Method-specific medians and robust standard deviations were calculated for all methods with ≥ 6 reported results (method of Tukey). Differences between methods were assessed by means of non parametric statistics (Wilcoxon test).

Results: All but three laboratories participated in the survey (response rate of 98.4%).

PT and aPTT: Both, dabigatran and rivaroxaban significantly prolonged the PT and aPTT in a concentration- and reagent-dependent manner. The PT was more influenced by rivaroxaban than by dabigatran, while the aPTT was more influenced by dabigatran than by rivaroxaban. There was a wide variation in responsiveness between reagent/instrument combinations. The PT reagents Neoplastin CI Plus and Neoplastin R (Diagnostica Stago, Asnières sur Seine, France) were the most sensitive to rivaroxaban and the reagents Innovin and Thromborel S (Siemens, Marburg, Germany) the least sensitive. The aPTT reagents most and least sensitive to dabigatran were CK Prest (Diagnostica Stago) and Actin FSL (Siemens). Converting PT results to INR did not reduce but even increased the variability between reagents.

Fibrinogen: Rivaroxaban did not influence the determination of fibrinogen but the presence of dabigatran led to a falsely reduced fibrinogen concentration when measured with a low thrombin concentration reagent.

Antithrombin: The presence of dabigatran caused an overestimation of the antithrombin level when measured with an assay based on thrombin inhibition while the presence of rivaroxaban caused an overestimation of the antithrombin level when measured with an assay based on FXa inhibition.

Summary/Conclusions: This study demonstrates that the influence of dabigatran and rivaroxaban on the routine coagulation assays used in Belgium largely depends on the reagent/analyser combination used and the drug concentration. All laboratories received a full report of the results in order to draw attention to the importance of careful interpretation of coagulation test results in patients taking dabigatran or rivaroxaban.

OC 82 – Cancer and Thrombosis

OC 82.1

The role of a prothrombinase – fibrinogen-like protein 2 in angiogenesis and tumorigenesis

Inbal A[1], Rabizadeh E[2], Lederfine D[2], Rosenbaum E[3], Yosipovitz O[3] and Inbal A[3]

[1]5Thrombosis and Hemostasis Unit, Hematology Institute, Beilinson Hospital, S; [2]Hemato-Oncology Laboratory, Hematology La, Felsenstein Medical Research Center; [3]Beilinson Hospital, Petah Tikva, Israel

Background: Hematologic and solid tumors are associated with hypercoagulability the reason for which has not been delineated. Prothrombinase named fibrinogen-like protein 2 (FGL-2) is a 70 kD transmembrane protein that was found to have a quality of a serine protease capable of directly cleaving prothrombin to thrombin. FGL-2 is synthesized by monocytes, T-lymphocytes and endothelial cells. FGL-2 protein and its mRNA have been previously found within different tumor cells. In our previous work we found that FGL-2 activity was increased in peripheral blood mononuclear cells (PBMC) from patients with prostate, colon and lymphoproliferative malignancies. Our hypothesis is that upregulation of FGL-2 activity in cancer patients may contribute to angiogenesis and tumorigenesis.

Aim: To study the role of FGL-2 in angiogenesis and tumor development using *in vitro* and *in vivo* assays.

Methods: Thrombin generation reflecting FGL-2 activity was measured in different cells after addition of prothrombin. mRNA of FGL-2 was measured in PBMC, HUVEC and PC3 (human prostate carcinoma cell line) by quantitative RT-PCR analysis. *In vitro*, FGL-2 angiogenesis induction was evaluated by matrigel assay. *In vivo*, FGL-2-induced tumor development was tested in SCID mice after injection of PC3 cell line, which has increased FGL-2 activity or PC3 cell line where FGL-2 activity was inhibited by specific siRNA.

Results: Increased mRNA of FGL-2 was found in PBMC from patients with either lymphoma, prostate or colon cancer and in PC-3 cell line. Following treatment of HUVEC and PC-3 line with interferon-gamma the amount of mRNA increased even further. FGL-2 activity was knocked out in either HUVEC or PC3 by specific siRNA. *In vitro*, a significant angiogenesis was observed in matrigel assay after addition of PC3 cells with intact FGL-2 while addition of PC3 with knock out FGL-2 completely inhibited blood vessel formation. Addition of hirudin had no effect on angiogenesis indicating that FGL-2 mediated pro angiogenetic effect is not induced by thrombin.

PCR array of HUVEC with knock out FGL-2 using specific panel of human angiogenesis genes revealed a 500-fold decrease in the expression of Epidermal growth factor gene and Insulin-like growth factor 1. *In vivo*, tumor development in SCID mice after injection of PC3 cell line with or without FGL-2 activity was assessed. Nine out of ten mice injected with PC3 expressing FGL-2 developed tumors after 3 weeks. In contrast, out of five mice injected with blocked FGL-2 clone of PC3, three have not developed tumors at all, and the remaining two showed small undefined cluster of cells at the injection site. Precise his-

topathology analysis of all the mice will be done at week 6 after the injection.
Conclusions: The results of this research indicate that FGL-2 may induce angiogenesis and tumor development. In the future FGL-2 targeting may have a potential therapeutic value.

OC 82.2
Brain metastasis depends on tumor cell initiated coagulation

Gay LJ, Day JL, LeBoeuf SE, Ritland M, Ruggeri ZM, Ruf W and Felding-Habermann B
The Scripps Research Institute, La Jolla, CA, USA

Background: The incidence of brain metastasis exceeds that of primary brain tumors 10-fold and is most frequently associated with lung cancer, breast cancer and melanoma. Despite the dismal prognosis of only 6–9 months for patients with brain metastases, the mechanisms of tumor cell brain colonization from the blood stream are unknown. Understanding this step could enable effective therapeutic strategies to prevent the development of incurable metastatic brain disease.
We found that metastatic cancer cells reside within the cerebral microvasculature for several days and associate with platelets while penetrating the blood brain barrier. Intravascular survival and extravasation of the tumor cells during this time may critically limit the success of brain metastasis. The brain microvasculature may uniquely influence hemostatic system function in tumor cell colonization. Activation of coagulation, platelets and fibrin formation contribute to tumor progression, cancer-associated thrombosis and metastatic spread to peripheral organs, however the function of coagulation in the seeding of brain metastases is not known.
Aims: We evaluated whether tumor cell-expressed tissue factor, an activator of coagulation, promotes tumor cell seeding of brain metastases by initiating critical tumor cell-vascular interactions.
Methods: We developed models of experimental brain metastasis to study how intravascular tumor cells cooperate with the coagulation system during the early stages of colonization across the blood brain barrier. Human breast cancer cells are injected into the left cardiac ventricle of immune deficient mice. The tumor cells are then followed during the initial phase of brain metastasis and progressive metastatic brain disease using detailed and quantitative histological analyses. We address how coagulation contributes to brain metastasis by targeting tissue factor or platelets. This is accomplished by initial treatment with antibodies that specifically inhibit human tissue factor function or by depleting platelets. We use *ex-vivo* bioluminescence imaging and immunohistochemical analyses at later stages of brain metastasis to determine the extent to which an early, transient treatment will result in long-term, diminished macrometastatic burden as the disease progresses.
Results: We demonstrate that inhibition of tissue factor expressed by tumor cells reduces brain colonization, which results in diminished progression of breast cancer brain metastasis and extended animal survival. We find that tissue factor properties which initiate coagulation and promote cytoprotective signaling pathways differentially contribute to brain metastasis development. Our findings indicate that the inhibition of coagulation can prevent the seeding of breast cancer cells into the brain and result in overall reduction of brain metastatic burden.
Summary/Conclusions: Our studies provide mechanistic insights into the process of tumor cell brain colonization and may lead to the identification of targets and development of therapeutics to prevent cancer metastasis to the brain and enhance patient survival rates.

OC 82.3
The heparin/heparan-sulphate interactome of human breast cancer cells exerts a pro-tumourigenic role associated with activation of the PI3K/Akt and MAPK/ERK signalling pathways

Chen Y[1], Scully M[1], Gloria D[1], Goodwin C[1], Min X[1], Xinjie L[1] and Ajay K[2]
[1]Thrombosis Research Institute; [2]Thrombosis Research Institute, University College London, London, UK

Background: Heparan sulphate (HS) interacting proteins form a tightly interconnected network – the heparin/HS interactome – that contributes to cell function in higher organisms. Heparin treatment which is able to modulate interactions between the heparin/HS interactome and HS proteoglycans (HSPGs) has been shown to prolong the survival of patients with cancer, but the fundamental mechanisms underlying this benefit are largely unknown.
Aim: To investigate the global effect of protein-heparin/HS interactions on the tumorigenicity of breast cancer cells.
Methods: Tow human breast cancer cells lines (MCF-7 and MDA-MB-231) were cultured under serum-free conditions in which the cellular response was maintained by secreted autocrine factors and other members of the heparin/HS interactome and in the presence of heparin to modulate HSPG interaction. Confirmatory observations were made using cells cultured in the presence of β-D-xyloside, which inhibits HSPG synthesis. The tumourigenicity of the cells was determined by measuring a wide range of indices including gene expression, and cell signalling through gene microarray, RT-PCR, Western blot and immunofluorescence analysis. Tumour cell properties were also evaluated by a series of cell function assays.
Results: Microarray analysis of MCF-7 cells cultured under these conditions showed that expression of 105 of 1357 genes potentially related to the pathogenesis of breast neoplasm was significantly altered by heparin treatment. The changes in gene expression correlated with a less tumourigenic phenotype, including reduction of cell adhesive, invasive and migratory properties. These effects were associated with an inhibition of the PI3K/Akt and Raf/MEK/ERK signalling pathways. The modulatory effect of heparin on HS-associated activity was confirmed with one member of the heparin/HS interactome: TGFβ, a key cytokine. The innate TGFβ activity of MCF-7 cells was reduced by heparin treatment, with specific interruption of the TGFβ–Smad signalling pathway. The pro-tumourigenic contribution of the heparin/HS interactome was verified in cells in which HSPG synthesis was blocked using β-xyloside.
Conclusion: Modulation of the HSPG-dependent action of the heparin/HS interactome induces a less tumourigenic genotype and phenotype associated with inhibition of the PI3K/Akt, Raf/MEK/ERK and TGFβ-Smad signalling pathways. The innate heparin/HS interactome of breast cancer cells makes a significant contribution to tumourigenicity, therefore establishing that the beneficial effect of heparin upon the survival of cancer patients is probably due to its ability to reduce the pro-tumourigenic activity of the heparin/HS interactome.

Systemic venous thrombotic events are associated with significantly increased loss of central venous catheters in pediatric cancer patients: a Multicenter Study

Kulkarni K[1], Halton J[2], Spavor M[3], Evan S[4], Sara I[5], Dietrich K[6], Abish S[7] and Lesley M[8]

[1]Stollery Children's Hospital, Edmonton, AB; [2]Children's Hospital of Eastern Ontario, Ottawa, ON; [3]Stollery Children's Hospital, Edmonton, AB; [4]BC Children's, Vancouver, BC; [5]Winnipeg Children's Hospital, Winnipeg, MB; [6]University of Alberta, Edmonton, AB; [7]Montreal Children's Hospital, Montreal, QC; [8]Stollery Children Hospital, University of Alberta, Edmonton, AB, Canada

Background: Central venous catheters (CVCs) have greatly improved the care of pediatric oncology patients. Loss of CVC necessitates immediate replacement, requiring general anesthesia, surgical intervention and is a significant cost burden to the health care system. Convincing evidence shows that venous thrombotic events (VTE) occur frequently during childhood cancer and that VTE are associated with CVC use. However, clinical significance of VTE with respect to CVC management has never been studied. We wanted to explore our hypotheses that VTE in childhood cancer patients are significantly associated with increased CVC loss and that VTE maybe causal in some children, as indicated by an association of CVC loss with location of VTE.

Aim: (i) investigate the association of VTE with loss of CVCs and (ii) assess association of location of VTE with CVC loss.

Methods: In this multicenter case-control study, after ethics approval and informed consent, childhood cancer survivors with and without symptomatic VTE during their cancer therapy were recruited from 5 Canadian centers. Additionally, patients in whom an asymptomatic VTE was detected were assessed. Number and location of CVCs was compared between the three groups.

According to location, VTE were categorized into two groups (i) systemic VTE or (ii) non-systemic VTE. Systemic VTE included (i) central VTE: VTE in veins proximal to and including axillary and femoral veins and (ii) peripheral VTE: VTE in veins distal to axillary and femoral veins.

Results: Seventy-seven survivors (cases) with symptomatic VTE, 10 with asymptomatic VTE (systemic VTE $n = 7$, non-systemic $n = 3$) and 178 controls (no VTE) were recruited. The locations of symptomatic VTE were: systemic VTE ($n = 58$) (central VTE $n = 49$ and peripheral VTE $n = 9$) and non-systemic ($n = 19$) (sinovenous thrombosis $n = 7$ and other sites $n = 12$).

Among the controls, 11.8% required > 1 CVC. In comparison, > 1 CVC was required by a significantly increased proportion of children with (i) systemic VTE (53.4% $P = 0.0001$), (ii) central VTE (55.1%, $P = 0.0001$), (iii) peripheral VTE (44.4%, $P = 0.017$) and (iv) systemic asymptomatic VTE (57.1%, $P = 0.007$). Similar to controls, only 10.5% in the nonsystemic VTE group required > 1 CVC ($P = 0.592$).

The mean number of CVCs in the control group was 1.12 ± 0.37. In comparison, the mean number of CVC was significantly increased in the systemic VTE group (1.75 ± 0.872, $P = 0.0001$) and central VTE group (1.81 ± 0.86, $P = 0.0001$). In contrast, the mean number of CVC in nonsystemic VTE group (1.28 ± 0.958) was similar to controls ($P = 0.301$).

Central VTE and location of CVCs showed a concordance of 55% ($n = 27$) with probable concordance in additional 10.2% ($n = 5$) patients.

Summary: The current study is the first to demonstrate a significantly increased CVC loss as an adverse clinical outcome of both symptomatic and asymptomatic systemic, especially central, VTE. Non-systemic VTE do not contribute to increased CVC loss. A > 55% concordance in CVC location and central VTE suggests a significant contribution of CVCs in VTE development.

Given the clinical and economic implications of CVC loss, future trials need to focus on safety and efficacy of primary prophylaxis in VTE prevention in childhood cancer patients.

OC 82.5

Coagulant activity and cellular origin of circulating tissue factor exposing microparticles in cancer patients – two forms of TF-exposing microparticles

Kleinjan A[1], Böing AN[1], Di Nisio M[2], Twint D[3], Kamphuisen PW[4], Nanayakkara P[3], Büller HR[1] and Nieuwland R[1]

[1]Academic Medical Center, Amsterdam, the Netherlands; [2]G.D'Annunzio University, Chieti, Italy; [3]VU Medical Center, Amsterdam; [4]University Medical Center Groningen, Groningen, the Netherlands

Background: Because plasma of cancer patients presenting with venous thrombosis contains high numbers of tissue factor (TF)-exposing microparticles (TF-MP[1]), TF-MP have been causally linked to the occurrence of venous thrombosis in cancer patients. The relationship between numbers of TF-exposing MP and the TF-MP dependent coagulant activity, however, is unclear. In addition, to which extent TF-MP originate from cancer cells is also unknown.

Aim: We investigated the relationship between TF-MP numbers and coagulant activity, and the cellular origin of circulating TF-MP in cancer patients.

Methods: Citrate-anticoagulated blood was collected via a single blood withdrawal from cancer patients undergoing chemotherapy. The number of TF-MP was measured by flow cytometry and TF-MP coagulant activity was measured in a fibrin generation test (FGT) in the presence or absence of an inhibitory antibody to human factor VII. Patients were categorised as having a low or high number of TF-MP (≤ or > 95th percentile), and as having low or high TF-MP coagulant activity (≤ or > 13% TF-dependent prolongation of clotting time as determined by FGT). The cellular origin was determined by flow cytometry in those patients with number of TF-MP above the 95th percentile of the total cohort.

Results: Of the total cohort of 209 cancer patients, 98 had metastasis (47%). Overall, no correlation was present between the numbers of TF-MP and the coagulant activity ($r = 0.029$, $P = 0.69$). When comparing patients with a high and low number of TF-MP, respectively three of the 12 (25%) and 60 of the 192 (31%) patients had high TF-MP coagulant activity. Conversely, when comparing patients with high and low TF-MP coagulant activity, respectively only three of the 63 (4.8%) and nine of the 141 (6.4%) patients had a high number of TF-exposing MP.

There was a marked variation between patients with regard to the cellular origin of the TF-MP. Of the 13 patients with high TF-MP numbers, the cellular origin of TF in five patients was variable and added up to above 100%; including 67% and 44% staining for two independent tumor markers, 66% for a platelet marker, and 59% for a monocyte marker (all medians). In the other eight patients, the origin of > 25% of TF-MP could be established, and most of these TF-MP originated from platelets and no tumor-derived vesicles were detectable.

Summary/Conclusions: Because increased numbers of TF-MP and coagulant activity are almost mutually exclusive, we postulate that two forms of TF associated with MP circulate in cancer patients, a coagulant form which is present in minute quantities and below the detection limit of flow cytometry, and a non-coagulant form which is detectable by flow cytometry. Taken together, although at least part of the TF-MP can derive from tumor cells, the cellular origin of circulating and coagulant TF-exposing MP in cancer patients remains to be elucidated.

OC 82.6

Colon adenocarcinoma cell recruitment to platelets and thrombi under shear

Baker S, Itakura A, Gruber A and McCarty OJT
Oregon Health and Science University, Portland, OR, USA

Background: Cancer metastasis involves separation of cancer cells from a primary tumor, entrance of tumor cells into the blood or lymphatic circulation, adhesion to or entrapment at a distal site, and proliferation to form of a secondary tumor. The anatomical site-specificity of cancer metastasis, the effect of antithrombotic treatments on metastasis, and the role of the vessel microenvironment in cancer metastasis remain to be explored.
Aims: We aimed to investigate the kinetics and molecular mechanisms of metastatic colon adenocarcinoma cell recruitment to fibrillar proteins and thrombi under shear flow, *ex vivo*.
Methods: SW620 cells (1×10^6 cells/mL; colon adenocarcinoma cells from lymph node) were perfused over immobilized fibrillar collagen, fibrinogen, laminin, fibronectin, or von Willebrand factor at physiologically relevant shear rates ranging from 25 to 200/s. Platelet aggregates were formed by perfusing citrate anticoagulated whole blood over fibrinogen or collagen. Thrombi were formed by perfusing recalcified whole blood over fibrinogen or collagen in the presence of coagulation. Tumor cells were perfused either during or following platelet aggregate or thrombus formation. The role of polymorphonuclear leukocytes (PMNs) in tumor cell recruitment was investigated by perfusing purified PMNs over both platelet aggregates and thrombi. The degree of transient tumor cell interactions (recruitment, rolling and release) and the number of firmly adhered tumor cells were quantified using fluorescence microscopy.
Results: The extracellular matrix proteins, fibrillar collagen, fibrinogen, laminin, fibronectin, and von Willebrand factor supported tumor cell recruitment and adhesion in a shear-dependent manner, with a maximal degree of binding observed at the lowest shear rate (25/s). The rate of transiently interacting SW620 cells varied from nearly 200 cells/mm^2/min on collagen to > 30 cells/mm^2/min on fibrinogen. Platelet aggregates and thrombi formed on either fibrinogen or collagen supported SW620 cell interactions and adhesion under shear. Increased SW620 cell interactions and binding was observed on platelet aggregates and thrombi formed on collagen as compared to fibrinogen. Moreover, thrombi supported a greater degree of SW620 cell interactions and adhesion as compared to platelet aggregates formed on either collagen or fibrinogen. Interestingly, in the absence of anticoagulation, we observed SW620 preferentially binding to clot-bound leukocytes. Along these lines, addition of purified leukocytes (1×10^6 PMNs/mL) to thrombi resulted in a doubling of the number of interacting and bound SW620 cells.
Conclusion: Our findings demonstrate that colon adenocarcinoma cell tethering, rolling and firm adhesion to extracellular matrix proteins, platelet aggregates, leukocytes, and thrombi under flow are enhanced in recalcified blood and reduced by shear. The results suggest that metastasizing cancer cells may preferentially home to sites of blood vessel injury and inflammation that induce local thrombin generation.

OC 83 – Coagulation Factor VII

OC 83.1

Novel insights into the therapeutic mode of action of recombinant FVIIa

Augustsson C and Persson E
Novo Nordisk A/S, Bagsvaerd, Denmark

Background: Recombinant FVIIa (rFVIIa, NovoSeven®) is used as bypassing agent in haemophilia patients with inhibitory antibodies against factor VIII (FVIII) or IX. The need for supraphysiologic doses of rFVIIa has been explained in two ways; to efficiently compete with endogenous FVII for tissue factor (TF) or to obtain a sufficient amount of rFVIIa bound to activated platelets, that is, to allow rFVIIa to activate factor X in a TF-dependent and -independent manner, respectively.
Aims: To evaluate the influence of zymogen FVII competition for TF and FVII (auto)activation on thrombin generation induced by rFVIIa. To assess the relative contributions of the TF-dependent and -independent pathways under haemophilia A conditions.
Methods: Thrombin generation was quantified in FVII-deficient, FVIII-depleted platelet-rich plasma (PRP) (zymogen effect studies) or FVIII-depleted PRP (pathway studies) and initiated with TF (Innovin, 1 pM), Ca^{2+} and fluorogenic substrate. Recombinant FVII, $FVII_{R152A}$, FVIIa and $FVIIa_{DVQ}$ were produced in house. $FVII_{R152A}$ cannot be converted to FVIIa. $FVIIa_{DVQ}$ contains three amino acid changes (V158D/E296V/M298Q) resulting in enhanced TF-independent capability to activate factor X.
Results: Zymogen competition with FVIIa for TF and its influence on thrombin generation were studied using both FVII and $FVII_{R152A}$ in order to simultaneously assess the importance of FVII (auto)activation. In the presence of 6 nM FVIIa, a concentration-dependent lowering of thrombin generation was seen in the presence of $FVII_{R152A}$ (10–100 nM) but not with FVII. The reduction at 100 nM $FVIIa_{R152A}$ (15-fold excess over FVIIa) was the same as that obtained with a 15-fold reduction in TF in the absence of any FVII. In line with this, addition of $FVII_{R152A}$ and FVII at increasing $FVII_{R152A}$/FVII ratios (100 nM in total) resulted in gradually decreasing thrombin generation. A similar observation was made when lowering the FVIIa concentration in the presence of 100 nM FVII. To distinguish between the sites of FVIIa action, the effects of $FVIIa_{DVQ}$ and FVIIa in FVIII-depleted PRP were compared. At concentrations ≤ 100 pM, similar thrombin generation was observed. Above 100 pM, thrombin generation was higher with $FVIIa_{DVQ}$ than FVIIa, suggesting that the TF-independent contribution became evident and predominant above this threshold. In contrast, FVIIa and $FVIIa_{DVQ}$ behaved much more similarly in FVII-deficient PRP where they act as replacement agents.
Conclusions: Zymogen FVII competed with FVIIa for binding to TF but a subsequent rapid (auto)activation to FVIIa prevented a negative effect on thrombin generation. This rapid activation relied on a certain TF (TF:FVIIa complex) density. Because the thrombin generation potentials of FVIIa and $FVIIa_{DVQ}$ under haemophilia A conditions were indistinguishable at concentrations ≤ 100 pM the activity appears to be TF-dependent (saturation of membrane TF). Above 100 pM, the TF-independent activity became evident as seen by a much larger effect of $FVIIa_{DVQ}$. At therapeutic concentrations of rFVIIa (above 5 nM, typically 25 nM) the major component of its mode of action appears to be TF-independent.

OC 83.2

Multicentre, randomised, double-blinded, active-controlled, cross-over phase 3 trial on safety and efficacy of rFVIIa analogue (vatreptacog alfa) in haemophilia patients with inhibitors (adept™2)

Lentz SR[1], Mahlangu J[2], Abdul Karim FA[3], Andreeva T[4], Economou M[5], Ehrenforth S[6] and Windyga J[7]
[1]*The University of Iowa Carver College of Medicine, Iowa City, IA, USA;* [2]*University of the Witwatersrand, Johannesburg, South Africa;* [3]*National Blood Centre, Kuala Lumpur, Malaysia;* [4]*Republican Center for Hemophilia Treatment, St Petersburg, Russia;* [5]*Aristotle University of Thessaloniki, Thessaloniki, Greece;* [6]*Novo Nordisk A/S, Søborg, Denmark;* [7]*Institute of Hematology and Transfusion Medicine, Warsaw, Poland*

Background: Vatreptacog alfa is a recombinant factor VIIa (rFVIIa) analogue which was developed to provide an improved resolution of bleeds in patients with haemophilia and inhibitors. Its amino acid sequence is 99% identical to rFVIIa, with the only change being three

amino acid substitutions (V158D/E296V/M298Q). In a phase 2 dose-escalation trial, vatreptacog alfa demonstrated preliminary efficacy and safety, with no anti-drug antibodies (ADA) detected (JTH 10:81–89, 2012).

Aim: To evaluate the safety and efficacy of vatreptacog alfa in treating bleeding episodes in haemophilia patients with inhibitors.

Methods: This was a global, multi-centre, double-blind, cross-over, confirmatory trial in haemophilia A or B patients ≥ 12 years with inhibitors. Bleeding episodes were randomly assigned in a 3:2 ratio to treatment with vatreptacog alfa (1–3 doses at 80 μg/kg) or rFVIIa (1–3 doses at 90 μg/kg). If haemostasis was not achieved after three doses of trial product (TP), the patient was treated according to local standard of care. In addition to general safety assessments, ADA testing was performed prior to first drug exposure, at least every 3 months during the trial and at least 1 month after last TP administration.

Results: Seventy-two patients were enrolled, and 567 bleeds were treated with TP. Successful bleeding control (no use of additional haemostatic medication, other than TP, within 12 h; primary efficacy analysis) was similar for both vatreptacog alfa and rFVIIa, and was achieved in 93% of all treated bleeds with 1–3 doses. Vatreptacog alfa was superior to rFVIIa in several secondary efficacy analyses, including fewer doses used to treat a bleed and sustained bleeding control.

Incidence of serious adverse events reported after the treatment of bleeds was very low, with 0.9% for vatreptacog compared to 2.2% for rFVIIa, and general safety assessments revealed no safety concerns. However, 8/72 patients (11%) developed binding antibodies to vatreptacog alfa (including one with *in vitro* neutralising effect) following > 10 exposure days. In 4/8 patients, anti-vatreptacog alfa antibodies developed low titre cross-reactivity towards rFVIIa. The antibody binding to rFVIIa could, in all cases, be outcompeted by vatreptacog alfa, indicating that these antibodies are induced by vatreptacog alfa but cross-bound with lower affinity to rFVIIa.

Summary: The adept™ 2 trial, which is the largest of its kind ever conducted in inhibitor patients, confirmed the well-established efficacy and safety profile of rFVIIa and demonstrated that vatreptacog alfa is similar in primary efficacy outcome as rFVIIa and superior in secondary efficacy outcomes to rFVIIa. The high incidence of ADA development after vatreptacog alfa exposure indicates that even very small sequence changes can significantly alter the immunogenicity of rFVIIa compounds. Long term exposure would be needed to fully assess the immunogenicity of new rFVIIa compounds and to evaluate the risk that continued treatment could result in clinical inhibitor formation.

OC 83.3

EPCR binding to factor VIIa enhances its hemostatic function *in vivo*

Pavani G[1], Ivanciu L[2], Faella A[2] and Margaritis P[2]

[1]Università degli Studi di Ferrara, Ferrara, Italy; [2]The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Background: In addition to tissue factor (TF), human FVIIa is a ligand for the endothelial protein C receptor (EPCR), but the functional consequences of EPCR binding on FVIIa activity are still unclear and may influence the therapeutic effects of FVIIa administration in hemophilic patients. Due to FVIIa-TF species incompatibilities and the fact that murine FVIIa (mFVIIa) does not interact with murine EPCR (mEPCR), mouse models are not appropriate to investigate the role of FVIIa-EPCR interaction *in vivo*. However, we have previously shown that mEPCR binding capacity can be engineered in mFVIIa by three modifications (L4F, L8M and W9R; FMR-mFVIIa). This molecule allows further studies into the functional consequence of EPCR-FVIIa interaction in a mouse model of hemophilia.

