in the United States. There is 1 active phase II/III Investigational New Drug application (ClinicalTrials.gov NCT1056341) for the use of propranolol for the treatment of IH. On the basis of case reports and case series, oral propranolol appears to have a favorable safety profile in children. Deaths or acute heart failure have been associated with propranolol initiation only in the settings of intravenous administration or drug overdose.105,106

Given the variability in study design and the retrospective nature of most reports, the true incidence of adverse events in IH population is difficult to ascertain. For example, routine screening for bradycardia was only documented in 128 of 1175 (10%) of patients reported. Of the 85 articles, 48 (56%) reported no complications in any patient, although reports of complications with propranolol usage increased over time from 2008 to 2011 (Table 2). The most frequently reported serious complications were asymptomatic hypotension or hypotension for which no additional details were provided; pulmonary symptoms related to direct blockade of adrenergic bronchodilation; hypoglycemia or hypoglycemic seizure; asymptomatic bradycardia; and hyperkalemia. The most commonly reported nonpotentially life-threatening complications were sleep disturbances including nightmares, somnolence, cool or mottled extremities, diarrhea, and gastroesophageal reflux/upset.

**Bradycardia and Hypotension**

As a β-blocker, propranolol decreases HR and, in part, BP as a result of negative chronotropic and inotropic effects on the heart. Propranolol’s effects on BP and HR in children peak

around 2 hours after an oral dose.\textsuperscript{47} The reported protocols for initial dose, dose titration, and prospective monitoring were extremely variable and therefore difficult to compare in a uniform fashion. Three prospective studies, although limited by small patient numbers and significant missing data, provide useful information. During initiation of propranolol for IH in infants, bradycardia (2 SD of normal) and hypotension (2 SD of normal) after the first dose (2 mg/kg/day divided 3 times daily) were infrequent and asymptomatic.\textsuperscript{47} Changes (z scores) in systolic BP from baseline occurred in 7%, 22%, and 13% at 1, 2, and 3 hours postpropranolol dosing, respectively. For HR, there were no changes at any time point measured. As a group, significant changes in BP occurred only at 2 hours.\textsuperscript{47} In 28 patients treated for IH with doses up to 4 mg/kg/day, bradycardia was not noted as a side effect. In a separate study of 25 infants by Schiestl and colleagues, HR was continuously monitored during sleep and transient bradycardia was reported in 4/25 infants. Decrease in diastolic BP, 50th percentile was noted in 16 of 28 patients (57%) in 1 study, but only 1 patient developed clinically recognizable changes with cold extremities and prolonged capillary refill.\textsuperscript{59} Hypoglycemia Symptomatic hypoglycemia and hypoglycemic seizures have been reported in infants with IH treated with oral propranolol (Table 3).\textsuperscript{59,61,63,64,86,88,90,107} These cases occurred in both newborns and toddlers but were often ascribed to concomitant infection. The mechanism through which propranolol is induced hypoglycemia are not completely understood. Nonselective \( \beta \)-blockers, such as propranolol, may block \( \beta \)-receptors and lower glycogenolysis and gluconeogenesis. The mechanisms through which propranolol-induced hypoglycemia develop are not completely understood. Nonselective \( \beta \)-blockers, such as propranolol, may block \( \beta \)-receptors and lower glycogenolysis and gluconeogenesis.

ergic bronchodilation. Certainly, the result of its direct blockade of adrenergic receptors is a reduction of wheezing, bronchospasm, or exacerbation of asthma/bronchitis, is a recognized side effect of propranolol as the result of its direct blockade of adrenergic bronchodilation. Certainly, the use of propranolol in the setting of known reactive airway disease must be considered cautiously. The development of bronchial hyperreactivity in the setting of an acute viral illness in patients on propranolol has necessitated temporary discontinuation of therapy.