Aim: To investigate the effect of EPCR binding on FVIIa procoagulant activity *in vivo*.

Methods: Because of the sub-optimal species compatibility between clotting factors, we characterized the activity of FMR-mFVIIa or mFVIIa using homologous reagents that mimic the *in vivo* setting. Murine activated FX (mFXa) generation assays were performed on CHO-K1 cells expressing murine TF (mTF) only or mTF and mEPCR (CHO-K1-mTF and CHO-K1-mTF-mEPCR, respectively). Thrombin generation assays were conducted in mouse hemophilia B plasma supplemented with FMR- or mFVIIa. To investigate the hemostatic effects of EPCR-FVIIa interaction *in vivo*, we chose the $FeCl_3$ carotid artery injury model since EPCR is highly expressed in large arteries. A mild vessel injury was induced in hemophilic mice with a 2 min application of 7.5% $FeCl_3$ prior to FMR- or mFVIIa infusion, and blood flow was monitored for 30 min.

Results: A similar rate of murine FX activation was observed for mFVIIa and FMR-mFVIIa on CHO-K1-mTF (K_{cat} 0.16 ± 0.01 and 0.18 ± 0.01/s, respectively). The presence of mTF and mEPCR did not affect mFXa generation rates, which were similar to those observed on CHO-K1-mTF (K_{cat} 0.14 ± 0.01/s mFVIIa, 0.18 ± 0.02/s FMR-mFVIIa). In thrombin generation assays, FMR-mFVIIa showed a slightly reduced peak of thrombin (75% of mFVIIa), without affecting the endogenous thrombin potential between the two molecules. These results suggest that conferring mEPCR binding to mFVIIa does not impact proteolytic activity, therefore FMR-mFVIIa is an ideal molecule to investigate the role of EPCR in FVIIa-mediated hemostasis *in vivo*.

In a $FeCl_3$ carotid artery injury model in hemophilia B mice, FMR-mFVIIa infusion was more effective in forming occlusive thrombi compared to mFVIIa. Administration of 3 mg/kg FMR-mFVIIa resulted in complete vessel occlusion in 4.9 ± 0.3 min. In contrast, at the same dose, only 75% of mFVIIa treated mice exhibited stable occlusion, occurring after 12.9 ± 1.4 min. At a higher dose (5 mg/kg), FMR-mFVIIa was consistently more efficacious than mFVIIa (time to occlusion 2.6 ± 0.4 vs. 4.3 ± 0.6 min, respectively). Similar results were obtained in hemophila A mice, in which the infusion of 3 mg/kg FMR-mFVIIa resulted in complete occlusion in 2.8 ± 0.3 min compared to 13.8 ± 0.8 min for mFVIIa.

Conclusions: These results indicate that EPCR binding enhances the FVIIa procoagulant effects *in vivo*, suggesting a novel role of the endothelium in FVIIa-mediated hemostasis. The modulation of this interaction may suggest avenues for improved FVIIa-based therapeutics.

OC 83.4

Identification of novel platelet-targeting moieties that increase the activity of recombinant factor VIIa without affecting platelet function

Salas J[1], Tan S[1], Ashworth T[1], Kistanova E[1], Chen K[1], Tan X[2], Acosta M[1], Pierce GF[1], Jiang H[1], Peters RT[1], Johnson B[3], Pape B[3] and Light D[3]

[1]Biogen Idec Hemophilia, Waltham, MA; [2]Biogen Idec, Cambridge, MA, USA

Background: Recombinant activated factor VII (rFVIIa) is approved for on-demand treatment of bleeding episodes in hemophilia patients with inhibitors. However, multiple doses of rFVIIa at high concentration are often required to control a bleeding episode in part due to its low affinity for platelets. We have previously shown that rFVIIa variants fused to antibody fragments or peptides that interact with platelet receptors display enhanced activity and affinity for platelets. Here we describe the generation of novel platelet-targeting moieties that interact with platelet receptor αIIbβ3 with high affinity. These moieties are single-chain fragment variable (scFv) antibodies selected on the basis of their affinity for the receptor and their inability to activate or inhibit platelet function.

Aims: To enhance the activity and efficacy of rFVIIa by increasing its affinity for platelets.

Methods: Monoclonal antibodies against human αIIbβ3 were raised in mice. Hybridoma supernatants were screened for αIIbβ3 and subunit specificity (αIIb vs. β3) by ELISA methods. Binding to human platelets, competition with fibrinogen, and platelet activation were mea-

sured by flow cytometry-based methods. In addition, purified rFVIIa variants containing αIIbβ3-specific scFv were tested for inhibition of platelet aggregation using a platelet aggregometer, and their effect on human platelet clearance was evaluated in human platelet transfused NOD/scid/gamma (NSG) mice. The activity of these platelet-targeted rFVIIa variants was measured by rotational thromboelastometry (ROTEM) and soluble tissue factor-dependent prothrombin time (sTF-PT) assays.

Results: A panel of hybridomas was categorized into six groups based on the following characteristics: affinity for αIIbβ3, subunit specificity, fibrinogen competition and platelet activation. Among these, only one group was found to activate platelets and thus excluded from further analysis. Sequencing of the variable regions revealed that all antibodies within each group shared a similar sequence. The variable regions of representative antibodies from each group were recombinantly fused as scFvs to the C-terminus of rFVIIa. The fusion proteins did not activate platelets, inhibit platelet aggregation in platelet-rich plasma or affect human platelet clearance in NSG mice. Binding assays revealed a broad range of affinities of the platelet-targeted rFVIIa variants for human and monkey platelets as a well as for purified human αIIbβ3 receptor. While the activity of these variants determined by the sTF-PT method was comparable to rFVIIa on an equal molar basis, their activity was enhanced by 10- to 50-fold relative to rFVIIa in ROTEM using whole-blood from hemophilia A donors. Furthermore, these platelet-targeted rFVIIa variants did not affect platelet clearance or demonstrate any evidence of thrombogenicity in monkeys administered with a dose equivalent in moles to 100 μg/kg of rFVIIa.

Summary/Conclusions: We have generated platelet-targeting moieties that do not affect platelet function and, when fused to rFVIIa, significantly increase its activity. These improvements in activity were only observed when tested in the presence of platelets, such as in whole-blood ROTEM assay. Moreover, these platelet-targeting rFVIIa variants were well tolerated in monkeys. Taken together these results suggest that platelet targeting rFVIIa has the potential to be a safe and effective alternative for the treatment of bleeds in hemophilia patients with inhibitors.

OC 83.5

Anti-drug antibody formation induced by recombinant activated FVII analogue (vatreptacog alfa) – results from the phase 3 adept™ 2 trial in haemophilia patients with inhibitors

Mahlangu J[1], Abdul Karim F[2], Gorska-Kosicka M[3], Kaicker S[4], Matsushita T[5], Recht M[6], Serban M[7], Lentz SR[8] and Nana Weldingh K[9]

[1]University of the Witwatersrand, Johannesburg, South Africa; [2]National Blood Centre, Kuala Lumpur, Malaysia; [3]Medical University, Lublin, Poland; [4]Maimonides Medical Center, New York, NY, USA; [5]Nagoya University Hospital, Nagoya, Japan; [6]Oregon Health and Science University, Portland, OR, USA; [7]"Louis Turcanu" Emergency Hospital for Children, Timisoara, Romania; [8]The University of Iowa Carver College of Medicine, Iowa City, IA, USA; [9]Novo Nordisk A/S, Maalov, Denmark

Aim: To evaluate the immunogenicity of vatreptacog alfa in haemophilia patients with inhibitors.

Methods: This multicentre, randomized, double-blinded, active-controlled, cross-over confirmatory trial evaluated the safety and efficacy of vatreptacog alfa in the treatment of bleed episodes in haemophilia patients with inhibitors. Patients ≥ 12 years of age with bleeding episodes were treated on demand in a blinded random sequence with either vatreptacog alfa or rFVIIa (NovoSeven®). Anti-drug antibody (ADA) testing was performed prior to drug exposure, at least every 3 months during the trial and at least 1 month after last trial product administration. A multi-tiered antibody analysis approach was applied and assays were validated according to international recommendations and guidelines. All samples were screened for binding antibodies towards vatreptacog alfa and rFVIIa in radioimmuno assays (RIA or RIPA) by a central laboratory. Samples above the specified cut point in the screening assays were subjected to a confirmatory radioimmuno precipitation assay to confirm that antibodies were binding to vatreptacog alfa and/or rFVIIa. Antibody positive samples were then tested for neutralizing activity in two neutralizing clot assays (measuring neutralization of vatreptacog alfa and of endogenous human FVII respectively).

Results: Seventy-two patients were enrolled in the trial, and a total of 567 bleeding episodes were treated with trial product (TP). The well-established efficacy and safety profile of rFVIIa was confirmed in this trial, but 8/72 patients (11%) developed non-inhibitory binding antibodies to vatreptacog alfa, including one patient with an *in-vitro* neutralising effect. In 4/8 patients the anti-vatreptacog alfa antibodies developed cross-reactivity towards rFVIIa after subsequent exposures. The antibody binding to rFVIIa could in all cases be competed out by vatreptacog alfa. This suggests that the antibodies were induced by vatreptacog alfa, but, due to the high amino acid sequence homology, cross-bound with lower affinity to rFVIIa. The antibody responses to vatreptacog alfa were observed in most cases following > 10 exposure days (EDs), but in one patient an antibody response was first detected after 28 EDs.

Summary: Immunogenicity is difficult to predict, and data from adept [TRADEMARK]2 indicate that even very small changes to the molecule can change the immunogenicity profile of rFVIIa products.

The high incidence of antibody development towards vatreptacog alfa (11%) observed in in this study population and the potential risks thereof should be taken into consideration for future development of rFVII-derived products. It is not possible to predict if the antibodies would disappear or develop further with continued vatreptacog alfa. Long term exposure will be needed to fully assess the immunogenicity of new rFVIIa compounds.

OC 83.6

A long-acting FVIIa -CTP proposing an improved prophylactic and on demand treatment for hemophilic patients following SC and IV administration – evaluation in animal models

Hart G, Hershkovitz O, Bar-Ilan A and Fima E

PROLOR Biotech, Nes Ziona, Israel

Introduction: Prolor Biotech Inc. is a clinical stage public company developing biobetter long acting versions of existing therapeutic proteins utilizing a technology termed CTP. The technology involves fusion of the C terminus peptide of hCG to one or both ends of the target protein. The technology was clinically validated and proven as a safe and efficient way for prolonging the half-lives of several therapeutic proteins while maintaining their biological activity. The aim of this study was to determine the pharmacokinetic (PK), pharmacodynamic (PD) and long term hemostatic effects of FVIIa-CTP in murine FVIII−/− mice following IV and SC administrations.

Methods: FVIIa-CTP was expressed in CHO cells, purified and activated utilizing a CTP specific purification process. FVIIa-CTP was administered to FVIII−/− mice, and following IV and SC injection the PK and PD profiles were determined. In addition, the long term hemostatic effect was evaluated following bleeding challenge by tail clip assay and tail vein trisection as compared to commercial rFVIIa. FVIIa-CTP *in-vitro* characteristics were also evaluated.

Results: FVIIa-CTP PK parameters following IV and SC administration, as assessed by a clotting assay, were superior to those of rFVIIa. Its half-life and AUC following IV administration were 5- and 3.5-fold higher, respectively and were also significantly superior following SC injection. In a IV and SC Tail Vein Transection study, FVIIa-CTP had a profound effect on survival rate, which was maintained for more

than 24 and 12 h respectively. Reduced duration and intensity of bleeding was also observed in the tail clip study in both routes. Following SC administration, FVIIa-CTP's bioavailability, was shown to be superior to commercial rFVIIa in both rats and hemophilic mice models. Correction of thromboelastography in FVIII −/− mice plasma was maintained longer with FVIIa-CTP than with rFVIIa. Finally, toxicological studies in rodents demonstrated that FVIIa-CTP is safe and tolerable at relatively high doses.

Conclusion: Attachments of CTP to FVIIa led to a markedly enhanced PK, increased exposure as reflected by AUC, improved recovery and a prolonged hemostatic effect in hemophilic mice with a comparable specific activity to rFVIIa. In addition, SC administration of FVIIa-CTP resulted in improved bioavailability and exposure was significantly prolonged relative to IV administration. Our data suggest that CTP fused FVIIa is safe and tolerable in rodents and has the potential to significantly improve the prophylactic and on demand treatment of hemophilic patients.

OC 84 – Fibrinolysis – II

OC 84.1

Characterization of knock-in mice harboring a variant of EPCR with impaired ability to bind protein C

Pepler L, Dwivedi DJ and Liaw P

McMaster University, Hamilton, ON, Canada

Background: The endothelial protein C receptor (EPCR) binds to protein C (PC) and increases the rate of activated protein C (APC) generation by the thrombin-thrombomodulin complex. APC exerts anticoagulant, anti-inflammatory, and cytoprotective effects, which are EPCR-dependent. Mutations and polymorphisms identified in the EPCR gene, which can affect the efficiency of protein C activation, have been associated with an increased risk of thrombosis. The physiologic importance of EPCR is also demonstrated in EPCR knockout mice, which show placental thrombosis and early embryonic lethality. Furthermore, overexpression of EPCR on endothelial cells protects animals against thrombotic and septic challenge.

Objectives: To study the role of EPCR *in vivo*, we have generated a knock-in mouse model harboring a variant of EPCR (R84A) with impaired ability to bind to PC. The objective of this study is to better understand the mechanism by which EPCR and its ligand(s) regulate coagulation and inflammation *in vivo*. We hypothesize that impaired PC/APC binding to EPCR will result in a procoagulant and pro-inflammatory phenotype.

Methods: Mice were given an intravenous injection of bovine thrombin (160 μg/kg) to activate PC, or factor (F) Xa (50 pmol/kg) and phospholipid vesicles (PCPS) (75 nmol/kg) to initiate thrombin generation. Blood was collected via the inferior vena cava 10 min post injection. PC antigen, APC, and thrombin-antithrombin complex (TAT) levels were measured by ELISA. Fibrin deposition in tissue sections was assessed by immunohistochemistry.

Results: EPCR R84A/R84A mice are viable, reproduce normally, and have a normal lifespan. EPCR expression at the endothelial surface of the aorta was not affected by the introduction of the R84A mutation in EPCR. Microscopic examination of the liver, heart, kidney, and lung from EPCR R84A/R84A mice did not reveal evidence of spontaneous thrombosis or morphological abnormalities. However, EPCR R84A/R84A mice developed splenomegaly, with spleen size 7-times higher than wild-type (WT) mice ($P > 0.05$). Circulating PC antigen concentration was higher in EPCR R84A/R84A mice (1.3 ± 0.12 μg/mL), compared to WT mice (1.0 ± 0.07 μg/mL) ($P > 0.05$). The APC levels of thrombin challenged EPCR R84A/R84A mice was only 8% ($P > 0.001$) of WT control mice. The circulating TAT complex levels, an indicator of thrombin generation, were not significantly increased in healthy EPCR R84A/R84A mice compared to WT mice, however TAT levels in FXa/PCPS challenged EPCR R84A/R84A mice increased by twofold compared to WT mice ($P > 0.01$). The elevated TAT levels in FXa/PCPS challenged EPCR R84A/R84A mice were also accompanied by an increase in fibrin deposition in the lungs (mean fluorescence intensity [MFI], 75.3 ± 20.3) compared to WT mice (MFI, 12.3 ± 5.2) ($P > 0.05$).

Conclusions: EPCR R84A/R84A mice are viable suggesting that defects in EPCR that impair PC binding do not affect embryogenesis or development. Introduction of the R84A mutation in EPCR results in impaired PC binding, PC activation, and upon thrombotic challenge, EPCR R84A/R84A mice develop a procoagulant phenotype. Enlargement of the spleen in EPCR R84A/R84A mice suggests that EPCR, which is expressed on endothelial cells as well as on hematopoietic stem cells, may play a biological role in the regulation of haematopoiesis.

OC 84.2

Inactivation of FVIIIa *in vivo* – insights into the physiological down-regulation of haemostasis

Holmberg HL[1], Pastoft A[2], Elm T[2], Bolt G[1], Lauritzen B[2] and Østergaard H[2]

[1]*Novo Nordisk A/S;* [2]*Novo Nordisk.com, Maaloev, Denmark*

Upon vascular injury, activated coagulation factor VIII (FVIIIa) plays a key role in propagation of the coagulation and subsequent clot formation. FVIIIa is unstable and quickly becomes inactive due to spontaneous dissociation of the A2 subunit with a half-life of approximately 2 min. Clinically, the importance of spontaneous dissociation is emphasised by the observation that patients with FVIII mutations such as the S298L mutation, giving rise to an increased dissociation of the A2 subunit, have mild haemophilia. Moreover, *in vitro* studies have shown that FVIIIa is inactivated by activated protein C (APC), but given the fast inactivation by dissociation it has been suggested that APC inactivation of FVIIIa may be of less relevance *in vivo*. However, until now the significance of either mechanism has only been explored *in vitro*.

To assess which inactivation pathway for FVIIIa that is predominant *in vivo,* we investigated the pro-coagulant effect of increasing doses of four different FVIII variants and compared to that of wt rFVIII in three different models of haemostasis in mice lacking FVIII. The FVIII variants were modified so that they either had (i) increased A2 domain dissociation (S289L) (ii), no A2 domain dissociation as the A2 and A3 domain was covalently linked by a disulphide bound (M662C-D1828C), (iii) were resistant to APC as the two APC cleavages site were mutated (R336/562A) or (iv) carried a combination of 2 and 3. All variants were purified to homogeneity following transient expression in CHO cells. The *in vivo* haemostasis models were (i) the tail bleeding model where blood loss over 30 min after amputation 4 mm of the tip of the tail was used as endpoint (ii) the $FeCl_3$ injury model where time to occlusion was determined after applying 10% $FeCl_3$ for 3 min to the carotid artery and (iii) vena saphenous bleeding model where the maximum bleeding time and number of clot formations was measured after vein puncture and repeated clot disruption.

Doses of the FVIII variants were selected to be on the linear part of the dose-response curves for wt rFVIII in the individual models, and accordingly wt rFVIII significantly and dose-dependently improved the coagulation in all three models. Destabilisation of the A2 domain (S289L) significantly reduced the haemostatic effect in the tail bleeding model and $FeCl_3$ injury model compared to wt rFVIII, whereas no significant difference between the A2 domain stabilised variant (M662C-D1828C) and wt rFVIII was observed. In contrast, APC-resistant FVIII variants (R336/562A and R336/562A/M662C-D1828C) showed superior haemostatic effect compared to wt rFVIII in all three animal models.

In conclusion, this is the first study to investigate the inactivation mechanism(s) of FVIIIa *in vivo* and our data suggest that APC mediated inactivation of FVIIIa may be the predominant inactivation mechanism *in vivo*. These data encourages for further investigations to increase our understanding of the inactivation mechanisms *in vivo*.

OC 84.3

Modulation of FXa zymogenicity yields variants that improve hemostasis in hemophilia

Ivanciu L and Camire RM

The Children's Hospital of Philadelphia, Philadelphia, PA, USA

There is tremendous interest in developing procoagulant hemostatic molecules to treat bleeding disorders. Recently, we generated a FXa variant (e.g. FXa^{I16L}) rendered partially inactive due to a defect in transitioning from zymogen to protease where residue 16 is critical to this process. While 'zymogen-like', the biologic activity of FXa^{I16L} is rescued when bound to its cofactor FVa. FXa^{I16L} is effective in correcting deficiencies in the intrinsic pathway; however the mutation site and general mechanism of action indicates that there is inherent flexibility in this new class of pro-hemostatic agent. To this end, we extended the mutational framework at position 16 to further alter the equilibrium position between zymogen and protease states to generate variants with a broad range of activities. Following screening and analysis, one mutant FXa^{I16T} showed high potential and had a markedly different zymogenicity compared to FXa^{I16L}. FXa^{I16T} active site function was severely impaired ($\ll$ 1% activity) compared to wild-type (wt)-FXa. Further it was less sensitive to physiologic inhibitors and exhibited a long half-life (~4 h) in human hemophilia B (HB) plasma vs. wt-FXa (> 1–2 min). Surprisingly, even though FXa^{I16T} had enhanced zymogen-like character, FVa was still able to rescue the variant as it exhibited only a 3–5-fold reduction in catalytic efficiency relative to wt-FXa. Intravenous administration of FXa^{I16T} (450 μg/kg; n = 6–9) in HB mice corrected thrombin generation over a 1 h period and the variant appears safe as platelet counts and D-dimer levels were not altered. In a tail clip assay, blood loss in HB mice (n = 7–10; 450 μg/kg) treated with FXa^{I16T} either 2 min after or 5, 15 or 30 min prior to injury was significantly reduced compared to PBS controls (n = 10). Moreover, FXa^{I16T} infusion in HB mice (n = 7–12) 5 min before injury reduced bleeding in a dose-dependent manner, where even 56 μg/kg was partially effective. Similar pro-hemostatic effects were found in a $FeCl_3$-induced injury model when the protein was infused either before or after injury in HB mice (n = 9). These data suggest that there must be sufficient amounts of FVa available at the site of injury in these models to at least partially restore the activity of FXa^{I16T}. To examine this further we evaluated whether addition of FVa with FXa^{I16T} would lower the effective dose range to correct the hemophilic phenotype. In a tail clip assay, no major reduction in blood loss was observed when FXa^{I16T} (28 μg/kg; n = 12) or FVa (400 μg/kg, n = 7) were infused individually. In contrast, co-infusion of FVa and FXa^{I16T} in HB mice (n = 12) significantly reduced bleeding. Collectively, our data indicate that the potential therapeutic advantage of the low activity zymogen-like FXa^{I16T} variant appears to be its ability to overcome the endogenous inhibitors and thus to impart a prolonged half-life and be rescued by FVa made available following coagulation activation. We conclude that the plasticity of this new class of FXa variants provides a useful and flexible platform to selectively bioengineer activity and half-life.

OC 84.4

Thrombosis and hemostasis in mice lacking factor VII activating protease (FSAP)

Subramaniam S[1], Thielmann I[2], Etscheid M[3], Morowski M[2], Pragst I[4], Nieswandt B[2] and Kanse SM[1]

[1]*Institute for Biochemistry, Giessen;* [2]*University Hospital and Rudolf Virchow Center, University of Würzburg, Würzburg;* [3]*Paul Ehrlich Institute, Langen;* [4]*CSL Behring GmbH, Marburg, Germany*

Background: Imbalance between coagulation and fibrinolysis is a major factor in the development of thrombosis and hemostasis. Factor VII activating protease (FSAP) is a serine protease that activates FVII or pro-urokinase, and inhibits tissue factor pathway inhibitor (TFPI). The Marburg I single nucleotide polymorphism (SNP) of the FSAP-encoding gene (*HABP2*) gives rise to a protein which has reduced enzymatic activity and is associated with thrombotic disorders, atherosclerosis and stroke.

Aims: Identify the role of endogenous FSAP in thrombosis and hemostasis using $FSAP^{-/-}$ mice and define the mechanism of action of FSAP.

Methods: Wild type (WT) and littermate $FSAP^{-/-}$ mice were compared in various *in vivo* and *ex-vivo* model systems. Infusion of collagen/epinephrine was used to induce pulmonary thromboembolism. Topical application of $FeCl_3$ was employed to injure the carotid artery and time to thrombus formation/occlusion was determined. Similarly, the mesenteric arteries were injured and time to thrombus formation/occlusion was determined by intravital microscopy via observing the movement of labeled platelets. Venous thrombosis was induced by topical application of $FeCl_3$ and thrombus weight and total protein content was determined. Tail bleeding test was performed to assess physiological hemostasis.

Results: In pulmonary thromboembolism model mortality was reduced in $FSAP^{-/-}$ mice ($P > 0.01$). In the carotid artery thrombosis model, 41% of $FSAP^{-/-}$ mice showed no occlusion compared to 5% in the WT group. Intravital microscopy revealed that the occlusion time was significantly increased in $FSAP^{-/-}$ mice ($P > 0.01$) and a larger fraction of $FSAP^{-/-}$ mice did not occlude at all. Partial Venous Thrombosis (PVT) displayed a trend in the reduction of thrombus weight and total protein content in $FSAP^{-/-}$ mice. In the tail bleeding assay a re-bleeding pattern in $FSAP^{-/-}$ mice was observed. Western blot analysis of plasma samples showed a slightly higher TFPI expression in $FSAP^{-/-}$ mice than the WT mice; whereas plasminogen levels were unchanged and active urokinase levels were increased. Systematic analysis of various other factors of the coagulation system as well as platelet revealed no major differences between WT and $FSAP^{-/-}$ mice.

Conclusions: The clinical relevance of Marburg I polymorphism to thrombosis is not fully understood and the associated risk for thrombosis is under discussion. Interestingly, our mouse studies reveal that the endogenous FSAP plays a role in extrinsic coagulation cascade *via* inhibiting TFPI. Thus, in $FSAP^{-/-}$ mice the instability or delayed coagulation may be due to the lack of degradation of TFPI and this could shift the balance against clot formation. Our results indicate that Marburg I SNP is associated with lower levels of thrombosis, which may reflect the human pathophysiology.

OC 84.5

Characterization of two monoclonal antibodies that inhibit the antifibrinolytic but not the anti-inflammatory activity of activated TAFI

Semeraro F[1], Ammollo CTC[1], Gils A[2], Declerck PJ[2] and Colucci M[1]

[1]*University of Bari, Bari, Italy;* [2]*University of Leuven, Leuven, Belgium*

Background and Aim: Thrombin activatable fibrinolysis inhibitor (TAFI), once activated by thrombin or plasmin (TAFIa), inhibits fibrinolysis by removing the plasminogen-binding sites from fibrin, and down-regulates inflammation by inactivating several mediators. The pharmacological inhibition of TAFIa is considered an attractive antithrombotic strategy, but carries with it the potential side effect of interfering with an anti-inflammatory pathway. We describe two anti-TAFI monoclonal antibodies (MA) that inhibit the antifibrinolytic but not the anti-inflammatory activity of TAFIa.

Methods and Results: Two anti-TAFI MA targeting plasmin-mediated activation (MA-TCK11A9 and MA-TCK26D6, referred to as *test-MA*), and two MA targeting either thrombin- or thrombin- and plasmin-mediated TAFI activation (MA-T12D11 and MA-TCK27A4, referred to as *reference-MA*), were studied. No MA

inhibited the cleavage of hippuryl-Arg by TAFIa. In two different plasma clot lysis models, *test-MA* (eightfold excess over TAFI) stimulated fibrinolysis (roughly doubling the efficiency of t-PA) through a TAFI-dependent mechanism as efficiently as PTCI (inhibitor of TAFIa) or *reference-MA*, regardless of whether the MA were incorporated into the clot (turbidimetric assay) or added to the plasma bathing fluid of a preformed clot (labeled-clot lysis assay). Surprisingly, *test-MA*, similarly to *reference-MA*, displayed an even stronger profibrinolytic activity in the presence of thrombomodulin (TM), a condition in which TAFIa is almost entirely generated by the thrombin-TM complex. Moreover, the assay of TAFIa, thrombin, and plasmin generation during clot formation and lysis revealed that plasmin-mediated TAFI activation occurred when fibrinolysis had already entered the exponential phase, and accounted for only 5–20% of total TAFIa. Accordingly, when thrombin-mediated TAFI activation was prevented by argatroban or by the use of a prothrombin-deficient plasma, the profibrinolytic activity of *test-MA* was reduced by > 80%, suggesting that *test-MA* stimulated fibrinolysis by mechanisms other than the inhibition of plasmin-mediated TAFI activation. In a functional TAFIa assay using fibrin as substrate, *test-MA*, but not *reference-MA,* inhibited TAFIa activity by > 95%. On the contrary, *test-MA,* at variance with PTCI, did not inhibit TAFIa activity when thrombin-activated osteopontin was used as substrate, as assessed by a Jurkat cell adhesion assay, suggesting that the inhibition of TAFIa by *test-MA* is substrate-specific, and depends on the size of the substrate. Because the other known pro-inflammatory substrates of TAFIa (bradykinin, C3a, C5a) are smaller than osteopontin, it can be anticipated that their inactivation will not be influenced by *test-MA*.

Conclusions: MA-TCK11A9 and MA-TCK26D6 inhibit the antifibrinolytic activity of TAFIa without interfering with its anti-inflammatory properties. These MA may represent the prototype of a new class of TAFI-inhibitors with improved pharmacological activity.

OC 84.6

Identification of heparin binding sites on TAFI that modulate plasmin-mediated activation, thermal stability and antifibrinolytic potential

Marar T, Filipieva A and Boffa MB

University of Windsor, Windsor, ON, Canada

Thrombin activatable fibrinolysis inhibitor (TAFI) is a human plasma zymogen that provides a molecular connection between the coagulation and the fibrinolytic cascades. TAFI is activated through proteolytic cleavage by thrombin, thrombin in complex with the endothelial cell cofactor thrombomodulin (TM), or plasmin to generate the enzyme activated TAFI (TAFIa). TAFIa possesses basic carboxypeptidase activity which down-regulates fibrin clot lysis by removing carboxyl-terminal lysine residues from partially degraded fibrin thereby attenuating the positive feedback in the fibrinolytic cascade. Studies have shown that the presence of glycosaminoglycans (GAGs), such as heparin, is able to accelerate TAFI activation by plasmin and stabilize TAFIa causing a 2.3-fold increase in its half-life. However, the elements of TAFI structure that impart these characteristics are unknown. Potential GAG binding sites on TAFI have been suggested by homology to heparin-binding regions of other proteins as well as crystallographic data on bovine TAFI which revealed several bound sulfate molecules. To identify the GAG binding site(s) on TAFI we have expressed recombinant TAFI variants containing mutations in selected regions predicted to interact with heparin in order to determine the role of GAGs in regulating TAFI function. We examined the ability of the variants to bind GAGs by utilizing a heparin-agarose column. While wild-type TAFI bound quantitatively to the column and was specifically eluted by heparin, the variant R320A/R324A almost entirely eluted in the wash fractions. Variants K306A and H308F displayed similar elution profiles to wild-type whereas variants K211Q/K212Q and K327A/R330A exhibited a two peak elution profile where only a fraction of the total was specifically bound to the column. To determine the kinetics of activation the variants were activated by plasmin in the presence and absence of heparin. The variants H308F and K327A/R330A exhibited the greatest enhancement of catalytic efficiency in the presence of heparin of 2.3- and 2.4-fold, respectively, compared to 1.5-fold for wild-type. The variants K211Q/K212Q, K306A and R320A/K324A showed a lower degree of rate enhancement compared to wild-type. The intrinsic stability of each TAFIa variant in the presence and absence of heparin was determined. Variants R320A/K324A and K327A/R330A possessed substantially lower fold increases in half-life in the presence of heparin. We determined the antifibrinolytic potential of each variant in plasma clot lysis assays under conditions where (i) only plasmin was generated to activate TAFI or (ii) TAFI was quantitatively pre-activated such that only the effect of heparin on stability would be at play. Although not all variants with impaired heparin binding showed impaired stimulation of antifibrinolytic potential by heparin, in general, the effects on TAFIa stabilization were a better predictor of the properties of the variants in clot lysis assays than the effects on plasmin-mediated activation. Overall, the data show that connections can be made between impaired heparin binding, reduced effects on activation or stabilization of heparin and changes in antifibrinolytic potential. The data suggest that TAFI possesses multiple heparin binding sites which may contribute to the different functions of heparin in regulating TAFI activity.

OC 85 – Inflammation – Basic Studies

OC 85.1

Platelets promote immunopathology in *Plasmodium berghei* infection by inhibiting the development of interleukin-10 and interferon-? Expressing T-helper 1 cells

Schenk MP[1], Lamb TJ[2] and Gibbins JM[1]

[1]*Institute of Cardiovascular and Metabolic Research, University of Reading, Reading, UK;* [2]*Emory University, Atlanta, GA, USA*

Background: Malaria affects around 500 million people which result in 1 million fatalities mainly in children > 5 years. It has been shown that severe malaria pathology, especially cerebral malaria (CM) is inflammation driven. T cell cytokine interferon-ϒ has been shown to promote CM whilst T cell derived interleukin-10 has been shown to be protective. Thrombocytopenia is common in malaria pathology and studies have shown that platelet depletion can rescue mice from malaria-associated mortality, however, the underlying mechanism for survival remains incompletely understood.

Aims: We tested the hypothesis that platelet depletion in lethal *P. berghei* infection in mice leads to a more controlled inflammatory response leading to survival.

Methods: C57/BL6 mice were infected with 2×10^6 *P. berghei* via IP injection, or krebs saline as control. One day after inoculation, infected and naïve mice were split into three groups, one group receiving 100 μg of platelet-depleting GPIb antibody (Emfret, UK), one receiving 100 μg IgG control and the last group receiving PBS as control. Mice were either monitored for 10 days in the survival experiment, or were euthanized on day 5 after inoculation and spleens were harvested. 2×10^6 cells were added to anti-CD3 coated plates with addition of 4 μg/well of anti-CD28 (eBioscience, USA) and 20 μg/mL Brefeldin A (Sigma-Aldrich, USA). Cells were incubated at 37°C, 5% CO_2 and harvested after 6 h, and were surface stained with CD4-PerCP (eBioscience, USA) and CD8-FITC (eBioscience, USA), and stained for intra-cellular IL-10-APC (eBioscience, USA) and IFNϒ-PE (eBio-

science, USA). Using FlowJo software (Treestar) the CD4 and CD8 T cell populations were analysed for the expression of IL-10 and IFN-ϒ by flow cytometry.

Results: In line with previous reports our results showed that platelet depletion rescues mice from malaria associated pathology. Activation of malaria-specific CD4 T cells in *P. berghei*−-infected platelet-depleted mice ($n = 5$) lead to 1% CD4 T cells expressing IFNϒ, double that of *P. berghei* -infected IgG ($n = 5$) and *P. berghei*-infected PBS control ($n = 5$), 0.34% and 0.5% respectively. Similarly the population of IL-10 expressing CD4 T cells was also higher in infected platelet-depleted mice, 1%, compared to the IgG and PBS control, 0.43% and 0.63% respectively. Interestingly, there was an earlier emergence of self-regulating CD4 T cells expressing both IFNϒ and IL-10, which are critical for limiting immunopathology, in *P. berghei*-infected platelet-depleted mice compared to both IgG and PBS control indicating a more appropriate CD4 T cell response against *P. berghei*. CD8 T cell populations were unaffected by platelet depletion and both populations and the expansion of IFN-ϒ expressing CD8 T cells remained unaffected by platelet depletion.

Summary and Conclusions: It is becoming increasingly clear that platelets play an active role in the inflammatory mechanisms that lead to severe malaria pathology. Our results show that in lethal *P. berghei* infections platelets actively delay the development of Th1 cells leading to immunopathology and that CD8 T cells are unaffected by platelet depletion. Knowledge of this could lead to the development of treatments alleviating severe malaria pathology and reducing malaria associated fatalities.

OC 85.2
Histones and DNA in complex synergistically promote plasma coagulation

Ammollo CTC, Semeraro F and Simioni P
University of Padua Medical School, Padua, Italy

Background: Nuclear structures released as nucleosomes from dying cells or secreted as extracellular traps by activated immune cells are newly recognized pro-thrombotic agents in the setting of infectious, inflammatory and neoplastic diseases. Although their main components, DNA and histones, have been shown to exert discrete procoagulant activities through interaction with platelets, coagulation proteins and anticoagulant systems, less information is available on the effects of histone-DNA complexes (H/DNA).

Aims: To evaluate the procoagulant activity of H/DNA as compared with that of the isolated components.

Methods: H/DNA (1:1 histones to DNA weight ratio), histones and DNA were tested at concentrations ranging from 5 to 40 μg/mL. Thrombin generation and fibrin formation were investigated in plasma by calibrated automated thrombinography (CAT) and turbidimetry, respectively. Clotting was induced by recalcification.

Results: H/DNA, but not the isolated components, dose-dependently shortened the time to fibrin formation (up to 40% reduction at 40 μg/mL). This effect was not recapitulated in a clotting assay employing purified thrombin and fibrinogen, thus pointing towards an effect of H/DNA on the coagulation cascade upstream thrombin formation. In the CAT assay, H/DNA enhanced thrombin formation in a dose-dependent manner: at 20 μg/mL H/DNA shortened the lag time from 20.5 ± 4.2 to 14.9 ± 1.4 min ($P = 0.02$) and the time to peak from 27.1 ± 5.8 to 17.9 ± 1.6 min ($P > 0.01$), and increased the endogenous thrombin potential from 861.7 ± 221.8 to 1446.9 ± 142.8 nM*min ($P = 0.002$), the thrombin peak from 81.5 ± 36.4 to 258.9 ± 26.2 mM ($P > 0.001$) and the velocity of thrombin formation from 16.1 ± 12.2 to 88.9 ± 13.7 nM/min ($P > 0.001$). In contrast, histones and DNA (up to 40 μg/mL) had a negligible influence on thrombin generation when tested alone or when their association was prevented by addition to plasma prior to complex formation or by mixing in a high ionic strength buffer. Replacement of histones with other cationic polypeptides known to interact with DNA (protamine and poly-lysine) failed to produce the same enhancement of coagulation, indicating that histones possess specific procoagulant features. H/DNA, but not isolated histones and DNA, stimulated thrombin formation also in the presence of the FXIIa inhibitor CTI and in FXII- or kininogen-deficient plasma, ruling out the involvement of the contact phase of coagulation. On the contrary, H/DNA failed to induce thrombin formation if plasma was depleted of FXI, or any other factor downstream, suggesting that H/DNA might promote the activation of FXI by mechanisms that remain to be elucidated.

Conclusions: Histones and DNA, when associated in complexes, are able to promote and sustain the activation of coagulation. This adds to the pathogenetic role that intranuclear material plays when released in the extracellular space.

OC 85.3
Gas6 promotes macrophage recruitment and activation in venous thrombosis

Laurance S, Lemarie CA and Blostein MD
Lady Davis Institute for Medical Reseach, McGill University, Montreal, QC, Canada

Background: Gas6 is a member of the vitamin K-dependent protein family characterized by an enzymatic post-translational modification called g-carboxylation. Despite genetic data suggesting that Gas6 participates in vascular disease, a defined role for Gas6 in thrombus formation has remained elusive. However, we recently demonstrated the importance of Gas6 derived from the hematopoietic and the non-hematopoietic compartments in the pathophysiology of venous thrombosis. Interestingly, we found that gas6 induced the expression and activity of tissue factor in the vascular wall.

Aims: Venous thrombi are pervaded by a large numbers of leukocytes and it was recently shown that blood monocytes can provide the initiating stimulus for venous thrombus development by rolling and adhering to the venous endothelium. Studies have suggested a pro-inflammatory role for gas6 in the vasculature. Thus, we hypothesize that Gas6 may be involved in macrophage recruitment and activation in venous thrombosis.

Methods: Thrombosis was induced in the inferior vena cava of wild type (WT) and *Gas6* deficient (−/−) mice using 5% $FeCl_3$. Immunostaining were performed on thrombus sections for CD45 (leukocyte marker) and MOMA-2 (macrophage marker). Bone marrow derived macrophages (BM-DM) were also isolated from WT and *Gas6*−/− mice and differentiated for 7 days with M-CSF. Thereafter, macrophages were stimulated with thrombin for 4 h. RNA was isolated and the expression of integrins $alpha_M$, $alpha_L$, and $alpha_4$, as well as PSGL-1 (P-selectin glycoprotein ligand-1) and tissue factor were assessed by real time PCR.

Results: Immunohistochemistry showed a strong reduction in the number of leukocytes and macrophages within thombi of *Gas6*−/− compared to WT mice. The expression of the integrins $alpha_M$, $alpha_L$, and $alpha_4$ as well as PSGL-1 were increased in WT BM-DM treated with thrombin. However, in *Gas6*−/− BM-DM, incubation with thrombin did not affect the mRNA of these integrins or of PSGL-1. Finally, we found that tissue factor mRNA expression was up-regulated by thrombin in WT BM-DM but not *Gas6*−/− BM-DM.

Summary/Conclusions: In the present study, we show that Gas6 participates in macrophage recruitment and positively regulates the expression of tissue factor and several adhesion molecules well-known to interact with their countereceptors on endothelial cells or platelets. Thus, we provide significant insights in the understanding of the role of gas6 in macrophage involvement in venous thombus formation. Our study also reinforces the interest of targeting gas6 to develop new therapeutic strategies to treat thrombosis as loss of gas6 function results in reduced thrombus formation without excessive bleeding.

OC 85.4

Association of cell-free DNA with plasma von Willebrand factor levels in human and mouse models of inflammation

Michels A, Albánez S, Swystun L, Sponagle K, James PD and Lillicrap D

Queen's University, Kingston, ON, Canada

Background: von Willebrand factor (VWF) is an acute phase protein and has been demonstrated to increase in concentration during chronic and acute inflammatory conditions such as aging and sepsis, respectively. In acute inflammation, cell-free DNA (CF-DNA) and histone proteins have been shown to activate the contact pathway and platelets. CF-DNA concentrations have also been used as a measure of disease activity in thrombotic thrombocytopenic purpura (TTP) patients, where acute inflammation is present. Additionally, studies have shown that unfractionated histones induce the release of VWF in a murine model. Therefore, a possible mechanistic link exists between the release of CF-DNA and VWF in inflammatory states.
Aims: To investigate the correlation and potential mechanistic association between CF-DNA and VWF plasma levels in acute and chronic inflammatory states in humans and mice.
Methods: CF-DNA in plasma was quantified using a PicoGreen assay. VWF antigen (VWF:Ag) levels were quantified in plasma samples through an ELISA. Lipopolysaccharide (LPS) was administered with an intraperitoneal injection (5 mg/kg) to 9- and 55- week old C57BL/6 normal and ADAMTS13 KO mice, and sampled at 3 and 6 h after injection. Hydrodynamic injections (HI) of 100 μg of a plasmid containing murine VWF cDNA were performed on 9-week old VWF KO and VWF/ADAMTS13 KO mice and sampled 1-, 2- and 6-weeks after injections.
Results: CF-DNA increased significantly in middle-age (30–49, $n = 42$) and old (55–87, $n = 78$) healthy human subjects compared to young (1–17, $n = 52$) individuals ($P > 0.05$). CF-DNA also increased significantly between 9 and 55 weeks old normal mice ($P > 0.0001$, $n = 27$). In humans, CF-DNA and VWF:Ag were not correlated in the young and middle-age groups, although a correlation was observed in the old age group ($P > 0.05$). This positive correlation was also observed in normal mice, regardless of age ($P > 0.0001$). The inflammatory state documented in acute exacerbations of TTP was also associated with correlations between CF-DNA and VWF:Ag ($P > 0.0001$, $n = 12$). In a murine LPS model of acute inflammation, there was a marked increase in CF-DNA at 3 and 6 h ($P > 0.05$) and an increase in VWF:Ag at 3 h ($P > 0.05$) after LPS administration ($n = 15$). In a mouse model of prolonged supraphysiological VWF expression (> 20 U/mL, $n = 32$) induced by HI, there was no increase in CF-DNA. These levels remained the same in the absence of proteolytic processing of supraphysiological VWF in VWF/ADAMTS13 KO mice, suggesting that an increase in VWF concentration and multimer size does not cause an increase in CF-DNA. Similarly, in the absence of VWF, as seen with type 3 von Willebrand disease patients, CF-DNA concentration was positively correlated with age ($P > 0.01$, $n = 17$) independent of any increase in VWF:Ag.
Summary/Conclusions: The release of CF-DNA in acute and chronic inflammation models was associated with VWF plasma levels; however, supraphysiological expression of VWF did not stimulate CF-DNA release. Activation of inflammation may simultaneously stimulate CF-DNA release and endothelial activation, leading to the coordinated release of VWF and CF-DNA. CF-DNA and histones may also directly trigger endothelial and platelet activation to increase plasma VWF levels.

OC 85.5

Soluble TREM LikeTranscript-1 (sTLT-1) enhances thrombin induced actin polymerization through a Rac1 and P38 mediated pathway

Fernández de Soto M[1] and Washington AV[2]

[1]University of Puerto Rico, Mayaguez, Mayagüez; [2]University of Puerto Rico, Rio Piedras, San Juan, Puerto Rico

Background: The TREM like transcript-1 (TLT-1) is a membrane receptor that plays an important role in inflammation derived hemostasis and/or thrombosis. To date TLT-1 has only been identified in the α-granules of megakaryocytes and platelets and is released to the platelet surface upon platelet activation. Activated platelets release a soluble form of TLT-1 (sTLT-1) that is found in serum but not in the plasma of healthy mice and humans. Patients diagnosed with sepsis have been found with plasma levels of sTLT-1 averaging more than 300 μg/mL, moreover high sTLT-1 levels correlate with the presence of disseminated intravascular coagulation (DIC). These studies are further supported by our investigations in *treml1−/−* mice. LPS induced sepsis in mice demonstrate that they have increases in plasma sTLT-1 levels during acute sepsis and that *treml1−/−* bleed where wild type mice do not in the Shwartzman model of vasculitis.
Aims: With this study it is our goal to elucidate the pathway that sTLT-1 initiates to enhance platelet function after low dose thrombin treatment in order to better understand TLT-1's role during sepsis and DIC.
Methods: Here we identify a multimeric form of sTLT-1 that is stored in resting platelets and released upon activation suggesting that sTLT-1 may play an important role during activation. Using a recombinant sTLT-1 (rsTLT-1), in *in vitro* static assays we show that rsTLT-1 enhances agonist induced actin polymerization. Subsequently, we developed a whole blood flow cytometry (WBF) assay to demonstrate sTLT-1 effects on thrombin induced secretion and gpIIb IIIa activation. Rac and Rho small GTPases play important roles in regulating actin polymerization, therefore we hypothesized that sTLT-1 may activate one of these pathways during activation to increase actin formation. Using the WBF assay we demonstrate that the Rac inhibitor NSC23766 and not the Rho inhibitor, C3, inhibits sTLT-1 (50 μg/mL) augmented activation, suggesting that sTLT-1 uses a Rac1 pathway to enhance platelet activation. To verify these results we evaluated the binding of activated Rac1 to the CRIB domain of PAK 21 at low doses of thrombin in the presence or absence of sTLT-1.
Results: We found that sTLT-1 induces a dose-dependent increase of Rac1 starting at doses of sTLT-1 as low as 5 μg/mL. The enhanced activation is reversed by the TLT-1 antibody, C10. Furthermore, we investigated p38 and p42 pathways as potential downstream mediators of the Rac1 signaling pathway. Consistent with current paradigms of Rac1 signaling and actin polymerization, sTLT-1 enhanced the phosphorylation of p38 and not p42.
Summary/Conclusion: This work is the first to demonstrate a pathway detailing how sTLT-1 leads to enhanced platelet activation as shown in our previous publications. Here we define a pathway of activation that is initiated with sTLT-1 and thrombin causing increased activation of both Rac1 and p38 leading to increased actin polymerization. Collectively our data outlines a mechanism of how high levels of sTLT-1 could mediate sepsis progression and propagation of DIC during sepsis.

OC 85.6

Platelets persistently enhance Treg responses, but biphasically regulate Th1/Th17 responses in platelet-CD4+ T cell co-cultures

Zhu L, Huang Z, Stålesen R, Hansson G and Li N

Karolinska Institute, Stockholm, Sweden

Background: Atherogenesis involves both inflammatory and thrombotic mechanisms, in which platelets and $CD4^+$ T cells play important

roles. Our recent study showed that platelets can simultaneously enhance differentiation and cytokine production of type 1 T helper (Th1), Th17, and regulatory T (Treg) cells via platelet derived chemokines in co-cultures of autologous human platelets and $CD4^+$ T cells.
Aims: To investigate if platelets persistently enhance $CD4^+$ T cell differentiation, of if platelet-enhanced $CD4^+$ T cell differentiation leads to an enhanced cross-talk among $CD4^+$ T cell subsets.
Methods: Human $CD4^+$ T cells were cultured without or with autologous platelets in the presence of anti-CD3/CD28 MAbs. Th1, Th17, and Treg cell differentiation were monitored during 5 days by intracellular staining of IFNg, IL-17, and FoxP3, respectively.
Results: We confirmed our previous findings that platelets can simultaneously enhance Th1, Th17, and Treg cell differentiation. At day 2, platelets increased Th1 cell phenotype from 14.9 ± 1.7% of $CD4^+$ T cells alone to 18.6 ± 2.1%, Th17 cells from 1.8 ± 0.4% to 2.4 ± 0.5%, and Treg cells from 13.0 ± 1.4% to 20.6 ± 1.7%. At day 3 and 5, platelets remained augmentative for Treg differentiation (29.3 ± 4.3% and 21.7 ± 4.8%, respectively), but turned suppressive for Th1 activation (11.0 ± 2.1% with vs. 13.1 ± 1.7% without platelets and 7.8 ± 2.2% vs. 11.8 ± 1.9%, respectiverly; $n = 9$, $P > 0.05$ for all). The latter was also seen with Th17 responses. In platelet-T cell co-cultures, the FoxP3-blocking peptide P60 mildly reduced Treg cell differentiation, but had no effect on Th1 cell activation. Transforming growth factor b (TGFb) and interleukin (IL)-10 blockade with neutralizing antibodies inhibited Treg cell differentiation, but did not reverse the suppression of Th1 cell differentiation. In $CD4^+$ T cells cultured alone, the same inhibitions of Treg differentiation had no influence on the dynamics of Th1 phenotyping. All evidence suggests that Treg cells had limited impact on, whilst platelets were likely accounted for Th1 suppression during the second phase. Using a BrdU incorporation assay, we showed that platelets attenuated aCD3/CD28-induced $CD4^+$ T cell proliferation, and that the inhibitory effect was more selective among FoxP3-negative cells.
Conclusion: Platelets constantly promote anti-CD3/CD28-stimulated Treg cell differentiation in human platelet-$CD4^+$ T cell co-cultures. However, platelets exert a biphasic regulation on Th1/Th17 cell differentiation, namely a transient enhancement that followed by a secondary suppression. Our findings suggest that platelets can foster more rapid and robust Th1/Th17 responses, but also cast a secondary inhibition on Th1/Th17 differentiation. This represents a novel mechanism of platelet-regulated $CD4^+$ effector cell responses, and may have a major significance in adaptive immunity.

OC 86 – Negative Regulation of Platelet Function

OC 86.1
Shedding'light on platelet CD84

Vögtle T[1], Hofmann S[1], Kraft P[2], Morowski M[1], Bender M[1], Braun A[1], Stoll G[2], Rose-John S[3] and Nieswandt B[1]
[1]Rudolf Virchow Centre for Experimental Biomedicine, University of Würzburg; [2]University Hospital Würzburg, Würzburg; [3]Christian-Albrechts-University of Kiel, Kiel, Germany

Background: CD84 is a type I transmembrane receptor of the *signalling lymphocyte activation molecule* (SLAM) family which is widely expressed in immune cells and platelets and undergoes homophilic interactions. Although members of the SLAM protein family have been shown to contribute to signalling during platelet aggregation, neither the role of CD84 in platelet physiology, nor its regulation is well explored. Acute ischaemic stroke is a 'thrombo-inflammatory' pathologic process where infarct progression strictly depends on early platelet adhesion/activation mechanisms and immune cell recruitment, but the exact mechanisms how these processes are linked are unknown.
Aims: We investigated the role of CD84 in thrombus formation, haemostasis and ischaemic stroke and further analysed the mechanisms regulating CD84 surface expression and degradation in platelets.
Methods: We generated CD84-deficient mice and analysed their platelets *in vitro* and *in vivo*. Further, *Cd84−/−* mice were subjected to *transient middle cerebral artery occlusion* (tMCAO), a highly standardised experimental model for ischaemic stroke. In addition, the regulation of platelet CD84 was studied by biochemical approaches (ELISA, Western blot) and use of three different genetically modified mouse lines.
Results: We demonstrate that CD84 is cleaved from the surface of human and murine platelets in response to platelet receptor agonists. Studies in transgenic mice identified ADAM10 as the principal sheddase responsible for CD84 cleavage, whereas ADAM17 was dispensable. Shedding of CD84 via ADAM10 occurs constitutively *in vivo* and also during blood clotting, since the robust plasma and serum levels of soluble CD84 of wild-type mice were reduced in ADAM10 deficient mice. Moreover, Western blot analysis revealed calpain-mediated cleavage of the intracellular CD84 *C*-terminus, occurring simultaneously with, but independently of ectodomain cleavage.
Studies on *Cd84−/−*mice showed that the lack of CD84 in platelets does not affect classic platelet functions such as integrin activation, granule release and aggregation in response to major agonists or spreading on fibrinogen. In contrast, mice lacking CD84 displayed significantly reduced brain infarctions and a better neurological outcome 24 h after tMCAO, revealing a previously unknown role of SLAM family receptors in ischaemic stroke.
Summary/conclusions: Our results reveal a tight regulation of platelet CD84 by simultaneous extra- and intracellular cleavage. The analysis of CD84 deficient animals indicates that CD84 may not serve an essential function in haemostasis and thrombosis. Instead, the protection of *Cd84−/−* mice in a model of ischaemic stroke implicates a functional importance of CD84 in thrombo-inflammatory processes.

OC 86.2
BMP and activin membrane bound inhibitor (BAMBI): A novel regulator of thrombus formation

Salles I, Monkman JH, Ahnström J, Lane DA and Crawley JTB
Imperial College London, London, UK

Background: *In vivo* thrombus formation after vascular injury requires a myriad of simultaneous events involving critical roles of components of the vessel wall, circulating platelets and other blood cells as well as numerous plasma proteins. By gene expression studies, we previously identified a novel platelet transmembrane receptor, BAMBI that is highly expressed in megakayocytes and endothelial cells. Moreover, using a zebrafish model of thrombosis we demonstrated that BAMBI acts as a positive regulator of thrombus formation.
Aims: This study aimed to characterise the role/contribution of BAMBI in platelet function, thrombus formation and haemostasis.
Methods: Bambi−/− mice were generated using Cre/Lox technology backcrossed onto a C57BL/6J background. Haematological parameters (including platelet counts) were assessed using an automated cell counter and by flow cytometry. Platelet function was assessed by measuring the expression of P-selectin and the activation of αIIbβ3 after stimulation with ADP, collagen-related peptide (CRP) or thrombin using flow cytometry. Thrombin generation in platelet poor plasma was investigated using calibrated automated thrombography. The tail bleeding time was performed on anaesthetised mice by cutting 2 mm of the tail and immersing it in PBS. The time needed to arrest bleeding was recorded as well as the volume of blood lost after 10 min. The thrombosis model was carried out by injuring the vessel wall of mesenteric arterioles with 10% $FeCl_3$-saturated filter paper after intravenous administration of $DIOC_6$. Thrombus formation was recorded in real time, and images analysed offline using Slidebook software. Genotypes of the mice were blinded.
Results: Although Bambi−/− mice were born at the expected Mendelian ratio, female Bambi−/− mice exhibited a small reduction in body

weight, and increased mortality at 5 weeks than littermates (15% of female Bambi−/− pups). Despite normal platelet counts, the bleeding time in Bambi−/− and Bambi+/− mice was significantly increased compared to Bambi+/+ littermates (587 ± 58, 553 ± 43 and 453 ± 42 s, respectively; $P = 0.02$) and was accompanied with a significant increase in blood loss at 10 min (70 ± 12, 67 ± 8 and 41 ± 5 μL, respectively; $P = 0.04$). In addition, using the $FeCl_3$ thrombosis model, a significant increase ($P = 0.003$) in the time to occlusion was observed in Bambi−/− and Bambi+/− mice compared to control littermates (1687 ± 190, 1500 ± 147 and 850 ± 156 s, respectively). No defects in thrombin generation in Bambi−/− plasma, expression of major platelet receptors and platelet activation after ADP, CRP and thrombin were detected that might account for the haemostatic defect.