**Hyperkalemia**

Hyperkalemia (without electrocardiographic changes) was reported in 2 children on propranolol for IH. The cause of the hyperkalemia is not known, but the authors postulate that it was tumor lysis from the large ulcerated IH combined with impaired potassium uptake into cells as the result of β blockade. Dental caries have been reported in 2 pediatric patients treated with propranolol, although this may be related to the formulation of the suspension (if it contains sucrose). β-adrenergic antagonism of salivary gland function resulting in decreased salivation has also been postulated as a contributing factor.

**Survey of Propranolol Use for IH**

A survey was designed and was distributed to established prescribers of propranolol in Fall 2011 for IH by Drs Sarah L. Chamlin, Beth A. Drolet, Anita N. Haggstrom, and Anthony J. Mancini. The response rate was 76%, and most respondents were pediatric dermatologists (88%), academicians (84%), and experienced clinicians with a mean of 15.25 years in practice. Before starting propranolol, the following studies were obtained with the noted frequency: electrocardiogram (ECG; 81%), BP measurement (41%), echocardiogram (38%), and HR measurement (38%). Cardiology consultation was “always obtained” by 34% of respondents and “never obtained” by 25%, with the remainder (41%) stating that they “sometimes obtained” such consultation. Seventeen (53%) prescribers “always” or “sometimes” admitted patients to the hospital to initiate therapy, with only 3 of these prescribers stating that they always admitted. The other respondents admitting children did so under special circumstances, including young age (under 6–8 weeks), extreme prematurity, significant comorbidity, PHACE syndrome, airway hemangioma, and poor social situations. Most respondents (81%) started propranolol at 0.5 to 1.0 mg/kg per day, with a goal dose of 2.0 mg/kg per day in 84% of patients. Dosing was twice daily for 38% and 3 times daily for 47%, with the remaining 15% dosing 3 times daily initially with a change to twice daily when the child was older (6–12 months of age).

**Consensus Methods**

A consensus conference was held in Chicago, Illinois, on December 9, 2011. This conference was sponsored by the National Institute of Arthritis and Musculoskeletal and Skin Diseases (1R34AR060881-01). Twenty-eight participants attended from 12 institutions, representing 5 specialties. Collectively, the group has treated >1000 infants with propranolol for IH. Given the inconsistencies in current institutional policies, consensus was difficult to obtain on all issues. Because of the especially vulnerable patient population of infants aged 1 to 6 months, the group chose to remain cautious in the approach to these recommendations. Where there was considerable controversy, the more conservative approach was selected until additional safety data can be obtained.

Results of the survey were shared, and participants were asked to review all existing literature on the use and adverse effects of propranolol in the treatment of IH, PHACE syndrome, and other indications in the pediatric population. These data were summarized, and work groups were assigned specific
topics to propose protocols on the following subjects: contraindications, special populations, pretreatment evaluation, dose escalation and monitoring, and patient education. These protocols were presented to the entire group and debated using an iterative process (nominal group technique).110 Consensus protocols were recorded during the meeting, refined after the meeting, and resubmitted to the entire group for discussion by teleconference and electronic review. Comments were recorded and discussed, and when appropriate, protocol clarifications and revisions were made and agreed on by the group via teleconference.

Because of the absence of high-quality clinical research data, evidence-based recommendations are not possible at the present time, and these are not American Academy of Pediatrics—endorsed recommendations. However, the multidisciplinary team agreed on a number of recommendations that arose from a review of existing evidence. It is acknowledged that, in many areas, evidence is generally confined to expert opinion, case reports, observational or descriptive studies, and uncontrolled studies. We acknowledge that the following recommendations are conservative in nature, and we anticipate that they will be revised as more data are made available.

CONSENSUS RECOMMENDATIONS

When to Treat IH

Given the wide spectrum of disease and the natural tendency for involution, the greatest challenge in caring for infants with IH is determining which infants are at highest risk for complications and in need of systemic treatment. Medical management is highly individualized, and treatment with oral propranolol is considered in the presence of ulceration, impairment of a vital function (ocular compromise or airway obstruction), or risk of permanent disfigurement. Before the initiation of therapy, the potential risks of adverse effects are carefully considered and weighed against the benefits of intervention. A medical team with expertise in both the management of IH and the use of oral propranolol in infants provides the most optimal care to patients in need of systemic therapy with propranolol.