Conclusions: Together, these data provide compelling evidence for an important role for BAMBI not only in haemostasis but also in thrombus formation. These results are in agreement with the phenotype observed in zebrafish and also confirm the role of BAMBI as a positive regulator of thrombus growth. *Ex vivo* and additional *in vivo* thrombosis models are currently under way to further elucidate the role of BAMBI in thrombosis.

OC 86.3

Paxillin is an intrinsic negative regulator of platelet activation in mice

Sakata A[1], Ohmori T[1], Nishimura S[2], Suzuki H[3], Madoiwa S[1], Mimuro J[1], Kario K[1] and Sakata Y[1]

[1]Jichi Medical University, Tochigi; [2]The University of Tokyo; [3]Nippon Medical School, Tokyo, Japan

Background: Paxillin is a LIM domain protein that is localized at integrin-mediated focal adhesions. Considering the multiple interaction motifs located within its structure, paxillin seems to serve as a signaling platform for the recruitment of numerous regulatory proteins near integrins. Although direct interactions of paxillin with the cytoplasmic tail of integrins are believed to be involved in a number of cell processes by modulating integrin functions, little is known about the contribution of this LIM domain protein to integrin signaling pathways for platelet activation.

Aims: The aim of this research is to clarify the role of paxillin in integrin signaling pathways for platelet activation in mice.

Methods and Results: To inhibit the expression of paxillin in anucleate platelets, we transplanted bone marrow cells transduced with a lentiviral vector that simultaneously expressed EGFP and short hairpin RNA (shRNA) sequences for paxillin into lethally-irradiated recipient mice. The Pxn-KD platelets slightly increased in size, and showed augmented integrin αIIbβ3 activation following stimulation of multiple receptors, including GPVI and G protein-coupled receptors. TXA_2 biosynthesis and the release of α-granules and dense granules in response to agonist stimulation were also enhanced in Pxn-KD platelets. Conversely, talin-dependent conformational changes in integrin αIIbβ3 expressed in Chinese hamster ovary cells were not affected by Pxn-KD. Although Pxn-KD did not affect intracellular calcium mobilization in platelets, Pxn-KD significantly enhanced Rap1b activation. Intravital imaging confirmed that Pxn-KD enhanced platelet adhesion to the endothelium and thrombus formation.

Conclusions: Our findings suggest that paxillin negatively regulates several common platelet signaling pathways, resulting in the activation of integrin αIIbβ3 and release reactions, possibly through altered Rap1b activation.

OC 86.4

Apelin acts as an endogenous antithrombotic factor

Adam F[1], Lopez-Barba JJ[1], Vatier C[2], Turpin S[1], Muscat A[2], Valet P[3], Bobe R[1], Feve B[2] and Siegfried G[1]

[1]Inserm U770, Le Kremlin-Bicêtre Cedex; [2]Inserm U938, Paris; [3]Inserm U1048, Toulouse, France

Background: Apelin is a bioactive peptide identified as the endogenous ligand of the G protein-coupled receptor APJ. This peptide displays a number of physiological roles, including regulation of cardiovascular functions, fluid and energy homeostasis, and blood vessel formation. In contrast, among its pleiotropic functions, the effects of apelin/APJ system in platelets are unknown.

Aims: The aim of this study is to investigate the role of apelin on platelet function.

Methods: The expression of apelin/APJ in platelets was detected by RT-PCR, western blotting and immunofluorescence. The involvement of apelin in platelet function was investigated (i) *in vivo* in a tail bleeding assay and in a mouse model of arterial and venular thrombosis after intravenous injection of apelin, and (ii) *in vitro* in platelet aggregation induced by thrombin, collagen and ADP, and in platelet adhesion and thrombus formation over a collagen matrix under blood flow conditions.

Results: RT-PCR, immunoblot analysis and immunofluorescence studies revealed that human and mouse platelets express apelin and its receptor APJ. In tail bleeding assays, the intravenous injection of apelin in wild-type (WT) mice exhibited significantly increased bleeding times (70% of mice injected with apelin had a bleeding time > 10 min). Interestingly, the bleeding time of apelin-deficient mice ($apelin^{-/-}$) is significantly reduced compared to WT mice.

In addition, the role of apelin in thrombus formation was assessed *in vivo* in a ferric chloride-induced thrombosis model, followed by intravital microscopy in mice. The injection of apelin induced a significant delay of vessel occlusion. This observation of reduction of thrombus formation by apelin was confirmed *in vitro* in a whole-blood perfusion assay over a collagen matrix. Altogether, these *in vivo* and *in vitro* studies provide evidences that apelin plays a role for normal hemostasis and thrombus formation.

As thrombus formation and platelet function, including integrin αIIbβ3 engagement, are closely associated, the effect of apelin was studied in platelet aggregation induced by various agonists. In the presence of apelin, platelet aggregations induced by suboptimal concentration of thrombin or collagen were inhibited by 67 ± 3% and 37 ± 5%, respectively for human platelets. Interestingly, no effect of apelin was noticed in ADP-induced platelet aggregation. Flow cytometry analysis of integrin αIIbβ3 activation and P-selectin exposure revealed an inhibitory effect of apelin, suggesting that apelin is able to modulate platelet activation.

Conclusion: In the current study, we reveal for the first time the functional importance of apelin in hemostasis. Indeed, we have identified that this hormone, and its receptor (APJ), are present in platelets and that apelin can inhibit platelet functions. Thereby, besides to its previously reported effects, our study revealed the potential antithrombotic function of apelin, offering new therapeutic opportunities for patients with high thrombotic risk.

OC 86.5

The role of NADPH oxidase (NOX) 1 and 2 in GPVI-dependent platelet activation and thrombus formation

Walsh TG, Carrim N, Berndt MC and Metharom P

Royal College of Surgeons in Ireland, Dublin, Ireland

Background: Glycoprotein (GP) VI is an essential platelet receptor regulating thrombosis and haemostasis. Collagen, the most thrombogenic constituent of the extracellular matrix, signals primarily through GPVI, inducing a signaling pathway culminating in platelet activation,

granule secretion, spreading and thromboxane A_2 production. Additionally, GPVI activation regulates the production of reactive oxygen species (ROS), which have been implicated as important secondary messengers mediating various platelet functions. Previous studies have implicated NADPH Oxidase-2 (NOX2) as the isoform of the NOX complex catalytic subunit regulating ROS production in platelets, whilst a recent study identified a functional role for NOX1. One major disadvantage of these studies is the overreliance on non-specific NOX inhibitors, especially those that can also act as radical scavengers (antioxidants), which may confound interpretation of the origin of platelet-derived ROS.

Aim: The aim of this study was to explore the role of NOX1 and NOX2 in GPVI-dependent platelet activation and collagen-induced thrombus formation using a pharmacological inhibitor specific for NOX1 (ML171) and a NOX2-deficient mouse model.

Methods: Washed platelets from wildtype (WT) or NOX2 knockout (KO) mice were incubated with vehicle control or ML171. Platelets were then stimulated with the GPVI-specific agonist, CRP, and monitored in multiple platelet function tests including platelet aggregation, intracellular ROS production (using the oxidation-sensitive dye, H_2DCFDA), integrin $\alpha_{IIb}\beta_3$ activation, dense body and α-granule release (ATP and P-selectin, respectively), platelet spreading, thromboxane (Tx) B_2 production and activation of intracellular kinases (ERK1/2, Akt and p38) by western blot. Blood from WT or NOX2 KO mice, pretreated with vehicle control, ML171 or aspirin (as positive control) was also perfused over a collagen-coated surface at arterial shear (1500/s) and monitored for thrombus formation.

Results: ML171, a specific NOX1 inhibitor with no ROS scavenging activity, significantly reduced CRP-dependent ROS production, while NOX2 KO mice showed similar ROS formation to that of WT platelets following CRP stimulation. The absence of functional NOX1 and NOX2 did not significantly affect CRP-mediated platelet aggregation, $\alpha_{IIb}\beta_3$ activation, platelet spreading, and dense body and α-granule release, whereas TxA_2 production required NOX1-derived ROS. NOX1, but not NOX2, was essential for early (1 min) activation of p38 following GPVI stimulation, but was not involved in ERK1/2 or Akt activation. Both NOX1 and NOX2 were crucial for collagen-mediated thrombus formation under arterial shear as quantified by thrombus volume analysis, whereas platelet surface coverage was similar between experimental conditions.

Conclusions: NOX1 is the key NOX homologue regulating GPVI-dependent ROS production, which is necessary for p38 activation and TxA_2 formation. Both NOX homologues are crucial for collagen-mediated thrombus formation, but the mechanism pertaining to the defective thrombus phenotype observed with the NOX2 KO remains unclear.

An essential role of the inhibitory Fc gamma receptor IIb in antibody-induced glycoprotein VI ectodomain shedding *in vivo*

Stegner D[1], Popp M[2], Dütting S[2], Lorenz V[2], Gessner JE[3] and Nieswandt B[2]

[1]University Hospital Würzburg; [2]University Hospital and Rudolf Virchow Center for Experimental Biomedicine, Würzburg; [3]Hannover Medical School, Hannover, Germany

Background: Glycoprotein VI (GPVI) mediates platelet activation on exposed subendothelial collagens at sites of vascular injury and thereby contributes to normal haemostasis, but also to the occlusion of diseased vessels. GPVI is an attractive target for antithrombotic therapy, particularly because previous studies have shown that anti-GPVI antibodies induce irreversible down-regulation of the receptor in circulating platelets. GPVI down-regulation, which occurs through ectodomain shedding and/or internalisation, is accompanied by a transient thrombocytopenia. We have recently shown that GPVI ectodomain shedding *in vitro* depends on the presence of the two metalloproteinases ADAM10 and ADAM17. However, *in vivo* anti-GPVI antibody induced effects were unaltered in mice with a platelet-specific ADAM10 deficiency and mice lacking functional ADAM17 in the haematopoietic system. Fc gamma receptors (FcγR) are capable of binding antibodies and might thus contribute to the *in vivo* effects of anti-GPVI antibodies. Mice bear three different activating FcγRs (FcγRI, FcγRIII and FcγRIV), which are expressed on different immune cells. FcγRIIb, the only inhibitory FcγR in mice, is present on various immune cells and some endothelial cells, but not platelets.

Aims: We speculated that another cell-type might be involved in mediating anti-GPVI antibody triggered effects *in vivo* via FcγRs.

Methods: We studied the *in vivo* effects of the rat anti-GPVI antibody JAQ1 in mice pretreated with the FcγRIIb / FcγRIII blocking antibody, 2.4G2, and in mice genetically modified to lack either FcγRIII or FcγRIIb.

Results: In contrast to control mice, 2.4G2 pre-treated mice developed no thrombocytopenia upon JAQ1-injection and the FcγR blockade abolished GPVI ectodomain shedding. Studies in FcγRIII-deficient mice unexpectedly revealed that this FcγR was dispensable for both JAQ1-induced thrombocytopenia and GPVI ectodomain shedding. In contrast, both processes were completely blocked in mice lacking the inhibitory FcγRIIb. Histological analyses revealed that the transient thrombocytopenia of JAQ1-opsonized platelets was caused by platelet sequestration to the liver through a FcγRIIb-dependent mechanism. Remarkably, Kupffer cell depletion with clodronate-liposomes did not prevent the JAQ1-induced transient thrombocytopenia or the down-regulation of GPVI, indicating a contribution of endothelial cells in this process.

Summary/Conclusion: Our data demonstrate that anti-GPVI antibody triggered transient thrombocytopenia and GPVI ectodomain shedding *in vivo* occur through an unprecedented FcγRIIb-dependent mechanism. We speculate that FcγRIIb positions JAQ1-bound GPVI for shedding *in trans*, however, further studies are needed to verify this hypothesis.

Beta3 integrin PSI domain has thiol isomerase function: new insights into integrin function and for anti-thrombotic agent development

Zhu G[1], Chen P[2], Reheman A[1], Li J[3], Freedman J[3] and Ni H[4]

[1]St. Michael's Hospital; [2]Canadian Blood Services, St.Micheal's Hospital; [3]St. Michael's Hospital, University of Toronto; [4]Canadian Blood Services, St.Micheal's Hospital, University of Toronto, Toronto, ON, Canada

Background: Platelets are critical for maintaining hemostasis, but inappropriate platelet activation can lead to pathogenic thrombosis. Integrin αIIbβ3, the most abundant protein on the platelet surface, is a key molecule for platelet aggregation and thrombus formation. The PSI domain of β3 integrin is highly conserved among different species; however, the function of the PSI domain in the integrin family and in hemostasis and thrombosis is poorly understood. It has been reported that β3 integrin possesses PDI activity, which may play a role in integrin activation and platelet aggregation. However, whether the PSI domain of β3 integrin has PDI function is currently unknown.

Aims: To investigate whether the PSI domain of β3 integrin has thiol isomerase function and the effect of anti-PSI domain antibody on platelet function, specifically aggregation and thrombus formation.

Methods: We generated recombinant protein of the PSI domain of mouse β3 integrin. Mouse anti-mouse PSI domain monoclonal antibodies (mAbs) were generated from β3-deficient mice ($\beta3^{-/-}$) immunized with the recombinant protein. Antibody specificity was

determined by flow cytometry and western blotting. A PDI activity assay of mouse PSI domain and native human β3 integrin was performed using reduced and denatured RNase (rdRNase). The effects of the mAbs on platelet function were measured *in vitro* using aggregometry and *in vivo* using an intravital microscopy laser-induced thrombosis model.

Results: Analysis of the PSI domain of β3 integrin revealed that it contains two CXXC amino acid sequences (the active site motif of PDI), which are exclusively conserved among different integrins (β1-β8 integrin) and species. Refolding of rdRNase showed that the PSI recombinant protein has endogenous PDI activity. Bacitracin, a well-known PDI inhibitor, inhibited PSI domain PDI function in a dose dependent manner. However we did not see any inhibitory function of Quercetin-3-rutinoside on the thiol isomerase function of the PSI domain of β3 integrin. Four anti-PSI domain mAbs were generated and showed different inhibitory effects on PDI function of the recombinant PSI domain and purified human platelet β3 integrin. *In vitro* and *ex vivo* studies showed that anti-PSI antibodies inhibited mouse and human platelet aggregation. Using intravital microscopy we demonstrated that anti-PSI mAbs inhibited mouse platelet aggregation and thrombus formation *in vivo*.

Conclusions: To the best of our knowledge, this is the first study to demonstrate that the PSI domain of β3 integrin has endogenous PDI activity, which may play important roles in cell biology of platelets and other cells. Our data suggest that the PSI domain of β3 may be a new target in controlling platelet function and our mAbs may have potential in anti-thrombotic therapy.

OC 87.2

A role for CD40L signalling in platelet activation and thrombus formation that is independent of CD40

Kuijpers MJE[1], Mattheij N[1], Cipolla L[2], Cosemans JMEM[1], Lievens D[3], Donners MPC[1], Swieringa F[1], Mastenbroek TG[1], Torti M[2], Lutgens E[4] and Heemskerk JWM[1]

[1]Maastricht University, Maastricht, the Netherlands; [2]University of Pavia, Pavia, Italy; [3]Ludwig-Maximilians-University, Munich, Germany; [4]University of Amsterdam, Amsterdam, the Netherlands

Background: The glycoprotein CD40 (TNFRSF5) is a member of the tumour necrosis factor receptor (TNFR) superfamily, while its counter-receptor or ligand CD40L (TNFSF5, CD154) is a membrane protein of the TNF superfamily. The latter can be cleaved from the membrane surface by extracellular proteases, yielding a soluble fragment (sCD40L). CD40 and CD40L are both highly expressed on megakaryocytes and platelets, and have been proposed to play a role in platelet activation, but the mechanisms are not well understood. The current view is that CD40L-CD40 interaction signals to cell activation via TNFR associated factors (TRAFs), phosphoinositide 3-kinase (PI3K) isoforms and NFkB.

Aims: Determine the role of the CD40L-CD40 axis in platelet activation and thrombus formation.

Methods: Human and mouse platelet activation was determined by flow cytometry (integrin αIIbβ3 activation and P-selectin expression) and by light transmission aggregometry. Phosphorylation of Akt at Ser-473 was measured by western blot analysis. Thrombus formation was measured *in vitro* by whole blood perfusion over collagen type I or plaque material (rich in collagen) at a shear rate of 1000/s. Thrombi were assessed for size, stability and for platelet activation using fluorescently labeled probes. All mice had a C57BL/6 Apoe$^{-/-}$ genetic background. Mice were deficient in CD40 (Cd40), CD40L (Cd40lg).

Results: Whereas mouse platelets lacking CD40 (Cd40$^{-/-}$) showed increased αIIbβ3 activation and secretion in response to collagen receptor (GPVI) stimulation, mouse platelets deficient in CD40L (Cd40lg$^{-/-}$) showed diminished integrin activation and secretion in response to GPVI stimulation. Response to ADP, thromboxane or thrombin receptor agonists was not affected. On the other hand, addition of sCD40L potentiated the activation and aggregation responses of mouse and human platelets at low GPVI stimulation, even in the absence of CD40. This potentiation was antagonized by inhibition of PI3Kα/β, but not of PI3Kγ/δ isoforms. Whereas sCD40L alone did not cause Akt phosphorylation at Ser-473, it markedly enhanced the phosphorylation at low GPVI stimulation, which effect again was antagonized by PI3Kα/β inhibition. Whole blood thrombus formation was decreased in Apoe$^{-/-}$Cd40lg$^{-/-}$ mice, but unchanged in Apoe$^{-/-}$Cd40$^{-/-}$, in comparison to Apoe$^{-/-}$ controls. In Apoe$^{-/-}$ blood, perfused over collagen or atherosclerotic plaque material, thrombus formation was enhanced, platelet aggregates were denser, and platelet activation was increased by addition of sCD40L; effects that were antagonized by inhibition of PI3Kα/β.

Conclusions: These results indicate a role of released sCD40L to enforce collagen-dependent platelet activation, by supporting integrin αIIbβ3 activation, secretion and dense thrombus formation, via an activation pathway involving PI3Kα/β. This role of CD40L is not phenocopied by CD40, indicating that CD40 is not a main counter-receptor of CD40L and not the signal transmitter to PI3K.

OC 87.3

Integrin a5β1 and glycoprotein VI play important roles in mediating activation and aggregation of platelets adhering to fibrillar fibronectin

Maurer E[1], Receveur N[1], Bourdon C[1], Nieswandt B[2], Lanza F[1], Gachet C[1] and Mangin PH[1]

[1]UMR_S949, Inserm, Université de Strasbourg, EFS-Alsace, Strasbourg, France; [2]Rudolf Virchow Center, DFG Research Center for Experimental Biomedicine, Würzburg, Germany

Background: Fibronectin (Fn) is a high molecular weight glycoprotein (440 kDa) present in the plasma as a dimer and in the subendothelium in a fibrillar form. A pioneer study using a flow-based assay, reported that plasma Fn allows recruitment of platelets through a mechanism involving integrins $\alpha_5\beta_1$ and $\alpha_{IIb}\beta_3$ (Beumer et al., *Blood* 1994). More recently, *in vitro* and *in vivo* experiments have suggested that plasma Fn also participates in thrombus growth upon binding to the surface of activated platelets, thereby enhancing platelet recruitment and thrombus stability (Cho et al., *Blood* 2006; Ni et al., *PNAS* 2003). To date, the ability of fibrillar fibronectin, which is exposed after vessel injury, to promote platelet adhesion and activation remains unknown.

Aims: The aim of this study was to generate fibrillar fibronectin *in vitro* and investigate its ability to support platelet adhesion, activation and aggregation.

Methods: Dimeric fibronectin was immobilized onto glass microcapillaries and multimerized through a mechanical stretch applied by aspiration with a vacuum pump (Robert et al., *Scientific Reports* 2011). Anticoagulated (hirudin 100 U/mL) human or mouse whole blood was perfused through these capillaries at various shear rates. Platelet adhesion was monitored by video-microscopy using differential interference contrast microscopy. Platelet activation was evaluated by observing morphological changes and variations in intracellular Ca^{2+} levels. Thrombus volumes were measured by confocal microscopy.

Results: The mechanical forces applied to immobilized dimeric Fn allowed the formation of a fibrillar network. Blood perfusion at low shear rates (300 s) showed that fibrillar Fn, contrary to dimeric Fn, was able to support efficient platelet adhesion in a process which relied on integrin $\alpha_5\beta_1$ and $\alpha_{IIb}\beta_3$. The glycoprotein (GP)Ib-IX complex did not play a crucial role in the initial steps of platelet recruitment, despite evidence that von Willebrand factor (VWF) binds to Fn in a purified system using an ELISA. Activation following platelet adhesion was evidenced by: (i) morphological changes comprising cell body contraction and extension of numerous filopodia; (ii) strong increases in intracellular Ca^{2+} concentrations above basal levels (872 ±

117 nM). Interestingly, the use of inhibitory peptides and blocking antibodies showed that this activation was dependent on integrins $\alpha_5\beta_1$ and $\alpha_{IIb}\beta_3$. Fn also led to the formation of thrombi at low (150/s) and intermediate wall shear rates (750/s) in a process relying on the interplay of various receptors including integrins $\alpha_5\beta_1$ and $\alpha_{IIb}\beta_3$, the GPIb-IX complex and GPVI.

Conclusions: This study provides evidence that fibrillar Fn supports efficient platelet adhesion, activation and aggregation through the interplay of a series of receptors including the known receptors for the soluble form, $\alpha_5\beta_1$ and $\alpha_{IIb}\beta_3$ integrins, but also the collagen receptor GPVI and the GPIb-IX/VWF axis.

OC 87.4

CD40L deficiency protects from a pro-thrombotic phenotype induced by angiotensin-II in mice

Jurk K[1], Hausding M[2], Münzel T[2], Grabbe S[3] and Daiber A[2]

[1]Center for Thrombosis and Hemostasis (CTH), University Medical Center, Mainz; [2]2nd Medical Clinic, University Medical Center, Johannes Gutenberg-University; [3]University Medical Center, Johannes Gutenberg-University, Mainz, Germany

Background: CD40 ligand (CD40L), a transmembrane protein belonging to the tumor necrosis factor family, is an important player in inflammatory-thrombotic disorders, such as atherosclerosis and cardiovascular disease. In addition to leukocytes and vascular cells platelets express functional CD40L on the surface which facilitates platelet aggregation and thrombus stability. However, the contribution of CD40L in haemostasis under conditions of inflammatory arterial hypertension is not known so far.

Aims: Investigating CD40L-deficient ($CD40L^{-/-}$) mice we hypothesized that CD40L may modulate platelet-dependent haemostatic function in mice treated with the vasoactive peptide angiotensin-II.

Methods: Angiotensin-II (1 mg/kg/d) was infused in wild-type (C57/Bl6) littermates and $CD40^{-/-}$ mice for 7 days using osmotic minipumps. The tail vein bleeding time was determined according to standardized protocols. Citrate-anticoagulated whole blood was taken by retro-orbital vein puncture. Platelet-monocyte association was analysed in diluted and fixed whole blood by flow cytometry. Platelets were identified by anti-CD41-FITC antibody and monocytes by anti-F4/80-PE antibody staining. CD41-positive and F4/80-positive leukocytes were defined as platelet bound monocytes / platelet-monocyte associates. Platelet-dependent thrombin generation in recalcified platelet rich plasma was triggered with 0.6 pM active recombinant tissue factor and assessed by calibrated automated thrombography.

Results: Angiotensin-II treated wild-type mice showed a significant ($P > 0.05$) shortening of the tail bleeding time accompanied by a significant ($P > 0.05$) increase of the platelet-dependent endogenous thrombin potential (ETP) triggered by tissue factor and significantly ($P > 0.05$) increased blood levels of platelet-monocytes associates compared to untreated wild-type mice. Although, untreated $CD40L^{-/-}$ mice exhibited prolonged bleeding times, as expected, platelet-dependent thrombin generation (ETP) as well as platelet-monocyte association did not differ significantly compared to untreated wild-type mice. However, angiotensin-II reduced significantly ($P > 0.05$) the prolonged tail bleeding time in $CD40L^{-/-}$ mice. Moreover, elevated levels of platelet-dependent ETP and blood platelet-monocyte associates observed in angiotensin-II treated wild-type mice were reversed in angiotensin-II treated $CD40L^{-/-}$ mice.

Summary/Conclusion: Angiotensin-II induces platelet hyperreactivity and hypercoagulability in wild-type but not in $CD40L^{-/-}$ mice. These results indicate that CD40L contributes crucially to a pro-thrombotic tendency in mice with angiotensin-II mediated arterial hypertension.

OC 87.5

Differential effects of platelet-derived MMPs on thrombus formation and collagen matrix degradation

Mastenbroek TG[1], Feijge MAH[1], Kremers RMW[2], Van Den Bosch M[3], Johnson JL[3], Heemskerk JWM[1] and Cosemans JMEM[1]

[1]Maastricht University; [2]Synapse b.v., Maastricht, the Netherlands; [3]University of Bristol, Bristol, UK

Background: Platelet thrombus formation is essential in the acute prevention of excessive blood loss at sites of vascular injury. However, platelets have also been implicated in longer term processes, such as wound healing and vascular remodelling. Platelets contain a pool of bioactive proteins, among which the matrix metalloproteinases (MMPs)-1, -2, -3 and -14. The platelet-derived MMPs may regulate platelet activation, but also remodelling of the extracellular matrix.

Aims: I) To assess the roles of MMP isoforms on thrombus formation. II) To determine the collagenolytic/gelatinolytic activity and extracellular matrix degradation capacity of platelet and thrombus-derived MMPs.

Methods: Human blood or blood from MMP-deficient mice was flowed over a fibrillar collagen matrix at high shear rate. Confocal microscopy and scanning electron microscopy was used to measure thrombus formation, thrombus surface localisation of MMP-1, -2, -9 and -14 isoforms, and collagen matrix degradation by the thrombus. Activity of MMP isoforms was measured in membranes and releasate of activated platelets, employing a panel of fluorogenic MMP substrates.

Results: Pharmacological inhibition of MMP-1 or -2 (human) or deficiency in MMP-2 (mouse) markedly reduced platelet activation and secretion in thrombus formation, whereas MMP-9 deficiency increased these processes. Deficiency in MMP-3 was without effect. Immuno-fluorescence staining of human thrombi showed that both the membrane type MMP-14 and the soluble MMP-1 and -9 isoforms accumulated at the thrombus surface. Fluorogenic substrate measurements with activated platelets in suspension indicated high collagenolytic and high gelatinolytic activity (Omni-MMP substrate, DQ-collagen, DQ-gelatin), which was predominantly present in the platelet membrane fraction. Strikingly, platelet-associated MMP activity was not induced by stimulation with ADP or thrombin, but only by stimulation with potent Ca^{2+}-rising agonists, convulxin or ionomycin. This suggested that collagen stimulation can provoke the exposure of proteolytically active MMPs. In agreement with this, thrombi formed on a collagen surface actively degraded the underlying collagen fibers. The characteristic triple-helical structure of type I collagen fibers disappeared within 2 h, while the fibers were resolved within 4 h. This pointed to a role of platelet-derived MMP-1 and -2 activity, since the collagen degradation: a) was not affected by the absence of blood or plasma; b) was blocked by general MMP inhibition, but not by serine/cysteine/threonine protease inhibition; c) was decreased by specific inhibition of MMP-1 (FN439) or MMP-2 (MMP-2 inhibitor I), but not by inhibition of MMP-9 (MMP-9 inhibitor-I).

Conclusions: MMP-1 and -2, surface-exposed after collagen-induced activation, support thrombus formation as well as collagen matrix degradation. MMP-9 does not phenocopy the MMP- and -2 effects. These data suggest a key role of platelet-derived MMP isoforms in matrix remodelling.

OC 87.6

Role of EphB2-Ephrin signalling in platelet function

Rana RH, Sage T, Kriek N, Sasikumar P, Jones CI and Gibbins JM

University of Reading, Reading, UK

Background: Eph receptors are the largest family of cell surface receptor tyrosine kinases and with their counter receptors, the Ephrins, form a vital cell communication system that controls tissue patterning, axonal guidance and cardiovascular development. Little is known of

the mechanisms that regulate stable and sustained interactions between platelets within a thrombus, although members of the Eph receptor family have been proposed to play a role. Human platelets are known to express the Eph receptors EphA4 and EphB1 as well as the ligand EphrinB1.

Aims: In this study we report the expression of a second B family Eph receptor (EphB2) in human and mouse platelets, and through the use of transgenic mouse models (EphB2-deficient (EphB2 −/−) and kinase-defective EphB2) and recombinant proteins which interfere with EphB2-Ephrin interactions, we demonstrate the importance of the EphB2 receptor for platelet function.

Methods: Platelet aggregation and dense-granule secretion were measured in platelet rich plasma (PRP) by optical aggregometry. Fibrinogen binding assays and alpha-granule secretion (P-selectin exposure) measurements were performed on whole blood using flow cytometry. The spreading of gel-filtered platelets on fibrinogen and collagen related peptide (CRP-XL) was assessed using light microscopy. *In-vitro* and *in-vivo* thrombus formation was measured using Vena8 biochips and laser-induced injury to cremaster muscle arterioles, respectively.

Results: EphB2-deficient platelets exhibited enhanced aggregation, fibrinogen binding and granule secretion (alpha and dense) in response to either collagen or the GPVI selective agonist CRP-XL. This was not accompanied by an equivalent increase in early signalling by receptor-proximal components within the GPVI signalling pathway, suggesting that the defect was mediated further downstream. Conversely, EphB2 kinase-defective platelets displayed negligible change in these assays when compared to sibling-matched control platelets, suggesting that EphB2 kinase activity may not be critical for these functions. The absence of EphB2 on platelets was also associated with enhanced spreading on fibrinogen or CRP-XL. Interestingly, kinase defective EphB2 platelets adhered well to the matrix and began to form filopodia, but very few spread fully. In spreading assays, platelets attached directly to the matrix where conventional Eph-Ephrin interactions are unlikely to occur, suggesting a role for EphB2 in the modulation of other molecules at the platelet membrane. Recombinant external domains of EphB2, EphrinB1 and EphrinB2 were used in separate assays with human platelets to investigate the effect on platelets of disrupting Eph-Ephrin signalling (aggregation, fibrinogen binding, alpha-granule secretion). Exposure to recombinant EphB2 reduced platelet function, while recombinant EphrinB1/B2 enhanced platelet function. The size of thrombi formed (*in-vitro* and *in-vivo*) were similar in both EphB2-deficient and control mice, although deficiency was associated with reduced thrombus stability.

Summary/Conclusion: Our data are consistent with the EphB2 receptor performing a negative regulatory role in platelets. Data suggest that the EphB2-Ephrin interactions modulate platelet function following the assembly of a platelet aggregate/thrombus. EphB2 deficiency also resulted in defective function in the absence of platelet-platelet contact (spreading assays) suggesting a role for EphB2 in Ephrin-independent functions.

OC 88 – Platelet Collagen Receptors

OC 88.1

Activated STIM1 controls GPVI signaling and enhances calcium store release in platelets

Braun A[1], Rivera-Galdos R[1], Gotru SK[1], Varga-Szabo D[2], Stritt S[1], Hermanns HM[1] and Nieswandt B[1]

[1]University of Würzburg, Würzburg; [2]Helios Clinic Wuppertal, Wuppertal, Germany

Background: *Stromal interaction molecule 1 (*STIM1) is a major Ca^{2+} sensor that activates store operated Ca^{2+} entry (SOCE) in platelets. Constitutively active STIM1 mutation in Saxcoburgski mice (*Stim1-Sax/+*) induced a severe macrothrombocytopenia associated with megakaryocyte hyperplasia and splenomegaly. Additionally, increased Ca^{2+} levels in the cytoplasm and permanently opened Ca^{2+} channels in the plasma membrane of unstimulated platelets were found. Interestingly, GPVI mediated Ca^{2+} responses, integrin activation and P-selectin exposure were strongly altered in *Stim1Sax/+* platelets while G-protein coupled receptor (GPCR) induced platelet activation was normal.

Aims: The Ca^{2+} overload phenotype in mutant platelets indicated that STIM1 might regulate Ca^{2+} release and/or the refilling of the Ca^{2+} store. The selective GPVI signalling defect in *Stim1Sax/+* platelets indicated that activated STIM1 might induce a negative feedback mechanism to GPVI signalosome which could down-regulate Ca^{2+} store release during SOCE.

Methods: The physiological function of the constitutively active STIM1 in store depletion was studied in *Stim1Sax/+/Orai1−/−* double mutant mice to exclude Orai1 mediated Ca^{2+} responses and its signaling mechanism. Due to the severe developmental complication and early lethality of *Stim1Sax/+/Orai1−/−* mutant mice, irradiated recipient C57Bl6 mice were transplanted with fetal liver cells isolated from *Stim1Sax/+/Orai1−/−* and control embryos (E13.5).

Results: The pathological phenotype described in *Stim1Sax/+* mice was almost completely reversed in the *Orai1−/−* knockout background. *Stim1Sax/+/Orai1−/−* mice displayed nearly normal platelet counts, size and absence of splenomegaly. In unstimulated *Stim1Sax/+/Orai1−/−* platelets cytoplasmic Ca^{2+} concentration was reduced whereas abnormal Ca^{2+} entry was absent in comparison to *Stim1Sax/+* platelets. Moreover, activated STIM1 strongly enhanced PAR-phospholipase C (PLC) β induced Ca^{2+} store release, but in sharp contrast, GPVI-PLCγ2 mediated Ca^{2+} store depletion was severely reduced. The defective GPVI mediated Ca^{2+} response was based on the nearly abolished inositol triphosphate (IP_3) production which could be attributed to a strongly reduced phosphorylation of PLCγ2 at Tyr759 while phosphorylation of Linker of activated T cells (LAT) and other components in the GPVI signalosome were normal.

Conclusions: The rescue of the *Stim1Sax/+* phenotype by deleting Orai1 function suggests that STIM1 regulates Ca^{2+} influx only through Orai1 in murine platelets. The leaky Ca^{2+} store and the accelerated store release after thrombin stimulation indicates that activated STIM1 positively influences store depletion during SOCE by a yet undefined mechanism.

OC 88.2

Novel loci associated with glycoprotein VI expression identified by a genome-wide association study and locus-specific fine-mapping

Smethurst PA[1], Radhakrishnan A[2], Al-Subaie A[1], Garner SF[3], Jansen BG[1], Goodall AH[4], Gardiner E[5], Tomlinson MG[6], Ouwehand WH[1] and Rendon A[1]

[1]University of Cambridge, Cambridge; [2]Wellcome Trust Sanger Institute, Hinxton; [3]NHS Blood and Transplant, Cambridge; [4]University of Leicester, Leicester, UK; [5]Monash University, Melbourne, Vic., Australia; [6]University of Birmingham, Birmingham, UK

Background: The *GP6* gene on 19q13.4 encodes glycoprotein (GP) VI, which is complexed with the common Fc receptor gamma chain (encoded by *FCER1G*) on the platelet membrane to form the major collagen receptor. Common variants in *GP6* explain a significant proportion of the population variation in GPVI expression, particularly rs1613662 (encoding S219P). Its major allele is associated with a higher platelet response to collagen than the minor allele and with an increased risk of deep venous thrombosis (DVT)[1].

Aims: We postulated that a further proportion of the sequence variation underlying GPVI expression would be revealed by a genome-wide association study (GWAS), with rare variants being identified by fine-mapping of the *GP6* locus.

Methods: The Cambridge Platelet Function Cohort (PFC) comprising almost 1000 individuals with known platelet GPVI expression levels

and functional responses were genotyped for the GWAS. Individuals with extreme phenotypes were sequenced at the *GP6* locus.

Results: The GWAS confirmed the previous observation that variant rs1613662 accounts for about 14% of the population variation in GPVI expression ($P = 2.7 \times 10^{-24}$). In addition, 46 unique *GP6* haplotypes were inferred by analysing 39 SNPs with a Minor Allele Frequency (MAF) range from 0.024 to 0.496, in 500 PFC samples. Their association with GPVI expression was explored in the five most frequent haplotypes. GPVI expression levels in five individuals homozygous for the 5th haplotype (5/5) were significantly higher than in those for haplotypes 1 and 2 ($P = 0.012$). Typing 8000 individuals from the Cambridge BioResource identified another 18 homozygous (5/5) individuals. Further testing of an additional three haplotype 5/5 individuals replicated the original association with increased GPVI expression.

In addition to the *GP6* variants, the GWAS identified two novel common variants associated with GPVI expression; at 2q37.2 (MAF = 0.318) and at 1q23.3 (MAF = 0.388) with $P = 2.87 \times 10^{-8}$ and $P = 2.16 \times 10^{-7}$, respectively, being below and just above the genome-wide significance cut-off. The rare variant rs3557 (MAF = 0.095) in the *FCER1G* gene showed a weak signal of $P = 2.1 \times 10^{-4}$, in line with observations in our earlier candidate gene study[2].

Two PFC individuals with approximately 50% normal GPVI surface expression and low P-selectin expression (> 12%) and fibrinogen binding (> 5%) after activation through GPVI were selected for targeted Sanger sequencing of the *GP6* exons. In one case this revealed a novel non-synonymous SNP in exon 4 encoding the 2nd Ig-domain, leading to a P194T substitution. In the second case a S195N substitution was observed.

Summary: An association study using haplotype and fine-mapping analysis of the *GP6* locus revealed novel rare variants with larger effect sizes on GPVI expression than the common variants. Furthermore, the GWAS identified novel, potential *trans*-acting common variants at 2q37.2 and 1q23.3 exerting smaller effects. These newly identified features explain more of the population variation in GPVI expression and their discovery is of possible clinical relevance for the prediction of the risk of DVT.

OC 88.3

Disturbed glycoprotein VI-mediated signaling in platelets from hypercholesterolemic mice and humans

Korporaal SJA[1], De Angelis V[1], Hoekstra M[2], Gitz E[1], Bochem AE[3], Sjouke B[3], Hovingh K[3], De Groot PG[1] and Van Eck M[2]

[1]University Medical Center Utrecht, Utrecht; [2]Leiden Academic Centre for Drug Research, Leiden; [3]Academic Medical Center, Amsterdam, the Netherlands

Background: We recently showed that high plasma HDL-cholesterol levels are associated with platelet hyperreactivity in mice and humans.

Aim: The aim of this study was to elucidate platelet reactivity under conditions of elevated plasma LDL-cholesterol levels in mice and humans.

Methods: Experiments were performed with platelets from LDL receptor knockout (LDLr KO) mice, a commonly used hypercholesterolemic mouse model. When fed regular chow diet (5.7% (w/w) fat and no added cholesterol), LDLr KO mice show an elevation of cholesterol in the LDL fraction, which is further amplified after a Western-type diet (WTD; 15% (w/w) cacao butter and 0.25% (w/w) cholesterol) challenge. To verify the relevance for human physiology, platelets from four familial hypercholesterolemia (FH) patients suffering from reduced LDLr functionality due to a defect in the *ldlr* gene, were studied. At the time of blood collection, patients were not taking cholesterol-lowering medication. The study was approved by the institutional review board of the Academic Medical Center, Amsterdam. All participants provided written informed consent.

Results: The elevated LDL-cholesterol levels in LDLr KO mice were associated with significantly lower platelet counts ($1024 \pm 63 \times 10^9$ LDLr KO platelets/L vs. $1244 \pm 143 \times 10^9$ WT platelets/L; $P > 0.001$), which were further reduced when LDLr KO mice were fed WTD ($876 \pm 68 \times 10^9$ platelets/L; $P > 0.001$). In agreement with earlier studies, platelets from LDLr KO mice on WTD showed 1.3-fold more activated $\alpha_{IIb}\beta_3$ ($P > 0.05$) upon stimulation by ADP. Surprisingly, the collagen-related peptide CRP-XL showed a reduced ability to activate $\alpha_{IIb}\beta_3$ on these platelets as compared to wild-type platelets (chow: 0.9-fold, $P > 0.01$, WTD: 0.7-fold, $P > 0.001$). Similarly, surface-expression of P-selectin was attenuated after CRP-XL stimulation on platelets of LDLr KO mice on chow (0.4-fold, $P > 0.05$), and was almost completely blocked when mice were fed WTD ($P > 0.01$). ADP also enhanced fibrinogen binding to and P-selectin expression on platelets from FH patients as compared to platelets from healthy subjects. In contrast, CRP-XL was less effective in activating FH platelets, resulting in reduced GPVI-mediated tyrosine phosphorylation, diminished fibrinogen binding, lower P-selectin expression, and a reduced ability to adhere to collagen under conditions of flow. Since GPVI-mediated platelet signaling depends on its translocation to lipid rafts, Förster Resonance Energy Transfer (FRET) by time-gated fluorescence lifetime imaging microscopy (FLIM) was used to determine the amount of GPVI in lipid rafts of FH and control platelets. FRET/FLIM analysis revealed that although more GPVI resided in rafts of unstimulated FH platelets (FRET efficiency of $4.00 \pm 0.46\%$ for FH platelets vs. $1.68 \pm 0.45\%$ for control platelets; $P > 0.01$), significant translocation of GPVI into lipid rafts upon stimulation by collagen was only observed in control platelets (FRET efficiency of $3.28 \pm 0.22\%$ for FH platelets vs. $7.24 \pm 0.68\%$ for control platelets; $P > 0.01$).

Summary/conclusions: Hypercholesterolemia due to elevated plasma LDL-cholesterol impairs translocation of GPVI to lipid rafts, which could explain the diminished platelet responsiveness to collagen. These findings reflect an important protective mechanism to prevent early platelet activation in hypercholesterolemic mice and humans.

OC 88.4

Deletion of GPVI and CLEC-2 partially rescues macrothrombocytopenia in G6b-B-deficient mice

Mazharian A[1], Mori J[1], Heising S[1], Nieswandt B[2], Watson SP[1] and Senis YA[1]

[1]University of Birmingham, Birmingham, UK; [2]University of Würzburg, Würzburg, Germany

Background: G6b-B is a unique immunoreceptor tyrosine-based inhibition motif (ITIM)-containing receptor that is highly expressed in mature megakaryocytes and platelets. Unlike other megakaryocyte and platelet ITIM-containing receptors, G6b-B is constitutively tyrosine phosphorylated and associated with the protein-tyrosine phosphatases Shp1 and Shp2. One of the functions of G6b-B is to inhibit signalling from the immunoreceptor tyrosine-based activation motif (ITAM)-containing collagen receptor GPVI-FcR γ-chain and the hemITAM-containing podoplanin receptor CLEC-2. Mice lacking G6b-B exhibit a complex phenotype that includes macrothrombocytopenia, enhanced GPVI shedding and platelet hyper-reactivity to antibody-mediated cross-linking of CLEC-2 (Mazharian et al. Sci Signal. 2012).

Aim: In this study, we investigated whether the phenotype of *G6b* knockout mice is due to tonic GPVI and CLEC-2 signalling. Our hypothesis is that deletion of GPVI and CLEC-2 will rescue the macrothrombocytopenia in G6b-B-deficient mice.

Method: To test our hypothesis, we generated mice lacking both GPVI and G6b-B, and used an anti-CLEC-2 antibody to deplete CLEC-2 levels in these mice. *G6b* knockout mice were treated with the Src family kinase (SFK) inhibitor Dasatinib to inhibit tonic signalling. Platelet counts, aggregation and secretion, and tyrosine phosphorylation of SFKs and Syk were measured.

Results: Targeted deletion of both *Gp6* and *G6b* resulted in a 54% increase in platelet counts compared with deletion of *G6b* alone. Platelets from *Gp6*/*G6b* double-heterozygous mice were hyper-responsive to the GPVI-specific agonist collagen-related peptide compared with platelets from *Gp6* heterozygous mice, which express comparable levels of surface GPVI. This provides evidence that G6b-B is an inhibitor of GPVI-mediated functional responses in platelets. An additional 87% increase in platelet counts was observed in *Gp6*/*G6b* double-knockout mice following antibody-mediated depletion of CLEC-2 compared with *Gp6*/*G6b* double-knockout mice treated with an isotype control antibody. However, treatment of *G6b* knockout mice with the SFK inhibitor Dasatinib did not rescue platelet counts in these mice. Biochemical data demonstrated that Syk tyrosine kinase was hyper-phosphorylated on its activation loop (Syk Tyr 519/520) in resting G6b-B-deficient platelets, whereas SFKs were phosphorylated to the same extent on their activation loop and *C*-terminal inhibitory tyrosine residues compared with control platelets.
Conclusion: Findings from this study suggest that tonic GPVI and CLEC-2 signalling contribute to the phenotype of *G6b* knockout mice. The defect appears to be at the level of Syk tyrosine kinase rather than SFKs. This study provides important mechanistic insights into how G6b-B regulates platelet homeostasis in mice.

OC 88.5

Regulation of the platelet collagen receptor GPVI by the tetraspanin Tspan9

Haining EJ[1], Harris HJ[1], Lordkipanidze M[1], Yang J[1], Nieswandt B[2], Watson SP[1] and Tomlinson MG[1]
[1]University of Birmingham, Birmingham, UK; [2]University of Würzburg, Würzburg, Germany

Background: The platelet-activating collagen receptor GPVI recognises collagen as a GPVI-GPVI dimer and initiates signalling via its associated Fc receptor γ-chain. GPVI-deficient mice are protected from arterial thrombosis and ischaemic stroke but have no major bleeding complications, suggesting GPVI as a potential target for anti-thrombotic therapy. The tetraspanins comprise 33 transmembrane proteins in humans, and at least 10 are expressed by platelets. Advanced imaging techniques, such as single particle tracking in combination with total internal reflection fluorescence (TIRF) microscopy, have shown tetraspanins to regulate the lateral mobility of other proteins with which they associate. We have previously identified GPVI as a tetraspanin-associated protein, but it is unclear how this contributes to GPVI function and dynamics. We have also previously identified Tspan9 as a relatively platelet specific tetraspanin, but have not addressed Tspan9 function and whether it could regulate GPVI.
Aims: The aims are to functionally characterise Tspan9-deficient platelets and to investigate whether the absence of Tspan9 affects GPVI lateral mobility using single particle tracking.
Methods: The Tspan9-deficient mouse was generated by gene trapping and platelet function assessed using aggregometry, spreading and flow adhesion studies. Single particle tracking was used to assess the dynamics of GPVI in wild-type and Tspan9-deficient platelets. The single particle tracking used single fluor labelled anti-GPVI Fab fragments to label single GPVI molecules on the platelet surface. Live cell imaging using TIRF microscopy allowed various parameters of GPVI dynamics to be measured.
Results: The Tspan9-deficient mouse was viable and healthy. The platelet count, size and expression levels of major surface proteins, including GPVI, were normal. Additionally, Tspan9-deficient mice had no tail bleeding phenotype. Aggregation studies highlighted a delay in response to the GPVI agonists collagen related peptide and collagen in the Tspan9-deficient platelets, which was overcome at high agonist concentrations. Aggregation was normal in response to thrombin and CLEC-2 stimulation, suggesting a GPVI-specific defect. Static platelet spreading on collagen related peptide was reduced in the absence of Tspan9, and aggregate formation on collagen under flow was delayed. These findings suggested that the absence of Tspan9 might be delaying GPVI signalling by affecting GPVI lateral mobility, which could impact on its dimerisation and response to agonists. Therefore single particle tracking was employed to assess the dynamics of GPVI in the platelet membrane. In wild-type platelets GPVI molecules followed trajectories that had elements of both Brownian and confined motion. The Brownian diffusion coefficient was ~0.11 $\mu m^2/s$ and the area of confinement was ~250 nm in diameter. We hypothesise that future analysis of Tspan9-deficient platelets will reveal defective GPVI dynamics.
Summary/conclusions: The functionally uncharacterised tetraspanin Tspan9 appears important for the fine tuning of GPVI function in platelets, potentially by regulating GPVI membrane dynamics. Additionally, for the first time, the membrane dynamics of a platelet receptor have been studied at the single molecule level.

OC 88.6

Combined *in vivo* depletion of GPVI and CLEC-2 severely compromises hemostasis and abrogates arterial thrombosis in mice

Bender M[1], May F[1], Lorenz V[1], Thielmann I[1], Hagedorn I[1], Finney BA[2], Voegtle T[1], Braun A[1], Watson SP[2] and Nieswandt B[1]
[1]University Hospital Würzburg and Rudolf Virchow Center, Wuerzburg, Germany; [2]University of Birmingham, Birmingham, UK

Background: Platelet inhibition is a major strategy to prevent acute ischemic cardiovascular and cerebrovascular events which may, however, be associated with an increased bleeding risk. The (hem)ITAM-bearing platelet receptors, GPVI and CLEC-2, might be promising antithrombotic targets as they can be depleted from circulating platelets by antibody treatment leading to sustained antithrombotic protection but only moderately increased bleeding times in mice.
Aim: We investigated whether both (hem)ITAM-bearing receptors can be targeted simultaneously, and what the *in vivo* consequences of such a combined therapeutic GPVI/CLEC-2 deficiency are.
Methods: For this, we induced single- or double-receptor depletion of GPVI and CLEC-2 by the administration of the anti-GPVI JAQ1 and/or anti-CLEC-2 antibody, respectively. Moreover, we verified our results by the generation of double-genetically deficient *Gp6−/−/Clec-2 fl/fl, Pf4-Cre*mice.
Results: We demonstrate that isolated targeting of either GPVI or CLEC-2 *in vivo* does not affect expression or function of the respective other receptor. Moreover, simultaneous treatment with both antibodies resulted in the specific and sustained loss of both GPVI and CLEC-2 receptors while leaving other activation pathways such as G protein-coupled receptor signaling and GPIb function intact. In addition, neither the coagulation system (aPTT and PT) was impaired nor relevant cytokine levels were released in double depleted mice further excluding off-target effects of antibody treatment. However, GPVI/CLEC-2-depleted mice displayed surprisingly a dramatic hemostatic defect and profound impairment of arterial thrombus formation. Furthermore, a strongly diminished hemostatic response could also be reproduced in mice genetically lacking GPVI and CLEC-2.
Conclusion: These results demonstrate that GPVI and CLEC-2 can be simultaneously downregulated in platelets *in vivo* and reveal an unexpected functional redundancy of the two receptors in hemostasis and thrombosis. These findings may have important implications of the potential use of anti-GPVI and/or anti-CLEC-2 based agents in the prevention of thrombotic diseases.

Non-myeloablative conditioning with busulfan prior to hematopoietic stem cell transplantation leads to phenotypic correction of murine Bernard Soulier Syndrome

Kanaji S[1], Fahs SA[1], Ware J[2], Montgomery R[1] and Shi Q[1]
[1]*Blood Research Institute, Wauwatosa, WI;* [2]*University of Arkansas for Medical Sciences, Little Rock, AR, USA*

Background: Bernard Soulier Syndrome (BSS) is an autosomal recessive disease characterized by macrothrombocytopenia and bleeding symptoms. BSS is caused by a defect in the platelet glycoprotein(GP) Ib/IX complex. The primary treatment for BSS is platelet transfusion but repeated platelet transfusion often results in allo-immunization. We recently showed that following myeloablative total body irradiation (TBI) conditioning, transplantation of hematopoietic stem cells (HSCs) transduced with a lentivirus that expresses hGPIbα under integrin αIIb promoter control could rescue the macrothrombocytopenia and prolonged bleeding of murine BSS ($GPIb\alpha^{null}$).
Aims: For application of gene therapy to treatment of human patients, it is important to minimize treatment-related side effects. We aimed to model clinically relevant nonmyeloablative HSC transplantation using murine BSS and busulfan conditioning.
Methods: Using transplantation of bone marrow mononuclear cells (BMMNCs) from transgenic mice that express hGPIbα ($hGPIb\alpha^{tg+}$), 1) determine the percentage of $hGPIb\alpha^{tg+}$ HSCs required for therapeutic benefit, 2) evaluate the efficacy of non-myeloablative conditioning, and 3) test the effect of anti-thymocyte globulin (ATG) on prevention of immune reactions.
Results: (i) To determine the percentage of HSCs required for phenotypic correction of murine BSS, mixed BM chimeras were generated by reconstituting lethally irradiated $GPIb\alpha^{null}$ mice with variable mixtures (5–100%) of BMMNCs isolated from $hGPIb\alpha^{tg+}$ and $GPIb\alpha^{null}$ mice. Tail bleeding time assays performed after BM reconstitution demonstrated that 10% $hGPIb\alpha^{tg+}$ BMMNCs mixed with 90% $GPIb\alpha^{null}$ BMMNCs were sufficient to correct the tail bleeding time ($n = 5$). Platelet analysis showed that the bleeding phenotype was rescued in recipients having higher than $40 \times 10^3/\mu L$ of $hGPIb\alpha^{tg+}$ platelets, which corresponds to 6.5% of wild type mouse platelet counts ($630 \pm 57 \times 10^3/\mu L$, $n = 8$). These results suggest therapeutic potential for non-myeloablative conditioning regimens for treatment of BSS. (ii) Transplantation of $hGPIb\alpha^{tg+}$ mouse BMMNCs into $GPIb\alpha^{null}$ recipients conditioned with a non-myeloablative dose of busulfan (50 mg/kg total) showed that that tail bleeding times of busulfan-conditioned recipients were corrected and were not significantly different from lethally irradiated recipients (3.8 ± 3.8 min, $n = 23$ vs. 2.0 ± 1.3 min, $n = 12$). Antibody response to hGPIbα and immune-mediated thrombocytopenia was documented in eight of 29 recipient mice, suggesting immunogenicity of hGPIbα transgene protein in $GPIb\alpha^{null}$ mice preconditioned with busulfan. However, these antibodies disappeared without treatment in seven of eight mice 3–7 months after BM transplantation. (iii) When $GPIb\alpha^{null}$ recipients were conditioned with ATG and busulfan, all recipients showed a high percentage of hGPIbα-positive platelets ($93.3 \pm 3.3\%$, $n = 11$) and no antibody reactions were documented.
Conclusions: Non-myeloablative doses of busulfan conditioning prior to transplantation could achieve phenotypic correction of murine BSS. Lower immunotoxicity of busulfan led to higher incidence of humoral immune response compared to TBI, but pretreatment with ATG was shown to effectively prevent such immune reaction. A conditioning regimen of busulfan in combination with ATG could be utilized in non-myeloablative autologous gene therapy in human BSS.