Contraindications and Pretreatment History

Before initiating propranolol therapy for IH, screening for risks associated with propranolol use should be performed. Relative contraindications are listed in Table 4. The prescribing physician should perform, or obtain documentation of, a recent normal cardiovascular and pulmonary history and examination. Key elements of the history are poor feeding, dyspnea, tachypnea, diaphoresis, wheezing, heart murmur, or family history of heart block or arrhythmia. The examination should be performed by a care provider with experience in evaluating infants and children. The examination should include HR, BP, and cardiac and pulmonary assessment.

Pretreatment ECG

Routine ECG screening before initiation of propranolol for hemangiomas has been advocated, although the utility of ECG screening for all children with hemangiomas before initiation of propranolol therapy is unclear. In the future, a more indication-driven ECG strategy is likely to develop because the incidence of ECG abnormalities that would limit propranolol use in children with IH appears low.4,7,10,13,15,18,21,25,27,29 For example, congenital complete heart block is rare, with an estimated prevalence of 1 in 20,000 live births,111 and this is most commonly associated with maternal connective tissue disease.112 Consensus was not achieved on the use of ECG for all children with IH, but ECG should be part of the pretreatment evaluation in any child when

1. the HR is below normal for age113:
   - newborns (<1 month old), <70 beats per minute,
   - infants (1–12 months old), <80 beats per minute, and
   - children (>12 months old): <70 beats per minute.

2. there is family history of congenital heart conditions or arrhythmias (eg, heart block, long QT syndrome, sudden death), or maternal history of connective tissue disease.

3. there is history of an arrhythmia or an arrhythmia is auscultated during examination.

Because structural and functional heart disease have not been associated with uncomplicated IH, echocardiography as a routine screening tool before initiation of propranolol is not necessary in the absence of abnormal clinical findings.

Propranolol Use in PHACE Syndrome

PHACE syndrome (Online Mendelian Inheritance in Man database ID 606519) is a cutaneous neurovascular syndrome present in one-third of infants with large, facial hemangiomas; it is characterized by large, segmental hemangiomas of the head and neck and congenital anomalies of the brain, heart, eyes, and/or chest wall.114 Arterial anomalies of the head and neck are the most common noncutaneous manifestation of PHACE syndrome, and acute ischemic stroke is a known

complication. Although the arterial anomalies are widely variable, infants with PHACE syndrome believed to be at highest risk for stroke are those with severe, long-segment narrowing or nonvisualization of major cerebral or cervical arteries in the setting of inadequate collateral circulation, especially when there are coexisting cardiac and aortic arch anomalies (Table 5). Theoretically, propranolol may increase the risk of stroke in PHACE syndrome patients by dropping BP and attenuating flow through absent, occluded, narrow, or stenotic vessels. Furthermore, nonselective β-blockers, such as propranolol, have been shown to increase variability in systolic BP to a greater degree than β1-selective agents, and labile BP is a known risk factor for stroke. There are 2 reports of acute ischemic stroke in PHACE syndrome patients on propranolol to date. Both patients were concomitantly on oral steroids and had severe arteriopathy. Cardiac and aortic arch anomalies are also commonly seen in PHACE syndrome and require echocardiography to assess intracardiac anatomy and function. Propranolol administration in these patients should be managed in close consultation with cardiology.

Infants with PHACE syndrome present a unique management challenge because most affected infants have extensive facial hemangiomas, with high risk for both medical morbidities and permanent facial scarring. Such patients are thus prime candidates for propranolol therapy. The potential benefits of propranolol outweigh the risks, the consensus group recommends use of the lowest possible dose, slow dosage titration upward, close observation including inpatient hospitalization in high-risk infants, and 3 times daily dosing to minimize abrupt changes in systolic BP. PHACE be thoroughly evaluated with MRI/magnetic resonance angiography of the head and neck and cardiac imaging to include the aortic arch before considering propranolol. If imaging results place a patient into a higher risk category for stroke (Table 5), consultation and comanagement with neurology is appropriate. If the potential benefits of propranolol outweigh the risks, the consensus group recommends use of the lowest possible dose, slow dosage titration upward, close observation including inpatient hospitalization in high-risk infants, and 3 times daily dosing to minimize abrupt changes in systolic BP.