OC 89.2

MYH9-related disease in France: a growing cohort among inherited macrothrombocytopenias on behalf of the French network on MYH9 related disorders

Schlegel N[1], Binard S[1], Nurden AT[2], Nurden P[3], Alessi M-C[3] and Saposnik B[1]
[1]*Hôpital Robert Debré APHP, Paris;* [2]*PTIB Hôpital Xavier Arnozan, Pessac;* [3]*CHU La Timone Hématologie Biologique, Marseille, France*

Background: Inherited macrothrombocytopenias (IMTs) represent a group of heterogeneous disorders. Among the twelve genetically identified IMTs, MYH9-Related disease (MYH9-RD) is now considered to be the more frequent after Bernard Soulier Syndrome (Balduini C et al., Hämostaseologie, 2012, 32: 259–70). MYH9-RD represents a group of autosomal dominant macrothrombocytopenias associated with mutations in the *MYH9* gene that encodes the non muscle myosin heavy chain IIA (NMMHC-IIA). Macrothrombocytopenia döhle bodies and leukocyte myosin aggregates are common features; they are associated in many cases with various combinations of extra-hematological symptoms: deafness, nephropathy, cataracts. The other IMTs are quite rare or very rare. Due to the high frequency of sporadic cases, the frequent underestimation of platelet macrocytosis by the analyzers and the difficulty, at least for some patients, to detect the leukocyte inclusion bodies, the diagnosis of MYH9-RD may be difficult when not confirmed by the genotype. In addition, a suspicion of MYH9-RD is not infrequent in the presence of an isolated macrothrombocytopenia especially if familial cases are known.
Aim: To confirm or exclude the diagnosis of MYH9-RD in patients with macrothrombocytopenias and to further characterize the phenotype and genotype of new isolated or familial cases of MYH9-RD.
Methods: Patients with macrothrombocytopenia and a hypothesis of MYH9-RD were included in the study. The diagnosis of Bernard-Soulier and gray platelet syndromes, Paris Trousseau thrombocytopenia and Platelet-type von Willebrand disease was initially excluded. The 40 exons, exon A and exon-intron boundaries of the *MYH9* gene were PCR amplified and sequenced.
Results: A total of 188 propositi and 147 family members were screened. Direct sequencing could confirm the diagnosis of MYH9-RD in 115 (61%) propositi and 75/147 (51%) family members. All were heterozygous. Mutations affected 17 different exons. The majority were missense mutations affecting 31 different residues. We found also five deletions, one duplication, one insertion and three nonsense or frameshift alterations. Seven patients had two mutations. No mutation in the *MYH9* gene was identified in 73 propositi. Among them, we could distinguish two groups of cases. One ($n = 8$) presented with a 'MYH9-like' phenotype associating macrothrombocytopenia, deafness, nephropathy and eventually cataracts but without leukocyte inclusion bodies. Another group ($n = 65$) included patients with macrothrombocyopenia alone ($n = 44$) or associated with deafness ($n = 6$), nephropathy ($n = 1$), hematuria ($n = 1$), leukocyte inclusion bodies ($n = 10$, with one positive by immunofluorescence using an anti-myosin antibody). Familial cases of thrombocytopenia were reported in 27/65 cases. Finally, a mutation in the *TUBB1* gene was identified in 3/65 and will be reported separately.
Conclusion: These results confirm the high frequency of MYH9-RD among inherited macrothrombocytopenias and the importance of gene analysis for the confirmation of the diagnosis. The identification of a group of patients with a 'MYH9-like' phenotype suggests an abnormality in the regulation of MYH9 biosynthesis or the role of other genes. The discovery of *TUBB1* mutations shows that the role of beta-tubulin 1 should also be considered in the diagnosis of inherited macrothrombocytopenias. The definition of homogeneous groups of patients will also be of help in the search for new genes involved in the development of macrothrombocytopenias.

OC 89.3

Identification of a patient with bleeding diathesis, associated with dysfunctional platelet P2Y12 receptor

Lecchi A[1], Razzari C[2], Paoletta S[3], Nakamura L[4], Ohlman Ph[5], Gachet C[6], Jacobson KA[3] and Cattaneo M[2]

[1]Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico; [2]Università degli Studi di Milano, Milan, Italy; [3]National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, MD, USA; [4]University Medical Center Freiburg, Freiburg, Germany; [5]Inserm, Université de Strasbourg, EFS-Alsace; [6]UMR_S949 INSERM, Université de Strasbourg, EFS-Alsac, Strasbourg, France

Background: P2Y12, the Gi-coupled receptor for adenosine diphosphate (ADP), plays a central role in platelet function. Inherited and drug-induced defects of P2Y12 are associated with an increased risk of bleeding.

Aims: To describe a patient with lifelong bleeding diathesis, associated with dysfunctional P2Y12, due to a previously underscribed missense mutation in the encoding gene. Patient and Methods. The patient is a 45 year old man of Turkish origin, living in Germany who presented with recurrent epistaxis, postoperative bleedings after tooth extraction, thyroid explantation and spleen explantation. Platelet aggregation and secretion were measured by lumiaggregomety in 10.9 mM citrate-anticoagulated platelet-rich plasma (PRP). The platelet content of adenine nucleotides (luminometry) and serotonin (o-phthaldialdehyde, fluorometry) was measured. The platelet production of cyclic AMP was measured by a radioisotopic assay in the presence and absence of prostaglandin E1 (PGE1) (1 μM), ADP (0.1 and 1.0 μM) and epinephrine (0.1 and 1.0 μM). The platelet phosphorylation of the vasodilator stimulated phosphoprotein (VASP) was measured by flow cytometry, using a commercially available kit (BioCytex). The number of platelet P2Y12 receptors was measured in binding studies of the radiolabeled selective P2Y12 antagonist [3H]PSB-0413 to washed platelets. DNA was isolated from peripheral leukocytes: the entire coding sequence of the P2Y12 gene was amplified by PCR and subjected to DNA sequence analysis.

Results: The platelets from the patient changed shape normally after stimulation with 2–20 μM ADP, but their aggregation was markedly lower than normal and rapidly reversible. ADP did not induce platelet secretion. Platelet aggregation and secretion induced by other agonists was normal. The platelet content of nucleotides and serotonin was normal. Inhibition of VASP phosphorylation by ADP was impaired (PRI 30%). Inhibition of PGE1-induced increase in cAMP by ADP was impaired, but normal by epinephrine. The number of binding sites (Bmax) for [3H]PSB-0413, which was measured in two separate experiments, was normal (285 and 436 sites/platelet, normal values in 10 healthy subjects, 425 ± 50), but its affinity was reduced (KD 8.4 and 33 nM, normal values 3.3 ± 0.6). DNA from the patient showed a homozygous missense mutation, a T-to-A transition at nucleotide 847 that changed the codon for His-187 to Gln. Molecular modeling studies predicted that the mutated residue in the $P2Y_{12}$ Gln187 variant does not directly interact with the ligand in the binding site, but appeared to have effects on the trans-membrane (TM)5-TM6 contact region of the receptor, which could affect the conformational changes needed for receptor activation. In fact, the close proximity and the different interactions pattern of the H187Q mutation in TM5 with residues of the TM6-extracellular loop 3 region critical for the activation process in GPCRs, can explain its importance in influencing the function of the P2Y12 receptor.

Conclusion: These studies delineate a region of P2Y12 required for normal function after ADP binding.

OC 89.4

Platelet and megakaryocyte abnormalities in the Gray platelet syndrome

De Candia E[1], Larocca LM[2], Heller PG[3], Podda GM[4], Pujol-Moix N[5], Glembotsky A[6], Pecci A[7], Alberelli MA[8], Cattaneo M[4] and Balduini C[9]

[1]Catholic University of Rome; [2]Istituto di Anatomia Patologica-Università Cattolica di Roma, Roma, Italy; [3]Instituto de Investigaciones medicas Alfredo Lanari, Buenos Aires, Argentina; [4]Ospedale San Paolo-Università degli Studi di Milano, Milano, Italy; [5]Hosptial de la Santa Creu i Sant Pau, Barcelona, Spain; [6]Instituto de Investigaciones Medicas Alfredo lanari, Buenos Aires, Argentina; [7]University of Pavia-Policlinico San Matteo, Pavia; [8]Dipartimento di Medicina Interna-Università Cattolica di Roma, Roma; [9]Università di Pavia-Policlinico San Matteo, Pavia, Italy

Background: The Gray Platelet Syndrome (GPS) is a rare congenital platelet disorder characterized by mild to moderate bleeding symptoms, macrothrombocytopenia and gray appearance of peripheral platelets due to lack of α-granules. The genetic defect responsible for GPS was recently identified in biallelic mutations in the *NBEAL2* gene.

Aims: Although the GPS is considered a disease with a heterogenous phenotype, aim of the present study was the identification of bone marrow features and of platelet defects that could be considered specific for the disease.

Methods: Five GPS patients from four unrelated families were recruited in four different institutions to study the platelet function and the bone marrow features. All subjects or their legal guardians gave written informed consent according to the Declaration of Helsinky. Protocols were approved by the Ethics review Board at the Institution that enrolled the patients.

Four patients underwent extensive study of the platelet function and four patients underwent bone marrow (BM) biopsy. Patients underwent platelet studies at their Institutions. BM samples were obtained using standard procedures and embeded in paraffin. BM samples were shipped to the Catholic University of Rome for morphological and immunhistochemical analysis.

Platelet studies included: (i) platelet aggregation according to standard Born method, (ii) flow cytometric analysis of platelet activation, by measurement of anti-P-selectin and PAC-1 antibodies binding to platelets activated by several agonists (iii) binding of FITC-fibrinogen to washed platelets activated by thrombin (iv) measurement of PAR1 expression on platelet membrane by flow cytometry and anti-PAR1 monoclonal antibodies (v) immunofluorescence quantitative analysis of the thrombospondin-1 content of alpha-granules on peripheral blood slides.

BM studies included hematoxylin-eosin staining, reticulin staining and immunohystochemical analysis with the avidin-biotin-peroxidase complex method for the following proteins: (i) Platelet factor 4, (ii) P-selectin, (iii) CD61, (iv) c-MPL, (v) PAR1, (vi) PAR4.

Results: All GPS patients who underwent platelet studies had a severe defect of platelet response to PAR1-activating peptide. Specifically, the PAR1-mediated platelet aggregation and activation, as measured by exposure of p-selectin and PAC1 binding sites, were severely affected in 4 GPS patients. The platelet response to other agonists was slightly or moderately affected in two patients, normal in one. Expression of PAR1 on platelet membrane was reduced in all four patients (50–70% of control values). The binding of fibrinogen to GPS platelets activated by thrombin was severely reduced.

All four patients who underwent BM biopsy had marked fibrosis (grade 2-3) and marked emperipolesis. Fifthy to 80% of megakaryocytes contained up to four leukocytes engulfed within the cytoplasm. BM immunohistochemistry in two patients showed increased immunolabeling for P-selectin and decreased immunolabeling for PAR1, PAR4, thrombospondin and c-MPL on MKs.

Conclusion: Defective PAR1-mediated platelet responses and marked emperipolesis are typical features of GPS, as they were found in all patients studied. The defect of PAR1-mediated platelet responses can be used as a screening test for the diagnosis of the disease, which can be underdiagnosed. In fact, on the basis of the high number of compound heterozygous described so far, the disease might be more frequent than expected.

OC 89.5

A new autosomal dominant macrothrombocytopenia maps to chromosome 9

Morel-Kopp PE[1], Chen Q[1], Liang HP[1], Bromhead C[2], Britton S[1], Turakulov R[3], Bahlo M[2], Stevenson WS[1] and Ward CM[1]

[1]The University of Sydney, St Leonards, NSW, Australia; [2]The Walter and Eliza Hall Institute of Medical Research; [3]Australian Genome Research Facility, Melbourne, Vic., Australia

Background: We report a family with a new autosomal dominant bleeding disorder associated with red cell anisopoikilocytosis, macrothrombocytopenia and platelet dysfunction which is different from all reported α-granule defects and /or hereditary macrothrombocytopenia.
Case report: Affected family members report excessive bruising from childhood, epistaxes and prolonged bleeding from cuts and superficial injuries. Symptomatic bleedings occurred after tooth extraction, adenoidectomy, circumcision and vasectomy. The severity of bleeding is variable with some affected individuals developing spontaneous bleeding while other family members only experiencing abnormal bleeding with surgery.
Methods: The study protocol was approved by our local Ethics Committee and written informed consent was obtained to prepare and store proteins and DNA. Platelet function testing, proteomics and genome-wide association studies were used to characterise the disease and locate the genetic abnormality.
Results: In a four generation Caucasian Australian family, we have identified 14 affected individuals (10 males and four females). Blood film show macrothrombocytopenia with occasional giant platelets as well as anisocytosis and poikilocytosis. Using an automated platelet function analyzer (PFA-100™), all affected family members demonstrated prolonged closure times with the collagen/epinephrine cartridge (294 vs. 125 s, $P > 0.001$); collagen/ADP closure times were increased but still within the normal range (110 vs. 88 s, P:0.024). Platelet aggregation by light transmission aggregometry was markedly impaired in response to ADP, collagen, adrenaline, arachidonic acid and TRAP. By flow cytometry, surface glycoproteins were all within normal ranges but platelets failed to express P-selectin following ADP activation. Platelet proteomics revealed abnormal cytoskeletal and α-granule contents. By electron microscopy, platelets from affected individuals were larger and had reduced number of α-granules. Linkage analysis performed on family members genotyped by SNP array mapped the genetic abnormality to chromosome (chr) 9q.
Summary: We have identified a new genetic abnormality mapped to chromosome 9q and responsible for an autosomal dominant macrothrombocytopenia which differs from the previously reported mutated genes on chr 3 (GPIX, NBEAL2), chr 7 (GPIV), chr 17 (ITGB3, GPIbA), chr 22 (GPIbB, MYH9) or X chr (GATA1).

OC 89.6

Thrombotic tendencies and bleeding in a thrombocytosis mouse model

Strassel C[1], Mangin PH[1], Freund M[1], Cazenave J-P[1], Skoda R[2], Dupuis A[1], Herbrecht R[3], Gachet C[1] and Lanza F[1]

[1]UMR_S949, Inserm, Université de Strasbourg, EFS-Alsace, Strasbourg, France; [2]Department of Biomedicine, Experimental Hematology, University Hospital Basel, Basel, Switzerland; [3]Department of Oncology and Hematology, Hôpital de Hautepierre, Strasbourg, France

Background: Essential thrombocythemia (ET) is a myeloproliferative disorder presenting with thrombocytosis. Hemorrhages and arterial and venous thrombosis are major complications. The role of platelets in this disorder, in particular the contribution of their abnormal number and/or function, is still unclear.
Aims: The purpose was to evaluate the impact of abnormally increased platelet counts in hemostasis and thrombosis.
Methods: A thrombocytosis mouse model developed in an $Mpl^{-/-}$ background (Yall;$Mpl^{-/-}$) was used and thrombosis and bleeding tendencies (*in vitro and in vivo* models) have been evaluated.
Results: Thrombus formation evaluated *in vitro* by perfusing hirudin-anticoagulated whole blood over a collagen matrix (1500/s) showed a sevenfold increase in thrombus volume in Yall;$Mpl^{-/-}$ as compared to to wild-type (WT) mice (311 ± 43 vs. 43 ± 3 μm^3). The thrombotic tendency was also observed *in vivo* in a systemic thromboembolism model of collagen-adrenaline injection. In contrast, thrombosis was only modestly increased in a model of $FeCl_3$-induced lesion of carotid arteries (791 ± 128 mm^2 peak thrombus surface vs. 289 ± 41 mm^2) and was even less stable in a model of mechanical injury of the aorta when compared to WT. Yall;Mpl−/− mice exhibited severely prolonged tail bleeding times when compared WT (1452 ± 120 vs. 490 ± 149 s). The hemorrhagic trend was not caused by intrinsic platelet dysfunction, as normal aggregation and only slightly decreased [H^3]-serotonin secretion responses were observed in response to several agonists (ADP, collagen, U46619 and thrombin) after normalizing platelet counts to WT levels. Similarly, normal responses were observed in washed platelets from a series of patients with ET ($n = 5$). As reported in patients, a decreased proportion of VWF high molecular weight forms was observed in the plasma of Yall;$Mpl^{-/-}$ mice which could contribute to the hemostatic defect. A similar thrombo-hemorrhagic phenotype was recorded in two mouse models with the JAK2V617F mutation reproducing ET and PV.
Conclusion: these murine models recapitulate the bleeding tendency observed in certain ET patients, but only partially the thrombotic phenotype. Failure to reproduce this more prevalent complication in the patients could be linked to missing factors such as conditions of inflammation, leukocytosis and atherosclerosis.

OC 90 – Thrombophilia – II

OC 90.1

Risk assessment of venous thrombosis in families with known hereditary thrombophilia: the MARseilles-Nimes (MARNI) prediction model

Cohen W[1], Castelli C[2], Suchon P[3], Bouvet S[2], Aillaud M-F[3], Brunet D[3], Barthet MC[3], Alessi M-C[3], Tregouet DA[4] and Morange PE[3]

[1]AP-HM, Marseille Cedex 5; [2]Biostatistiques Epidémiologie clinique Santé Publique et Information Médicale, Nimes; [3]Laboratoire d'Hématologie, APHM, Hopital Timone, Marseille; [4]Université Pierre et Marie Curie, Paris, France

Background: Predicting the risk of venous thrombosis (VT) in a subject belonging to a family with inherited thrombophilia is often not feasi-

ble. We aimed to develop a simple risk assessment model that improves prediction of the risk of VT within these families.

Methods and Results: One thousand two hundred and one relatives from 430 families with inherited thrombophilia (deficiencies of antithrombin, protein C, or protein S, factor V leiden or *F2* 20210A mutations) were included. 122 had a personal history of VT. 16 variables known as VT risk factors were preselected and used for scoring: seven clinical variables (family history score of VT, number of VT episodes, age and triggering circumstances at first VT of the proband; gender, age and number of triggering circumstances without anticoagulant prophylaxis in relatives) and nine laboratory variables (severity of thrombophilia, ABO blood group and number of allele O or A2, fibrinogen, factor VIII and von Willebrand factor plasma levels, two single nucleotide polymorphisms in *F11* gene (rs2289252 and rs2036914) and 1 in *FGG* coding for the fibrinogen gamma chain [rs2066865]). The score based on the 16 variables or on the five most predictive variables performed similarly (areas under receiver-operating characteristic curves [AUC] of 0.85 and 0.83, respectively). For the 5-variables score (including family history score of VT, von Willebrand factor antigen levels, age of relative, severity of thrombophilia and *FGG* rs2066865), the risk of VT increased from 0.2% for individuals with a score of 0 (n = 186) to more than 70.25% for individuals with a score higher than 6 (n = 27). The model was validated using bootstrap method.

Conclusions: By use of a simple scoring system, the assessment of the risk of VT in subjects from families with inherited thrombophilia can be greatly improved.

OC 90.2

Antithrombin (AT) type II deficiency in Finland caused by a single point mutation – difficulties in detecting AT activity using commercially available assays

Puurunen M[1], Salo P[2], Perola M[2], Engelbarth S[1] and Javela K[1]

[1]Finnish Redcross Blood Service; [2]National Institute for Health and Wellfare, Helsinki, Finland

Background: AT deficiency is a rare thrombophilia. The method of screening for AT deficiency is measuring AT activity. We have observed that some patients receive conflicting results according to assay used.

Aim: The aim of the study was to determine, whether all commercially available AT activity assays give congruent results in known patients with type II AT deficiency. We also investigated the genetic background of AT type II deficiency in Finns, a population genetically characterized by a strong founder effect.

Methods: 1. All patients in Finland with prior AT deficiency diagnosis were approached with a questionnaire and new blood samples were drawn for analysis. 245 of 374 patients gave informed consent and participated in the study. Of these 109 had type II AT deficiency and belonged to 49 families. The study was approved by the medical ethical committee.

2. AT activity was measured using five commercially available assays, either thrombin- or FXa-based (A1 STA-Stachrom ATIII®, A2 STA-Stachrom ATIII® with prolonged incubation, B Berichrom Antitrombin®, C Innovance Antithrombin®, D HemosIL®).

3. One person in each family with either type I or II AT deficiency was sequenced using Sanger-sequencing for mutations in the exonal regions in the AT coding gene *SERPINC1*. All other family members were then studied for these detected mutations.

Results: 1. The AT activity assays gave conflicting results in 92 of 109 patients with known AT type II deficiency. Assays A1 and C were able to detect all AT deficient patients, whereas assays A2, B and D gave normal results in these patients. In the rest of the patients the activity results were congruent in all assays.

2. In all patients with AT deficiency regardless of subtype, 17 different point mutations were observed. In type II AT deficiency the large majority of cases (45 families of 49) was explained by a single point mutation Pro73Leu. In the remaining four families three other single point mutations (Val30Glu, Arg220Cys, Pro234Ala) were detected, and in one family no mutation was seen using our approach.

3. This founder mutation Pro73Leu explains the varying results in AT activity assays in type II AT deficient patients. Assays A1 and C were able to detect these patients reliably, but other tested assays missed the majority of cases.

Summary and Conclusions:

1 Type II AT deficiency in Finland is caused almost exclusively by a single point mutation Pro73Leu.

2 In carriers of Pro73Leu mutation, some AT activity measuring assays are unable to detect the change in AT function and therefore miss the correct diagnosis. This must be taken into account in the screening of this thrombophilia, at least in Finnish patients.

OC 90.3

Mutation spectrum of antithrombin deficiency in Hungary; prevalence of antithrombin Budapest 3 mutation in patients with venous and arterial thrombosis

Bereczky Z[1], Gindele R[1], Oláh Z[1], Pfliegler G[1], Losonczy H[2], Kovács B[1], Selmeczi A[1], Boda Z[1], Muszbek L[1] and Bereczky Z[1]

[1]Medical and Health Science Center, University of Debrecen, Debrecen; [2]University of Pécs, Pécs, Hungary

Background: Antitrombin (AT) is the major inhibitor of thrombin and activated factor X (FXa). It is a progressive inhibitor, but in the presence of heparin the rate of inhibition is highly accelerated. AT deficiency can be classified as type I (quantitative), and type II (qualitative) deficiency. In type II deficiency the defect may involve the reactive site (RS), the heparin-binding site (HBS) or may be pleiotropic (PE). Both RS and PE deficiencies confer a high thrombosis risk in heterozygous form; homozygosity is lethal. Type II HBS deficiency seems to be less severe. Homozygous patients are alive, although they often suffer from premature thrombosis. AT Budapest 3 (p.L99F), a missense mutation leads to type II HBS deficiency. Only sporadic data – mainly case-reports – exist concerning this mutation; no population-based studies have been conducted, yet. Presence of a founder effect was suggested, however only five probands were genotyped for DNA markers.

Aims: Description of the mutation spectrum of AT deficiency in the Hungarian population. Determination of the frequency of AT Budapest 3 variant in the general Hungarian population and in patients with venous thrombosis (VT) and with myocardial infarction (MI). Investigation of a founder effect.

Methods: Consecutive patients suffering from VT with the laboratory diagnosis of AT deficiency (n = 97), young adults, i.e. below the age of 40 with the history of MI (n = 81) and their age-matched controls (n = 320) were recruited. DNA samples of 1000 healthy individuals representing the general Hungarian population were kindly provided by the Department of Preventive Medicine, University of Debrecen, Medical and Health Science Center. Mutations within SERPINC1 were detected by direct DNA sequencing. The presence of AT Budapest 3 and rs2227596, rs941989, rs2227612, rs5877 and rs5878 intragenic SNP's were examined by real time PCR using melting point analysis and FRET detection on a LightCycler 480 instrument. Allelic frequency distribution of the above mentioned SNP's was determined in AT Budapest 3 carriers and healthy controls, then haplotype and – where possible – family tree analysis were performed.

Results: Among the 97 patients with low AT activity AT Budapest 3 was the most frequent (74%), while AT Basel (p.P41L) and Padua (p.R47H) were detected in 5–5% of the patients. Other mutations (p.L173P+, p.E237K, p.G392R, p.P407T, IVS5-14G>A, p.N418I+, p.R132X, p.T85K+) were identified only in one family each. (Marked mutations are novel or not yet characterized.) AT Budapest 3 was

associated with the same haplotype in all carriers. Family tree analysis also suggested founder effect. AT Budapest 3 mutation was absent in 1000 individuals representing the general population and in the age-matched controls of MI patients, while two patients with the mutation was identified among MI subjects.
Conclusions: The high frequency of AT Budapest 3 in Hungary can be explained by a founder effect. Our results indicate the importance of searching for AT Budapest 3 (and type II HBS deficiency) not only in VT patients but also in the background of MI especially in young individuals without 'classical' risk factors.

OC 90.4

The influence of ABO, Lewis and Secretor genotypes on von Willebrand factor and lipid levels in two population cohorts

Clark P[1], Hayward C[2], Rudan I[3], Wilson JF[3], Lowe GDO[4] and Rumley A[4]

[1]Department of Transfusion Medicine, Dundee; [2]MRC Human Genetics Unit, IGMM, University of Edinburgh; [3]Centre for Population Health Sciences, University of Edinburgh, Edinburgh; [4]Institute of Cardiovascular and Medical Sciences, University of Glasgow, Glasgow, UK

Background: Non-O blood groups are associated with an increased risk of arterial (AT) and venous (VTE) thrombosis that has been attributed to higher von-Willebrand factor (VWF) levels and possibly alterations in lipid profiles. However, the exact nature of these relationships in those potentially higher thrombotic risk genotypes associated with the least O(H) expression, in those with no history of thrombosis, and the parallel influence of Lewis and Secretor genotypes has not been defined in studies large enough to investigate less frequent genotypes.
Aims and Methods: We investigated whether there is a consistent relationship of blood group with VWF antigen and lipid levels in two population cohorts from Orkney and Croatia ('ORCADES' [n = 882] and 'CROATIA-Viz' [n = 924]). All participants gave informed consent and the studies were approved by the ethics committee of the medical faculty of Zagreb and the Multi-centre Research Ethics Committee for Scotland.
Results: In both cohorts (excluding those with a history of thrombosis, vascular disease or diabetes and coding A^2 as O), a stepwise increase in VWF from *OO* (ORCADES median 91 IU/dl, IQR 74–116, CROATIA-Vis median 106 IU/dl, IQR 85–134) to the combined group *A1O*/*A1A2*/*A2B*/*BO* (ORCADES median 124 IU/dl, IQR 99–151, MWU $P > 0.001$, CROATIA-Vis median 136 IU/dl, IQR 114–161, $P > 0.001$) and from this to the combined group of *A1B*/*BB*/*A1A1* (ORCADES median 137 IU/dl, IQR 112–161, $P = 0.01$, CROATIA-Vis median 149 IU/dl, IQR 121–182, $P = 0.02$) was seen. In both, VWF levels were significantly higher in those carrying A^1 compared with A^2 (difference in medians 24 and 28 IU/dl, respectively, $P = 0.001$). Although, as expected, VWF increased with age, the difference in VWF between non-O and O remained relatively constant. Of interest, however, a median VWF of 125 IU/dl (with its attendant ~twofold VTE risk and increased AT risk), was only achieved by *OO* Croatians at 61–70 years and *OO* Orcadians over 70, but reached at least 20 years earlier in non-O subjects. In this regard, VWF levels ≥ 150 IU/dl identify those at highest VTE risk and were found in 16 and 30% of the cohorts, respectively. By contrast, levels of this magnitude were 2–3 times more likely in *A1B*/*BB*/*A1A1* groups. No consistent influence of Secretor genotypes or Lewis status on VWF was observed.
Excepting higher HDL levels in non-O (median 1.7 mM vs. *OO* median 1.6 mM, $P = 0.002$) and particularly group B (median 1.7 mM vs. OO $P = 0.006$) Orcadians, no consistent influence of ABO on lipids was seen. Non-*Secretors* were, however, associated with significantly higher cholesterol and LDL in both cohorts, with, as expected by obligatory Secretor status, lower levels confirmed in Croatian *Le(b)* subjects.
Summary/Conclusions: Those ABO genotypes which may carry the highest thrombotic risk (*A1B*/*BB*/*A1A1*) also carry the highest levels of VWF. Levels which rise proportionately with increasing age. By contrast, Secretor/Lewis status does not consistently influence VWF, but does alter lipid profiles with higher LDL observed in non-Secretors. Routine consideration of ABO genotype may therefore assist in identifying those with increased VTE and AT risk.

OC 90.5

Identification of dominant thrombosis modifier loci using a sensitized ENU mutagenesis screen

Liu Y[1], Richter C[1], Maeder ML[2], Vo A[1], Huarng M[1], Swaroop A[1], Joung K[2] and Shavit JA[1]

[1]University of Michigan, Ann Arbor, MI; [2]Massachusetts General Hospital, Charlestown, MA, USA

Background: Pathologic blood clotting (thrombosis) is a leading cause of morbidity and mortality in the developed world. While a number of genetic risk factors have been identified for venous thrombosis, > 30% of recognized individuals will ever sustain an event, due to the presence of unidentified modifier genes.
Aims: Identification of such modifier loci would facilitate more accurate prediction of individuals at risk for thrombosis, but is difficult to achieve in human populations due to limited pedigree sizes. The zebrafish is a powerful genetic model in which the hemostatic system is nearly entirely conserved with mammals, and its ability to generate thousands of offspring makes it a powerful system in which to screen for modifier genes.
Methods: We have developed a zebrafish model of lethal thrombosis by targeted mutagenesis of the antithrombin III gene (*at3*) using zinc finger nucleases.
Results: Genotyping of offspring from heterozygous incrosses of 22 and 90 base pair deletions ($at3^{\Delta 22}$ and $at3^{\Delta 90}$) revealed a significant reduction of homozygotes compared to the expected Mendelian frequency as early as 1–2 months post fertilization (mpf), and no homozygotes have survived beyond 7 mpf. This lethality was rescued by an *at3* cDNA transgene, enabling survival to at least 15 months of age. Examination of homozygous mutants revealed large intravascular thrombi in the heart and liver. A sensitized ENU (ethylnitrosourea) mutagenesis screen was conducted for suppression of lethal thrombosis, and has produced 4017 total G1 offspring from intercrosses of $at3^{\Delta 90}$ mutants, corresponding to an expected ~1250 homozygotes (~2× genome coverage). Genotyping at 2–3 months of age identified 267 $at3^{\Delta 90/\Delta 90}$ mutants, 15 have survived beyond 7 mpf, and six of those are now 1 year old. These harbor potential suppressor mutants, and we are in the process of positionally cloning the underlying modifier genes.
Summary/Conclusions: This approach will identify novel pathways in the regulation of blood clotting beyond the canonical coagulation cascade. Zebrafish genes identified in this screen will be candidates for common variants that modify thrombosis in human populations, and may direct diagnosis and treatment for patients with venous thrombosis and other thrombotic disorders.

OC 90.6

Antithrombin defects in thromboembolism are underestimated when calculated only by Antithrombin activity measurement

Fischer R[1], Sachs UJ[2], Heidinger K[1], Alrifai M[1], Kelm C[1], Kirsch-Altena A[1], Pavlova A[3], Oldenburg J[3] and Kemkes-Matthes B[1]
[1]*Haemostasis Center;* [2]*Center for Transfusion Medicine and Haemotherapy, Giessen;* [3]*Institute of Experimental Haematology and Transfusion Medicine, Bonn, Germany*

Background: We previously (Blood Coagulation and Fibrinolysis, in press) were able to demonstrate Antithrombin (AT) defects determined by gene sequencing to be more common than AT deficiency calculated upon AT activity measurement in patients with thromboembolism. AT is the major inhibitor of blood coagulation, inactivating thrombin and factor Xa. Individuals with inherited AT deficiency have a markedly increased risk for thromboembolic events. The prevalence of inherited AT deficiency is estimated to be about 0.2% in normal population.
Aim: Aim of this study was to calculate prevalence of AT deficiency calculated by AT activity measurement in a large cohort of thrombosis patients. In total, 4259 subjects were examined: 2983 patients (1038 male, 1945 female) with thromboembolic events (average age at first thromboembolic event: 39 years, median 37 years, range 0–87 years) and 1276 (304 male, 972 female) family members.
Methods: Thrombophilia screening (Factor V Leiden mutation, Prothrombin (G20210A) polymorphism, protein C, protein S, Factor VIII:c, D-Dimer, antiphospholipid antibodies and AT) was done in all patients. Additionally, AT gene sequencing was determined in AT deficient patients.
Results: AT deficiency was diagnosed in 37 (11 male, 26 female) out of 4259 subjects. 24 out of these 37 AT deficient patients presented with thromboembolic events. Average age at first thromboembolic event was 26.1 years (median 24 years, range 0.1–61 years). 13 persons (average age at examination 29 years, median 20 years, range 11–49 years) were family members. Average AT level (n = 24) was 54% of normal (median 54%, range 19–78% of normal). AT gene sequencing in AT deficient persons predominantly showed heterozygous missense mutations.
Conclusion: Prevalence of AT deficiency in patients with thromboembolic events is about 0.8%. Patients with AT deficiency experience their first thrombotic event at a very young age – this demonstrates clinical severity of AT deficiency.
We previously demonstrated (Blood Coagulation and Fibrinolysis, in press) prevalence of AT Mutations in thrombosis patients calculated by AT gene sequencing to be up to 3%. Thus, using only AT activity measurement, prevalence of AT defects is severely underestimated in thrombosis patients.

OC 91 – Von Willebrand Factor – II

OC 91.1

Syntaxin binding protein 1 (STXBP1) modulates release of Weibel-Palade bodies from endothelial cells

Van Breevoort AED[1], Fernandez-Borja M[2], Snijders B[3], Carter T[4], Eikenboom HCJ[5], Valentijn K[5], Voorberg J[1] and Bierings R[1]
[1]*Sanquin-AMC Landsteiner Laboratory;* [2]*Sanquin Research, Amsterdam, the Netherlands;* [3]*MRC Clinical Sciences Centre;* [4]*MRC National Institute for Medical Research, London, UK;* [5]*Leiden University Medical Center, Leiden, the Netherlands*

Background: Vascular endothelial cells contain unique large rod-shaped granules, called Weibel-Palade bodies (WPBs). These granules function as storage organelles for various haemostatic and inflammatory components, such as von Willebrand factor (VWF), chemokines and P-selectin. Controlled release of these components into the vascular lumen through WPB exocytosis is essential for maintaining vascular homeostasis in response to vascular trauma or stress. Secretory granule exocytosis is tightly controlled by signalling pathways that are linked to G-protein coupled receptors. One of the final steps in exocytosis involves the assembly of the so-called SNARE-complex. SNARE-complexes are formed by zipper-like proteins, VAMPs (or v-SNAREs) on vesicles and syntaxins (or t-SNAREs) on the plasma-membrane. Formation of the SNARE-complex promotes fusion of secretory vesicles with the plasma membrane and subsequent release of granule content into the lumen. SNARE-complex formation is controlled by proteins belonging to the syntaxin binding protein (STXBP) family.
Aim – In this study we investigate the possible role of syntaxin binding protein 1 (STXBP1), also known as Munc18-1, in WPB exocytosis.
Methods: A proteomic screen for downstream effectors of Slp4-a was performed using a GST-fusion protein coupled to a Slp4-a-variant lacking theSHD-domain. Candidate proteins were identified using mass spectrometry. Expression of STXBP1 in endothelial cells was monitored by immunoprecipitation followed by Western blot analysis. Functional involvement of STXBP1 in endothelial cells was monitored by siRNA mediated knockdown of gene expression.
Results: STXBP1 was found in a proteomic screen for downstream effectors of the Rab27A effector synaptotagmin-like protein 4-a (Slp4-a), a positive regulator of WPB release. We assessed functional involvement of STXBP1 in WPB release by siRNA mediated knockdown of gene expression. Histamine-induced WPBs release was impaired in STXBP1 depleted cells indicating that STXBP1 is involved in Ca^{2+}-mediated release of WPBs. Depletion of STXBP1 also abolished cAMP-mediated release of WPBs as shown by the reduced forskolin-induced VWF release in STXBP1-depleted cells. We used an immunoprecipation approach to look for interactive partners of STXBP1 in endothelial cells. Both syntaxin-2 and -3 where found to associate with STXBP1 in endothelial cells. In contrast syntaxin-4 did not associate with STXBP1.
Summary/Conclusion: Our findings suggest that STXBP1 regulates WPB release through its interaction with Slp4-a, thereby docking WPBs to the plasma membrane and facilitating the release of haemostatic, inflammatory and angiogenic cargo from these organelles.

OC 91.2

A novel cleavage-resistant and highly prothrombotic von Willebrand factor mutant

Prevost N[1], Morioka Y[1], Casari C[2], Kurata S[1], Christophe OD[2] and Denis CV[2]
[1]*Kyoto University, Kyoto, Japan;* [2]*Inserm U770, Paris, France*

Background: Thrombus formation, whether in the context of hemostasis or thrombosis, requires von Willebrand factor (vWf) recruitment of platelets at the site of vascular injury. In patients suffering from thrombotic thrombocytopenic *purpura* (TTP), cleavage of large vWf multimers into smaller units by metalloproteinase ADAMTS13 is impaired, resulting in pervasive blood clot formation, platelet depletion and red blood cell shredding. The cleavage site of vWf is located within its A2 domain, and only becomes accessible to ADAMTS13 when elongational forces cause the A2 domain to unfold. Structural evidence suggests that the susceptibility of the A2 domain to unfolding is due, in part, to the absence of a *N*- to *C*-terminal disulfide bond present in other vWA domains. Another feature that may account for the susceptibility of A2 to unfolding is a disulfide bond shared by Cys_{1669} and Cys_{1670} in the *C*-terminal end of the domain.
Aims: Would the introduction of cysteine residues in the *N*-terminal end of the A2 domain of vWf allow for the simultaneous disruption of the Cys_{1669}-to-Cys_{1670} bond and the formation of an A2 *N*-terminal to *C*-terminal disulfide bond? In the event that it does, would such a mutation render vWf multimers resilient to deformation forces and proteolysis? Lastly, what would be the impact of one such mutation on platelet-vWf interactions *ex* and *in vivo*?
Methods: We have created 12 human and 11 matching murine vWf mutants, sporting various cysteine substitution combinations through-

out the A2 domain. All mutants were subjected to multimer analysis, proteolysis assays and hydrodynamic injection-driven expression in vWf-null mice. Complementary studies were also performed on isolated recombinant WT and mutant A2 domains.
Results: Mutant expression: all 12 mutants and WT control express at comparable levels in HEK293T cells. vWF S1494C showed impaired multimerisation and vWF S1494, 1534, 1671C an abnormal SDS-agarose electrophoretic migration profile. All other mutants showed multimerisation patterns similar to WT vWf. ADAMTS13 cleavage: Flow assay studies on recombinant and live cell-expressed vWf revealed that only vWf S1494, 1534C was resistant to proteolysis (shear rates up to 2500/s). DTT or b-mercaptoethanol pretreatment of recombinant vWf S1494, 1534C and isolated A2 S1494, 1534C was found restore their susceptibility to cleavage. Prothrombotic properties: Mutant 4, when expressed in HEK293T cells, formed long and highly pro-thrombotic strings. Mouse studies: Preliminary hydrodynamic studies performed in vWf-deficient mice suggest that expression of vWf S1494, 1534C, in itself, is sufficient to promote the formation of circulating microthrombi.
Conclusion: We have engineered a vWf mutant (S1494, 1534C in humans, S1494C,A1534C in mice) that shows complete resilience to proteolysis by ADAMTS13, even when subjected to very high flow rates. Treatment of this mutant by reducing agents was shown to restore its susceptibility to cleavage by ADAMTS13, suggesting that the presence of these two cysteine residues was sufficient to cause at least one novel disulfide bound to form. Lastly, vWf S1494, 1534C was found to support strong thrombotic responses in flow chamber assays and live animals.

OC 91.3
CTL-2 is a new von Willebrand receptor: role in antibody mediated neutrophil aggregation induced by anti-CTL-2 antibodies

Santoso S[1], Tjahyono Y[1], Bayat B[1], Berghöfer H[1], Werth S[1], Burg-Roderfeld M[1], Deckmyn H[2] and Sachs UJ[1]
[1]Clinical Immunology and Transfusion Medicine, Giessen, Germany; [2]Laboratory for Thrombosis Research, Kortrijk, Belgium

Background: Recruitment of neutrophils to endothelial cells lining the blood vessels is the key stage in inflammation. This process is controlled by a series of molecular interaction between difference adhesive molecule expressed on neutrophils and endothelial cells. Subsequently, neutrophils migrate into surrounding tissue. Recent evidence indicated that antibodies against neutrophils or/and endothelial cell could contribute as active players in neutrophil recruitment (Williams et al., 2011). Antibodies against choline transporter like protein-2 (CTL-2) are capable to induce stable neutrophil aggregation *in vitro*; a phenomenon that may associate with severe acute lung injury in patients who received anti-CTL-2 antibodies containing blood products (known as TRALI; Transfusion Related Acute Lung Injury). CTL-2 is a multiple membrane spanning glycoprotein, expressed on neutrophils and platelets as well on endothelial cells, abundantly found in human lung. To date, little is known about the function of CTL-2.
Aims: In this study, we sought to analyse the mechanism of neutrophil aggregation mediated by anti-CTL-2 antibodies.
Methods: Purified IgG fractions containing anti-CTL-2 antibodies were tested in granulocyte agglutination test (GAT) in the absence or presence of different purified plasma proteins (albumin, vWF, fibrinogen). ROS production was measured by the use of ferricytochrome-c reduction method. Stable transfected cells expressing CTL-2 and CD11b/CD18 were established and their interaction with purified plasma proteins was evaluated by adhesion assay and surface plasmon resonance (SPR) technology.
Results: Our results showed that neutrophil aggregation mediated by anti-CTL-2 antibodies depends on vWF. Washed neutrophils in PBS primed with IgG fraction of anti-CTL-2 antibodies did not form cell aggregates. In the presence of recombinant vWF-A1-A2-A3, vWF-A1 but not vWF-A3 domain, neutrophil aggregates could be observed. This phenomenon is Fc-independent; F(ab)2 fragment of anti-CTL-2 antibodies is capable to induce neutrophil aggregation. This aggregation could be inhibited by mab against vWF-A1 domain and mabs against CD11b or CD18. Cross-linking studies showed that CTL-2 on neutrophils could interact with CD11b/CD18 integrin. Interestingly, neutrophils incubated with anti-CTL-2 antibodies in the presence of soluble vWF did not lead to ROS production. In contrast, significant ROS production was detected when neutrophils interact with immobilized vWF. In cell adhesion assay, CTL-2 transfected HEK cells adhere strongly onto vWF immobilized on microtiterwell, but not on fibrinogen. This interaction, CTL-2 and vWF, was significantly stronger when compared to the adhesion capability of CD11b/CD18 transfected cells on vWF. In addition, CD11b/CD18 transfected HEK cells bound equally to fibrinogen compared to vWF. These results could be confirmed by real time protein-protein interaction analysis by SPR; CTL-2 bounds more efficiently to vWF when compared to CD11b/CD18.
Summary and Conclusions: Altogether, our findings indicated the important role of vWF for anti-CTL-2 mediated neutrophil aggregation. Furthermore, this study introduced CTL-2 as new binding partner for vWF (via A1-Domain). Together with CD11b/CD18 integrin, this molecular cross talk may open new insights on the mechanism of neutrophil recruitment during inflammation.

OC 91.4
Impact of ADAMTS13-mediated regulation of von Willebrand factor multimer (VWF) profile on hemostasis and VWF clearance

Shida Y, Brown C, Mewburn J, Sponagle K and Lillicrap D
Queen's Univeristy, Kingston, ON, Canada

Background: An essential biosynthetic processing step for von Willebrand Factor (VWF) is the formation of disulfide linked multimers that result in molecules of up to 20 mDa. Newly released VWF multimers undergo limited proteolytic processing by ADAMTS13 to generate molecules of an optimal size for the primary hemostatic function. While there is a consensus that the largest VWF multimers optimally support the protein's primary hemostatic function, there has been no systematic assessment of the influence of multimer size on hemostatic efficacy and clearance of this protein.
Aims: To evaluate the effect that VWF multimer size has on its role in hemostasis and rate of clearance from the circulation.
Methods: Full-length murine VWF and ADAMTS13 cDNAs were cloned into pCIneo and pcDNA3.1 plasmids, respectively and recombinant mouse VWF (rmVWF) and ADAMTS13 (rmADAMTS13) were produced. To reduce multimer size, rmVWF was treated with either rmADAMTS13 or N-acetylcystine (NAC). NAC reduces VWF multimer size by reduction of the intersubunit disulfide bonds. The loss of HMW multimers was confirmed by 1% SDS agarose gel electrophoresis and function of the VWF multimer subpopulations was assessed by an *in vitro* flow chamber system. Briefly, whole blood from ADAMTS13/VWF double knockout mice was perfused over a collagen/digested VWF coated surface at 2500/s and platelet accumulation was quantified by the Quorum WaveFX- X1 spinning disk confocal system. For the clearance study, digested VWF was injected into ADAMTS13/VWF double knockout mice and blood was collected by retro-orbital sampling and VWF:Ag was monitored.
Results: Treatment of VWF with 25 and 35 mM NAC resulted in a respective 62% and 78% reduction in HMW multimers, while cleavage with 0.5, 2.0 and 3.0 U/mL ADAMTS13 reduced HMW multimers by 65%, 75% and 81%, respectively. In the flow chamber experiment, surface coverage and thrombus volume were evaluated and showed very similar trends. 80.8%, 81.8% and 91.1% reduction of thrombus volume were observed when VWF was digested with 0.5, 2.0, 3.0 U/mL ADAMTS13, respectively. However, there was no difference in these parameters of thrombus generation between undigested or NAC-treated VWF. The loss of platelet adhesion to ADAMTS13-

cleaved VWF was partially mitigated with additional exposure to 35 mM NAC resulting in 25.0%, 18.2% and 30.2% increases in thrombus volume. Clearance of infused ADAMTS13 cleaved VWF was significantly faster than either the undigested or NAC-treated VWF. The half-life for infused undigested VWF was 27.8 min while the half-lives for NAC and ADAMTS13-treated VWF were 17.9 and 8.5 min, respectively.

Summary/Conclusion: Our data highlights the impact of VWF secondary structure on both hemostasis and protein clearance. Notably, the loss of HMW multimers through reduction of disulfide interactions does not alter thrombus formation and has only a moderate effect on VWF clearance. These effects are presumably the result of the reduction of intra-subunit disulfide linkages. In contrast, cleavage with ADAMTS13 is associated with significant loss of VWF function and rapid clearance from the circulation. These data reveal the efficient regulation of VWF activity by ADAMTS13 and document the preferential clearance of smaller, less functional VWF molecules.

OC 91.5

Analysis of ADAMTS13 proteolysis of Von Willebrand Factor under physiological shear stress conditions

McKinnon T, Nowak A, Wooding C, Mehdi A, Laffan MA and McKinnon T

Imperial College, London, UK

Background: Within the circulation the multimeric size and thus activity of Von Willebrand Factor (VWF) is controlled by ADAMTS13 that cleaves VWF in its A2 domain. *In vivo* the cleavage site becomes available under shear stress when VWF is anchored to endothelial cells or the exposed sub-endothelial matrix. The analysis of VWF proteolysis is hampered by the need to use small fragments of VWF that are readily cleaved, but do not represent the full length molecule or the use of denaturants to artificially expose the ADAMTS13 cleavage site. Alternatively cultured HUVECs can be stimulated under flow to release VWF, and in the presence of platelets these can be visualised as long strings that can be cleaved by ADAMTS13. However, this assay cannot be used to investigate different VWF variants. Several studies have used a vortex mixer to generate unfolding of the VWF molecule, however the mechanism behind this is not fully defined.

Aims: To develop a physiological flow based assay to investigate ADAMTS13 proteolysis of VWF and its variants under conditions of shear stress.

Methods: Collagen coated flow slides were perfused with washed erythrocytes and labelled platelets supplemented with plasma derived or recombinant VWF in the presence or absence of recombinant ADAMTS13. Real time movies were recorded and the extent of platelet capture determined. Alternatively, VWF and ADAMTS13 were perfused over collagen surfaces in the absence of platelets, the flow through and stripped surface proteins were analysed by multimer gels.

Results: ADAMTS13 reduced the extent of VWF mediated platelet capture in a concentration dependent manner, with 20 nM ADAMTS13 reducing surface coverage by ~45% after 5mins at 1500/s. The loss of platelet capture was specific to ADAMTS13 cleavage of VWF since the use of an inactive ADAMTS13 mutant or an anti-ADAMTS13-MP domain antibody prevented loss of platelet capture. Furthermore, analysis of the flow through and stripped collagen bound VWF demonstrated loss of VWF multimers only in the presence of ADAMTS13. Extent of cleavage was also correlated with increasing shear rate, with proteolysis most effective at the highest shear rates. Finally, time course experiments demonstrated that ADAMTS13 mediated both the initial rate of platelet capture and the final extent of surface coverage. Application of the assay to investigate different VWF variants demonstrated that as expected the type 2A variants G1629R and E1638K were proteolysed faster than wtVWF. In keeping with data obtained under static conditions, Asialo-VWF lacking terminal sialic acid residues was proteolysed slower under shear stress. Intriguingly, the VWF variant S1468A which we have recently shown to be proteolysed *slower* under static conditions was proteolysed *faster* under shear stress. Moreover, the ADAMTS13 P3 variant with a mutation at L1603, which has been shown to abolish cleavage of VWF under static conditions, was able to proteolyse VWF under flow to a similar extent to wtADAMTS13.

Early stages of Weibel-Palade body biogenesis revealed by light and electron microscopy

Mourik M[1], Bierings R[2], Valentijn K[1], Voorberg J[2], Koster A[1] and Eikenboom HCJ[1]

[1]Leiden University Medical Center, Leiden; [2]Sanquin-AMC Landsteiner Laboratory, Amsterdam, the Netherlands

Background: The hemostatic protein Von Willebrand factor (VWF) is stored by the vascular endothelium in specialized organelles called Weibel-Palade bodies (WPBs). WPBs have a typical elongated shape which is the result of many densely packed helical tubules of VWF. Correct packaging of VWF in these tubular structures is thought to be a hallmark for proper VWF functioning during hemostasis. Understanding the formation of WPBs could therefore provide new insights in the mechanisms that are disturbed in patients with the bleeding disorder Von Willebrand disease (VWD). It is known that the WPBs originate from the Trans Golgi Network (TGN). Upon formation of high molecular weight VWF multimers, VWF tubules are formed which are stored in WPBs. Previous electron microscopy studies have described several structures, including WPB-like vesicles with one or two tubules, most probably representing immature WPBs formed at the TGN. However it is not known how and when these structures are formed in time.

Aims: The aim of our study is to obtain new insights in WPB biogenesis using both light and electron microscopic techniques.

Methods: Identification of WPBs emerging from the TGN was achieved by Correlative Light and Electron Microscopy (CLEM). Human Umbilical Vein Endothelial Cells (HUVEC) were transfected with VWF propeptide-EGFP, to label the WPBs, and we also co-transfected cells with Rab1a-mCherry to label the TGN. Cells expressing fluorescently labeled WPBs at the Golgi region were imaged and afterwards prepared for TEM using conventional resin embedding. Previously imaged fluorescent WPBs were then correlated to the ultrastructure in serial TEM sections. In addition, we prepared cells using high pressure freezing and freeze substitution. Cells were embedded in Lowicryl HM-20. Immuno-gold labeling on TEM sections was performed in order to detect structures corresponding to VWF in newly forming WPBs.

Results: Using CLEM, we could correlate fluorescently labeled immature WPBs to TEM sections. We observed WPBs with loosely packed VWF tubules which showed clathrin coats around their membrane. These immature WPB contained between 4 and 8 tubules that were already aligned creating elongated organelles. With this technique we did not detect vesicles containing tubule-like VWF subunits which were previously hypothesized to be involved in WPB formation. However when we performed a VWF specific immuno-gold labeling on cells prepared by high pressure freezing and freeze substitution we did find VWF positive structures that seem to contain subunits of VWF tubules. The diameters of these structures ranged between 250 and 400 nm which would be rather large in case they represented cross sectioned WPB. Further analysis of Lowicryl embedded and immunolabeled TEM samples is required to obtain more information about WPB biogenesis, especially regarding the order in which the morphological changes occur.

Summary/Conclusions: Correlative light and electron microscopy shows that tubule containing, clathrin-coated vesicles in proximity to the TGN correspond to newly forming WPBs. Using immuno-gold labeling a population of VWF immunoreactive small vesicles is identified that contains building blocks for assembling tubules. Together our findings yields novel insight into the early stages of the biogenesis of WPBs.

Comparison of a new ELISA-based with the flow cytometric assay for vasodilator-associated stimulated phosphoprotein (VASP) phosphorylation to assess P2Y12-inhibition after ticagrelor intake

Hobl E-L, Derhaschnig U, Schoergenhofer C, Jilma-Stohlawetz P, Schwameis M and Jilma B

Medical University of Vienna, Vienna, Austria

Background: Ticagrelor is a $P2Y_{12}$ receptor antagonist, with superior effects but also ensuing enhanced bleeding risk as compared to clopidogrel. Determination of platelet inhibition may be useful to confirm efficient platelet inhibition on an individual patient level, and to identify patients at risk for bleeding, particularly in a pre-operative setting. The vasodilator-associated stimulated phosphoprotein (VASP) phosphorylation assay specifically measures platelet $P2Y_{12}$ inhibition, but has so far required special flow cytometric equipment and individual sample processing. A new ELISA-based VASP assay has been developed which allows batch analysis after initial platelet activation. Due to the reversible binding of ticagrelor it is unclear if the ELISA and flow cytometric assays provide comparable results.

Aims: The aim of the study was to compare the performance and reliability of a newly developed ELISA-based VASP assay with the currently available flow cytometric approach. We hypothesized that the conventional and new methods may be comparable when the reversible $P2Y_{12}$ inhibitor ticagrelor is used.

Methods: The clinical trial was approved by the Ethics Committee of the Medical University of Vienna and performed in accordance with Good Clinical Practice guidelines and ethical principles that have their origin in the Declaration of Helsinki. Written informed consent was obtained from all healthy volunteers.

Healthy volunteers received a single 180 mg loading dose of ticagrelor. Blood samples were drawn into non-wettable plastic tubes containing 3.8% sodium citrate (0.129 M) as anticoagulant. Overall, 84 data points were evaluated. To directly compare the performance of the new ELISA-based technique to the currently used flow cytometric assay, VASP phosphorylation was determined by the new ELISA VASP-P and the commercially available test (PLT VASP/$P2Y_{12}$, both BioCytex, Marseille, France). Venous blood samples were stored unopened at room temperature (RT, 18–25 °C) and were processed within 24 h after collection. All samples were handled following the manufacturer's instructions enclosed in the assay kits.

We pair-wise compared the platelet reactivity index (PRI) between. For correlation of the two different assays, the Pearson's coefficient was used and a linear regression analysis was performed. By means of the Bland-Altman analysis, a direct comparison of the ELISA and the flow cytometric method was possible and the agreements as well as the systematic error between the different assays were evaluated. The limits of agreement were specified as mean difference ± 1.96 SD.

Results: PRI-values of the two methods correlated well ($r = 0.97$, $P < 0.001$). Ticagrelor rapidly decreased PRI values on average after 50 min, but nadir levels 2–6 h after ticagrelor intake were 15% higher when PRI% was measured with the flow cytometric method. Bland-Altman analysis showed that the flow cytometric assay measured markedly higher PRI levels than the new ELISA-based technique (mean difference 13%).

Summary/Conclusion: The new ELISA-based VASP assay offers an alternative to the currently used flow cytometric method, but measures lower PRI levels, particularly when PRI falls below 20% after ticagrelor intake.

PA 1.01-2

Impact of body mass index on response to thienopyridines in patients treated after acute coronary syndrome

Cuisset T[1], Pankert M[1], Quilici J[1], Morange PE[2], Bonnet J-L[1] and Alessi M-C[2]

[1]Service de Cardiologie; [2]UMR Inserm 1062, Marseille, France

Background: Variability of response to thienopyridine has been described for both clopidogrel and prasugrel and the underlying factors are multiple.

Aims: The aim of the present study was to analyze the impact of body mass index (BMI) and different type of obesities on response to clopidogrel and prasugrel in ACS patients.