### Formulation, Target Dose, and Frequency

Propranolol is currently commercially available in propranolol hydrochloride oral solution (20 mg/5 mL and 40 mg/5 mL). It is recommended that the 20 mg/5 mL preparation be used because of the small volumes required for this indication. The consensus group recommends a target dose of 1 to 3 mg/kg per day with most members advocating 2 mg/kg per day, the median dose reported in the literature. Given the fact that dose escalation is required with propranolol and that IH often respond rapidly to even low doses, physicians will often use dose response to determine an individual’s optimal target dose. Dose escalation from a low starting dose is always recommended even in the presence of inpatient monitoring as the initial cardiac response to β blockade may be pronounced.

The consensus group advocates that the daily dose of propranolol be divided into 3 times daily dosing with a minimum of 6 hours between doses, balancing considerations of safety, efficacy, and convenience.

### Initiation of Propranolol in Infants With IH

Some facilities may have the resources and expertise to safely monitor all patients in an outpatient setting, and some practitioners continue to admit all infants. The following suggestions were made regarding monitoring for potential side effects while initiating oral propranolol for the treatment of problematic IH (Fig 1). We acknowledge that the data for safe outpatient initiation is mounting but still relatively limited for this indication. The recommendations are age-dependent with patients divided into 2 age groups. Inpatient hospitalization for initiation is suggested for the following: Infants ≤8 weeks of gestationally corrected age, or any age infant with inadequate

* Risk further increased if coexistent cardiac or aortic arch anomalies.

** defined as vessel narrowing >75%.

† internal carotid artery, middle cerebral artery, anterior cerebral artery, posterior cerebral artery, basilar artery, vertebral artery.

§ defined as vessel narrowing <75%, and categorized as standard risk given known frequency of overdiagnosis with MRI.

* any degree of severity.

It is recommended that infants with large facial hemangiomas at risk for
social support, or any age infant with comorbid conditions affecting the cardiovascular system, the respiratory system including symptomatic airway hemangiomas or blood glucose maintenance.

Outpatient initiation with monitoring can be considered for infants and toddlers older than 8 weeks of gestationally corrected age with adequate social support and without significant comorbid conditions.

**Cardiovascular Monitoring**

The peak effect of oral propranolol on HR and BP is 1 to 3 hours after administration. Patients should be monitored with HR and BP measurement at baseline and at 1 and 2 hours after receiving the initial dose, and after significant dose increase (>0.5 mg/kg/day), including at least 1 set of measurements after the target dose has been achieved. If HR and BP are abnormal, the child should be monitored until the vitals normalize. Dose response is usually most dramatic after the first dose; therefore, there is no need to repeat cardiovascular monitoring multiple times for the same dose unless the child is very young or has comorbid conditions affecting the cardiovascular system or the respiratory system including symptomatic airway hemangiomas. Bradycardia is important to recognize because the accurate measurement of BP in infants may be challenging. HR is simple to measure, and normative data for inappropriate bradycardia have been established as follows:

- Newborns (<1 month old), <70 beats per minute
- Infants (1–12 months old), <80 beats per minute
- Children (>12 months old), <70 beats per minute

Systolic BP varies significantly between 1 month and 6 months of age, so normative data are difficult to interpret. Moreover, most pediatric normative BP tables were designed to evaluate for hypertension, not hypotension, and are based on auscultatory measurements. Oscillometric devices are convenient and minimize observer error, but they do not provide measures that are identical to auscultation. Obtaining accurate BP measurements in neonates and infants may be challenging, and BP measurements should be obtained by experienced personnel. The infant should be in a warm room and in a resting state, awake or asleep. The use of an appropriately sized infant cuff is essential. The

inflatable portion of the cuff should encircle \( \geq 75\% \) of the limb circumference, and the length of the cuff should be at least two-thirds of the length of the upper arm. Specific age-based normative parameters for identification of systolic hypotension in infants are difficult to provide; as a general guide, we would describe systolic BP that is below normal (less than fifth percentile oscillometric or \(< 2\ SD \ of \ normal \ auscultation\))\textsuperscript{119} as follows:

- Newborn: \(< 57 \text{ mm Hg} \ (\ < 5\% \ \text{percentile \ oscillometric}) \) or \(64 \text{ mm Hg} \ (2\ SD \ auscultation)\)
- 6 months: \(< 85 \text{ mm Hg} \ (\ < 5\% \ \text{percentile \ oscillometric}) \) or \(65 \text{ mm Hg} \ (2\ SD \ auscultation)\)
- 1 year: \(< 88 \text{ mm Hg} \ (\ < 5\% \ \text{percentile \ oscillometric}) \) or \(66 \text{ mm Hg} \ (2\ SD \ auscultation)\)

Patients who have HR and systolic BP measurements below these values during propranolol initiation/dose escalation warrant careful evaluation for additional evidence of cardiovascular compromise and should be considered at higher risk for continued propranolol use at that dose/continued dosage escalation.

The inpatient and outpatient dose escalation recommendations are age-dependent with patients divided into 2 age groups, as shown in Fig 1.

**Ongoing Monitoring**

As discussed earlier, patients should be monitored with HR and BP measurement at baseline and at 1 and 2 hours after a significant dose increase (\(> 0.5 \text{ mg/kg/day} \)), including at least 1 set of measurements after the target dose has been achieved. There is no published information on the utility of Holter monitoring in infants after initiating propranolol to identify occult bradycardia or arrhythmias, and this group has not reached consensus on a recommendation for Holter monitoring after reaching a steady dose. Most centers represented at the conference do not perform or recommend Holter monitoring in this setting on a routine basis.

**Preventing Hypoglycemia**

Although recognition of signs or symptoms of hypoglycemia may prompt early intervention, measures should be taken to decrease the risk of hypoglycemia. Because asymptomatic hypoglycemia was not detected in studies that included a random serum glucose as part of routine monitoring, and the timing of hypoglycemic events, as outlined in Table 3, has been variable and unpredictable, routine screening of serum glucose is not indicated. Propranolol should be administered during the daytime hours with a feeding shortly after administration. Parents should be instructed to ensure that their child is fed regularly and to avoid prolonged fasts. In otherwise healthy children, the risk of hypoglycemia is age-dependent and begins after 8 hours of fasting in children 0 to 2 years of age.\textsuperscript{47} Infants <6 weeks should be fed at least every 4 hours, between 6 weeks and 4 months of age should be fed at least every 5 hours, and \(> 4\) months of age should be fed at least 6 to 8 hours. Propranolol should be discontinued during intercurrent illness, especially in the setting of restricted oral intake. Children undergoing procedures or radiologic imaging requiring fasting for sedation should be supported with Pedialyte (Abbott Nutrition, Abbott Laboratories, Columbus, OH) or glucose-containing IV fluids during periprocedural periods. Preoperative blood glucose levels may identify additional patients whose symptoms might otherwise be masked by preoperative medications and anesthesia. Particular care should be taken in using propranolol in preterm infant, patients prescribed other medications known to be associated with hypoglycemia or with medical conditions known to produce hypoglycemia.

**CONCLUSIONS**

Currently, the most significant barrier to the implementation of a multinstitutional clinical trial for the treatment of IH with oral propranolol is the lack of standardized toxicity monitoring in infants without anatomic cardiac/vascular anomalies, as well as in infants with PHACE syndrome. Despite the widespread use of this drug, no

</table>
systematic strategy currently exists to identify toxicities of therapy for infants with IH. The consensus team agreed on a number of recommendations that arose from a review of existing evidence supplemented by expert opinion and clinical experience (Table 6). These recommendations will provide the platform for large-scale phase II/III clinical trials to determine optimal dosing regimens and long-term safety profiles. We anticipate that these guidelines will be modified as more data are made available from these future studies.