Methods and Results: One thousand five hundred and forty-two ACS consecutive patients undergoing coronary stenting were included: 287 with clopidogrel 75 mg, 868 patients with clopidogrel 150 mg and 387 patients with prasugrel 10 mg. Platelet reactivity was assessed 1 month after discharge with PRI VASP. Three hundred and thirty-six patients (21.8%) were obese (BMI > 30) including 264 obesity type 1 (3040). Among, 1206 non obese patients, we identified 1.6% ($n = 24$) underweight patients (BMI < 18.5), 33.4 ($n = 515$) patients with normal BMI and 42.9% ($n = 429$) overweight patients. We observed a stepwise increase of on-treatment platelet reactivity according to the different groups with higher platelet reactivity in patients with higher BMI with all thienopyridine regimens ($P < 0.0001$). Using the predefined cut-off of VASP > 50% to define the HTPR, incidence of HTPR was higher in obese patients than in non obese patients with all regimens (OR[95%CI]: clopi. Seventy-five milligram; clopi.150 mg; prasu. Ten milligram: 2.7[1.4–5]; 1.4[1.1–2]; 10[4.7–21.2] respectively); $P < 0.05$ for all). Using PRI VASP < 20% to define LTPR on prasugrel linked with higher risk of bleeding, the incidence of LTPR was lower in obese patients: 13% (12/93) vs. 33% (97/294), OR [95%CI]: 0.30 [0.16–0.58], $P < 0.001$.

Conclusion: BMI has a strong impact on response to thienopyridine with a linear relationship between BMI and on treatment platelet reactivity. We also reported higher incidence of HTPR and lower incidence of LTPR in obese patients. These data suggest the potential value of tailored antiplatelet therapy based on BMI to improve prognosis of this high risk population.

PA 1.01-3

Evaluation of non-specific agents to control prasugrel-related bleeding in a rabbit model

Bonhomme F[1], Godier A[2], Samama CM[2] and Fontana P[1]

[1]Geneva University Hospitals, Geneva, Switzerland; [2]Hôtel-Dieu University Hospital, Paris, France

Background: Prasugrel is a thienopyridine that provides a more rapid and more effective inhibition of platelet aggregation compared to clopidogrel, thus leading to an increased bleeding risk.

Aims: The aim of the study was to evaluate the efficacy and safety of non-specific agents such as recombinant activated factor VII (rFVIIa), tranexamic acid (TA) and desmopressin (DDAVP) to limit blood loss after a prasugrel loading dose in a rabbit model of bleeding and thrombosis.

Methods: Anesthetized and ventilated rabbits ($n = 49$) were randomly assigned into five groups: control (placebo-placebo), placebo (prasugrel 4 mg/kg-placebo), rFVIIa (prasugrel 4 mg/kg-rFVIIa 150 μg/kg),

TA (prasugrel 4 mg/kg-TA 20 mg/kg), DDAVP (prasugrel 4 mg/kg-DDAVP 1 μg/kg). Two hours after a prasugrel loading dose, a stenosis and a vessel injury were performed on the carotid artery that induced cyclic thrombotic events detected as flow reductions. Non-specific agents were given during the following observation period (1 h before inducing bleeding for DDAVP, 30 min for TA and rFVIIa). Then, haemorrhage was induced by standardized hepatosplenic sections and blood loss was monitored for 15 min.

Results: Prasugrel decreased mean ADP-induced platelet aggregation from 66 ± 4% (mean ± SD) in the control group to 41 ± 8% in the prasugrel-treated rabbits ($P < 0.001$) and doubled the blood loss (median and interquartile range: 10.6 g [9.7–12.7] in the control group vs. 20.0 g [16.7–25.1] in the placebo group, $P = 0.004$).

Blood loss in the prasugrel-rFVIIa group did not differ from blood loss in the placebo group (17.9 g [11.2–26.5] vs. 20 g [16.7–25.1], $P = 0.43$). TA and DDAVP had no impact on hepatosplenic bleeding neither. Regarding safety, rVIIa induced more than three cyclic flow reductions for 33% of rabbits, vs. 0% in the placebo group ($P = 0.031$). TA and DDAVP were not associated with an increase of thrombotic events.

Conclusions: Neither rFVIIa, nor TA or DDAVP were able to significantly decrease prasugrel-related bleeding. rFVIIa-treated rabbits were more prone to thrombotic events.

PA 1.01-4

How to test the effect of aspirin and clopidogrel in patients on dual antiplatelet therapy?

Bagoly Z[1], Kovács EG[1], Sarkady F[1], Homoródi N[2], Kappelmayer J[3], Csiba L[4] and Muszbek L[1]

[1]Clinical Research Center, University of Debrecen, MHSC; [2]Institute of Cardiology, University of Debrecen, MHSC; [3]Department of Laboratory Medicine, University of Debrecen, MHSC; [4]Department of Neurology, University of Debrecen, MHSC, Debrecen, Hungary

Background: Dual antiplatelet therapy with clopidogrel and aspirin is currently the standard therapy in high-risk patients for the prevention of recurrent ischemic events. Monitoring antiplatelet therapy is an important issue in this patient group. However, some frequently used laboratory tests are clearly affected by both antiplatelet agents what makes interpretation of the results ambiguous.

Aims: To determine which laboratory tests, used for the detection of clopidogrel, are affected by aspirin and which laboratory tests, used for the detection of aspirin are influenced by clopidogrel.

Patients and Methods: Study population included 111 patients with the history of ischemic stroke being on clopidogrel monotherapy for at least 1 month. Among these patients, 62 showed good response to the drug as demonstrated by flow cytometric analysis of vasodilator stimulated phosphoprotein (VASP) phosphorylation and a newly developed P2Y12 receptor specific aggregation method in which ADP-induced aggregation is performed on prostaglandin E1 treated platelets (ADP [PGE1]). Laboratory tests routinely used for the detection of aspirin effect (ADP-, collagen-, epinephrine-, and arachidonic acid (AA) induced platelet aggregation and secretion, PFA-100 assay with collagen/epinephrine cartridge, VerifyNow ASA test and AA-induced thromboxane B2 (TXB2) production in platelet rich plasma) were carried out on samples obtained from these patients. The other arm of the study involved 52 patients with coronary artery disease being on aspirin monotherapy for at least 1 month. These patients showed good response to aspirin as demonstrated by the AA-induced platelet aggregation and TXB2 production. Methods used for testing the effect clopidogrel (ADP induced platelet aggregation and secretion, flow cytometric analysis of vasodilator stimulated phosphoprotein (VASP) phosphorylation and ADP[PGE1] aggregation) were performed on samples obtained from these patients. Besides, all tests were carried out on samples from 140 healthy volunteers. For each method, diagnostic cut-offs were determined according to the guidelines of Clinical and Laboratory Standards Institute. All patients and controls gave informed consent and the study was approved by the Regional Ethics Committee.

Results: Of the methods used for detecting the effect of aspirin resistance, clopidogrel monotherapy significantly inhibited all aggregation and secretion tests including tests using AA as agonist. AA-induced TXB2 production was also decreased ($P < 0.0001$). VASP phosphorylation and arachidonic acid induced platelet aggregation showed a surprisingly fair correlation in patients taking clopidogrel only (Spearman $r = 0.49$, 95% CI 0.23–0.67, $P < 0.001$). Clopidogrel therapy did not inhibit the VerifyNow ASA test. Of the methods used for testing clopidogrel resistance, aspirin monotherapy influenced ADP induced platelet aggregation and secretion ($P < 0.0001$), but did not have an effect on VASP phosphorylation and on the P2Y12 specific platelet aggregation test.

Conclusions: Interestingly, AA-induced platelet aggregation and TXB2 production are influenced by clopidogrel therapy and they are not recommended for testing the effect of aspirin in patients on dual therapy. For clopidogrel testing in patients on combined therapy the VASP phosphorylation test or the P2Y12 specific ADP[PGE1] aggregation test could be recommended. As ADP-induced platelet aggregation is affected by both antiplatelet agents, it should not be used to test the effect of either clopidogrel or aspirin in patients on dual therapy.

PA 1.01-5

Reversal strategy in antagonizing the P2Y12-inhibitor ticagrelor

Hobl E-L, Derhaschnig U, Firbas C, Schoergenhofer C, Schwameis M and Jilma B

Medical University of Vienna, Vienna, Austria

Background: Patients on anti-platelet therapy have a higher incidence of bleeding complications and reversal of anti-platelet drug effects is an important issue at trauma or emergency departments. For old and conventional anticoagulants, reversal strategies are established. However, there is no experience or recommendation how to antagonize the reversible and highly effective $P2Y_{12}$-inhibitor ticagrelor and how to restore platelet function following ticagrelor dosing.

Aims: The aim of the study was to describe an *ex vivo* model to reverse the effects of ticagrelor and to estimate the optimal quantity of platelet transfusions required to normalize platelet aggregation.

Methods: The clinical trial was approved by the Ethics Committee of the Medical University of Vienna and performed in accordance with Good Clinical Practice guidelines and ethical principles that have their origin in the Declaration of Helsinki. Written informed consent was obtained from all healthy volunteers.

To normalize platelet aggregation, increasing amounts of autologous platelet rich plasma (PRP) were added *ex vivo* to hirudin-anticoagulated blood which was obtained 3 h after the administration of ticagrelor, by spiking PRP into blood at ratios of 1:10, 1:5 and 1:3.

Platelet aggregation was assessed by whole blood multiple electrode aggregometry (MEA; Multiplate®; Dynabyte, Munich, Germany). For interpretation of aggregation, we defined a cut-off level of 40 A.U. as the lower limit of the range. Volunteers above this level were considered to exhibit normal platelet reactivity.

Nonparametric tests were used and statistical comparisons were performed with the Friedman ANOVA, and the Wilcoxon test for post-hoc comparisons. A two-tailed P-value of < 0.05 was considered significant.

Results: The strategy to reverse the effect of ticagrelor was tested in 20 healthy volunteers. Basal ADP induced platelet aggregation averaged 71 ± 16 A.U. Ticagrelor decreased ADP induced platelet aggregation to 16 ± 8 A.U.

A clear dose-response was obtained after spiking whole blood with increasing amounts of PRP. After addition of PRP at a ratio of 1:10, platelet aggregation increased to 31 ± 14 A.U. When assuming that one apheresis platelet concentrate (200 mL) typically contains a mini-

mum of 2×10^{11} platelets, the ratio of 1:10 corresponds to 0.5 units of apheresis platelet concentrates.
A ratio of 1:5 – equivalent to 1 unit of platelet concentrates – increased ADP induced platelet aggregation to 41 ± 14 A.U. Platelet aggregation increased further to 48 ± 18 A.U. following the addition of PRP at a ratio of 1:3, which corresponds to 1.5 units of platelet concentrates. All comparisons were significant at $P < 0.01$.
Summary/Conclusion: Platelets dose-dependently improve *ex vivo* platelet aggregation of subjects after a loading dose of 180 mg of ticagrelor. It is estimated that > 2 units of apheresis platelet concentrates will be necessary to completely restore baseline platelet aggregation in the majority of patients. Point-of-care platelet function tests may be suitable tools to verify this concept in emergency patients and to estimate the extent of the reversal and de-risk on an individual patient's level.

PA 1.01-6
Ticagrelor and endothelial dysfunction: platelet-independent effects

Reiner MF[1], Stivala S[2], Akhmedov A[1], Spescha RD[1], Camici G[1] and Beer JHJ[2]
[1]Physiology, Zurich; [2]Cantonal Hospital Baden, Baden, Switzerland

Background: Platelets play a crucial role in the pathogenesis of acute coronary syndromes (ACS) and in line with this, anti-platelet therapy is a key area of research in primary and secondary prevention of major adverse cardiovascular events (MACE). P2Y12 receptor inhibitors, such as clopidogrel, prasugrel and ticagrelor prevent ADP-induced platelet aggregation; different P2Y12 receptor blockers have shown different spectra of beneficial effects on mortality due to myocardial infarction (MI), stroke and bleeding. Since P2Y12 receptors are not only expressed in platelets but also in vascular smooth muscle cells, neurons and other cells, the reported data may also be the result of effects on other cells than platelets.
Aims: To investigate platelet-independent effects of P2Y12 receptor inhibitors with a special focus on endothelial dysfunction, an early mediator of cardio- and cerebrovascular disease.
Methods: Experiments were performed on human primary endothelial cells of aortic, cerebral and cardiac origin. To investigate the effect of ticagrelor on the production of free radicals, endothelial cells incubated with vehicle or tumor necrosis factor alpha (TNFalpha, 10 ng/mL) were treated with increasing concentrations of ticagrelor (10^{-7} M, 10^{-6} M and 10^{-5} M). ROS production was measured by electron spin resonance (ESR) and expressed as 0_2ˆ-/min/10^5 cells. Additionally, activation of endothelial nitric oxide (eNOS) as well as cell toxicity were assessed by western blotting and LDH assay, respectively. Finally, to confirm the expression of P2Y12 receptors at the protein and mRNA level, western blot analysis and qrt-PCR were performed. Data is expressed as mean ± SEM.
Results: Ticagrelor reduced TNFalpha-induced ROS production in human aortic endothelial cells (TNFalpha, 7.043 ± 1.632, 0_2ˆ-/min/10^5 cells; TNFalpha + ticagrelor 10^{-7} M, 2.647 ± 1.048, 0_2ˆ-/min/10^5 cells; TNFalpha + ticagrelor 10^{-6} M, 4.053 ± 1.662, 0_2ˆ-/min/10^5 cells, TNFalpha + ticagrelor 10^{-5} M, 5.233 ± 1.716, 0_2ˆ-/min/10^5 cells). Additionally, ticagrelor augmented activation of eNOS at Serine 1177 and increased cell survival.
Interestingly, P2Y12 receptor expression could not be detected neither at the protein nor at the mRNA level in either human aortic, cardiac or cerebral endothelial cells.
Conclusion: Ticagrelor treatment in human aortic endothelial cells
1 reduces generation of ROS in response to TNFalpha
2 increases eNOS activation and
3 reduces cell death
Lack of expression of P2Y12 receptor in endothelial cells not only confirms platelet-independent effects but also supports the concept of P2Y12 receptor-independent effects by ticagrelor.

PA1.02 – Platelet Activation: Novel Proteins – I

PA 1.02-1
Disabled-2 is required for efficient platelet activation by thrombin in mouse

Hui-Ju T[1], Chien-Ling H[2], Ding-Yuan H[2], Chung-Ching L[2], Cooper JA[3], Ju-Chien C[4] and Ching-Ping T[2]
[1]Graduate Institute of Biomedical Sciences/Chang Gung University; [2]Department of Medical Biotechnology and Laboratory Science/Chang Gung University, Taoyuan, Taiwan; [3]Division of Basic Sciences/Fred Hutchinson Cancer Research Center, Seattle, WA, USA; [4]Department of Medical Laboratory Science and Biotechnology/China Medical University, Taichung, Taiwan

Background: During blood vessel wall damage, platelets adhere on injury site to form a stable plug and prevent excessive blood loss. Platelet activation is a complex process that is regulated delicately. Disabled-2 (Dab2) has been reported to regulate platelet aggregation. Recently, megakaryocyte lineage-restricted Dab2 knockout ($Dab2^{-/-}$) mice were generated to assess the role of Dab2 in platelet function *in vivo*. $Dab2^{-/-}$ mice are normal in size and platelet production while bleeding time is prolonged and thrombus formation is impaired. However, the mechanistic insight leading to the impaired haemostatic phenotype in $Dab2^{-/-}$ mice is not clear.
Aims: In this study, the effects of Dab2 deficiency on platelet activation and integrin signaling are investigated with an aim to delineate the underlying mechanism of Dab2 function in haemostasis.
Methods: Washed platelets were isolated from wild type ($Dab2^{fl/fl}$) and $Dab2^{-/-}$ mice for agonist-induced platelet aggregation, granule secretion and integrin alpha(IIb)beta(3) activation analyses. In addition, the spreading of platelets on fibrinogen and the clot retraction assays were performed to investigate the role of Dab2 in cytoskeleton reorganization and outside-in signaling. The activation status of platelet signaling proteins in the assay conditions was analyzed by Western blot to delineate the signaling pathways regulated by Dab2.
Results: Agonist-induced platelet aggregation assays revealed that $Dab2^{-/-}$ platelets responded normally to collagen, U46619, ADP, and 1 U/mL of thrombin. However, the responsiveness of $Dab2^{-/-}$ platelets to low concentration of thrombin (0.05 U/mL) was significantly decreased. The percentage of light transmission was 49.4 ± 7.4% and 13.3 ± 8.5% for $Dab2^{fl/fl}$ and $Dab2^{-/-}$ platelets, respectively. In accordance with this notion, the activation of integrin alpha(IIb)beta(3) for $Dab2^{-/-}$ platelets was 64.6% of $Dab2^{fl/fl}$ platelets after thrombin (0.05 U/mL) stimulation. The percentage of clot retraction was 49.2 ± 6.3% for $Dab2^{-/-}$ platelets that was significantly different to 73.5 ± 6.0% for $Dab2^{fl/fl}$ platelets. Moreover, the increase in the surface area of $Dab2^{-/-}$ platelet induced by low concentration of thrombin was 56.7 ± 13.7% of $Dab2^{fl/fl}$ platelets. In contrast, the spreading of $Dab2^{-/-}$ and $Dab2^{fl/fl}$ platelets on fibrinogen induced by $MnCl_2$ was similar, implying that Dab2 is mainly involved in thrombin-induced inside-out but not outside-in signaling of integrin alpha(IIb)beta(3). Analyses of the thrombin-stimulated signaling revealed that the expression levels of thrombin receptors (PAR3 and PAR4) and PDK1-Ser241 phosphorylation were similar for $Dab2^{fl/fl}$ and $Dab2^{-/-}$ platelets. However, thrombin-stimulated phosphorylations of Akt-Ser473 and mTOR-Ser2448 in $Dab2^{-/-}$ platelets were significantly decreased, implying that Dab2-deficient platelets were impaired in thrombin-stimulated inside-out signaling.
Summary: Dab2 is a key haemostatic regulator by playing a selective role in cytoskeleton reorganization and mTOR pathway underlying thrombin-stimulated inside-out signaling and is required for efficient platelet activation by thrombin in mouse.

PA 1.02-2

Human platelet aminophospholipid translocase (APLT) ATP8A1 and TMEM16F are calpain substrates

Wang H[1], Bang A[2], McMillan-Ward E[3], Israels SJ[3] and Rand ML[1]
[1]Hospital for Sick Children; [2]Mount Sinai Hospital, Toronto, ON; [3]University of Manitoba, Winnipeg, MB, Canada

Background: Resting platelets have an asymmetrical distribution of phospholipids across their plasma membrane, with the anionic aminophospholipid phosphatidylserine (PS) residing mainly in the inner, cytoplasmic leaflet. APLT maintains membrane phospholipid asymmetry by rapidly and specifically transporting aminophospholipids from the outer to the inner membrane leaflet in a Ca^{2+}-sensitive manner; APLT is likely the P-type ATPase ATP8A1. Activated platelets express a procoagulant surface on a distinct platelet subpopulation due to Ca^{2+}-dependent scrambling of membrane phospholipids, exposing PS on the platelet surface. The Ca^{2+}-activated cation channel TMEM16F has recently been shown to be important in this scrambling. Calpain, a Ca^{2+}-dependent intracellular protease, is involved in many regulatory processes in platelets via limited proteolysis of its substrates.
Aim: To determine whether ATP8A1 and TMEM16F are substrates of calpain in activated human platelets.
Methods: Washed platelets were stimulated with the combination of 1 U/mL thrombin and 10 μg/mL collagen (T + C), which yields approximately 20% PS-exposing platelets, or 3 μM A23187, which yields approximately 95% PS-exposing platelets. We have previously shown that, under these conditions, calpain is not activated in T + C-stimulated platelets, but is activated in A23187-stimulated platelets (Gwozdz et al, Thromb Haemost 2010;103:1218). To inhibit calpain, platelets were pretreated with the cell-permeable calpain inhibitor calpeptin (300 μM) before stimulation. Western blot analysis of platelet lysates was done using a polyclonal antibody specific for the cytoplasmic C-terminus of ATP8A1 (Ding et al, J Biol Chem 2000;275:23378). Alternatively, to detect TMEM16F, commercial polyclonal antibodies reported to be specific for either the cytoplasmic N-terminus or an extracellular domain of the protein were used.
Results: ATP8A1: A single band of molecular weight approximately 120 kDa was observed by immunoblotting lysates of resting platelets and of platelets stimulated with T + C. This band was not detected in A23187-stimulated platelets, however pretreatment with calpeptin prevented the loss of the band following A23187 stimulation.
TMEM16F: Recognition of either cytoplasmic or extracellular domains of TMEM16F by the 2 commercial antibodies was confirmed by flow cytometry and immunofluorescence. Immunoblotting with either antibody demonstrated a single broad band of approximately 125 kDa in lysates of resting platelets and platelets stimulated with T + C. In A23187-stimulated platelets, this band was not detected with the cytoplasmic N-terminus specific antibody, and with the extracellular-domain specific antibody, the molecular weight of the band was reduced by approximately 15 kDa. Pretreatment with calpeptin before stimulation with A23187 prevented these changes, preserving the approximately 125 kDa band observed in control or T + C-stimulated platelets.
Summary/Conclusions: We have demonstrated that two membrane proteins involved in transport of phospholipids between the inner and outer bilayer leaflets, APLT ATP8A1 and TMEM16F, are substrates of calpain. ATP8A1 is cleaved at the C-terminus; the inhibition of APLT activity that we have previously observed in PS-exposing A23187-stimulated platelets (Leung et al, JTH 2007;5:560) may be due, at least in part, to the cleavage of ATP8A1 that is associated with calpain activation. TMEM16F is cleaved at the N-terminus; whether this cleavage plays a role in the regulation of PS exposure on the surface of activated platelets remains to be determined.

Platelet Toll-like receptor 9 stimulation enhances ATP- and ADP-dependent platelet activation and aggregation

Delierneux C[1], Lecut C[1], Hego A[1], Evans RJ[2], Massion P[3], Gothot A[1], Bours V[1] and Oury C[1]
[1]University of Liège, GIGA-Research, Liège, Belgium; [2]University of Leicester, Leicester, UK; [3]University of Liège Hospital, Liège, Belgium

Background: Damage-associated molecular patterns (DAMPs), released upon cell necrosis, act as endogenous danger signals to exacerbate the inflammatory response. Among these DAMPs, ATP and ADP are key players in platelet activation and aggregation as well as in immune cell functions. High mobility group box-1 (HMGB1) is a central mediator of Toll-like receptor 9 (TLR9) activation in immune cells, and increased levels of this protein have been associated with inflammatory diseases, including sepsis. However, the role of TLR9 and HMGB1 in platelet function remains unclear.
Aims: Since platelet hyper-activation and microvessel thrombosis is a hallmark of severe sepsis, we wondered whether ATP/ADP and HMGB1 cooperate with TLR9 activation by bacterial DNA to promote platelet activation and aggregation.
Methods: We used oligonucleotides bearing unmethylated CpG motifs (CpG ODN), as TLR9 agonists, control non-CpG ODN, recombinant HMGB1, platelet aggregometry, thromboxane B_2 enzyme immunoassay, and flow cytometric analyses of platelet activation in healthy human and mouse PRP, washed platelet suspensions and in whole blood. Responses of platelets isolated from $P2X_1^{-/-}$ mice were also studied.
Results: We found that a 30 min-preincubation with CpG ODN causes irreversible $\alpha_{IIb}\beta_3$-dependent platelet aggregation in human and mouse PRP, and in washed mouse platelet suspensions. CpG ODN-induced platelet aggregation was completely inhibited by the ATP/ADP scavenger, apyrase and by $P2Y_{12}$ antagonism with cangrelor. In human hirudinized-PRP, inhibition of $P2X_1$ receptors for ATP with NF449 significantly reduced platelet aggregation. Accordingly, platelets from $P2X_1^{-/-}$ mice displayed impaired CpG ODN-induced aggregation. Platelet activation analyses revealed increased exposure of P-selectin and fibrinogen binding on platelet surface upon incubation with CpG ODN, which involved released ATP/ADP and thromboxane A_2 production. In washed human platelets, CpG ODN promoted granule secretion, thromboxane A_2 production and aggregation triggered by low concentrations of collagen. Interestingly, CpG ODN-induced platelet aggregation was potentiated by addition of recombinant HMGB1 in human PRP. Furthermore, both CpG ODN and HMGB1 significantly augmented the number of platelet-leukocyte aggregates in whole blood.
Conclusion: Thus, platelet TLR9 stimulation may contribute to sepsis-associated platelet hyperactivation and aggregation by enhancing the release reaction and thromboxane A_2 production.

Regulation of platelet function by diacylglycerol kinase

Konopatskaya O[1], Naseem K[1] and Poole AW[2]
[1]University of Hull, Hull; [2]Bristol Heart Institute, Bristol, UK

Background: Platelets play a key role in preventing blood loss through haemostasis, but the uncontrolled platelet activation at the site of atherosclerotic plaque rupture can lead to occlusive thrombi. One of the key events in platelet activation is transient increase in levels of cellular diacylglycerol (DAG) levels through hydrolysis of phosphoinositides by the enzyme phospholipase C. DAG is a critical second messenger and is best known as an allosteric activator of protein kinase C (PKC), a central signalling molecule in platelets. Diacylglycerol kinase (DGK) phosphorylates DAG to produce phosphatidic acid and therefore controls DAG signalling and through this, PKC activation.

Aim: To investigate the role of DGK in functional responses in platelets and on PKC activation.
Methods: Optical aggregometry and ELISA-based 5-HT release were used to assess agonist-stimulated responses of isolated human platelets. The levels of protein expression were analysed by Western blotting.
Results: Immunoblotting of platelet lysates for class II DGK isoforms demonstrated for the first time the expression of DGKδ in both human and murine platelets, which is consistent with platelet transcriptome data indicating DGKδ as a predominant DGK family isoform (1). Incubation of human platelets with class II DGK-specific inhibitor R59949 caused a concentration-dependent increase in collagen-related peptide (CRP) (1.25 μg/mL) and PAR1 (1 μM) receptor activating peptide (PAR4 AP)-stimulated aggregation. The increased aggregation was paralleled by a concomitant increase in dense granule secretion (measured by 5-HT release) from CRP and PAR1 treated platelets. The observed events were associated with a time-dependent augmentation in pleckstrin phosphorylation and PKC translocation to the plasma membrane. Moreover, immunoprecipitation identified DGKd association with all main platelet PKCs -PKCα, β, θ and δ, suggesting cross talk between DGK and PKC isoforms.
Conclusion: This investigation demonstrates that class II DGK enzymes, specifically DGKδ, contributes to the modulation of platelet activity potentially through the regulation of PKC isoforms.

PA 1.02-5
A role for histone deacetylases in the regulation of platelet function

Ali M, Jones CI, Gibbins JM and Fry M
Institute for Cardiovascular and Metabolic Research, Reading, UK

Background and Aims: Eighteen human histone deacetylase (HDAC) genes have been described which are divided into four classes. HDACs deacetylate acetyl-lysine residues in histone and non-histone proteins. It has recently be proposed that acetylation of non-histone proteins may modulate non-genomic processes including cell signalling. This led us to ask question: Are HDACs present in anucleate platelets, and if so do they modulate platelet function?
Methods: The presence of platelet HDACs was investigated by immunoblot analysis. Platelets were prepared from human citrated blood and aggregation, in response to collagen, collagen-related peptide (CRP), was measured by optical aggregometry in the presence of selective HDAC inhibitors. Dense granule secretion was measured by changes in the adenosine triphosphate (ATP) concentration using the luciferin/luciferase system kit. Flow cytometry was used to examine fibrinogen binding and P-Selectin exposure. Thrombus formation was studied *in vitro* also using whole citrated blood with 3,3-dihexyloxacarbocyanine iodide labeled cells. Blood was perfused through collagen-coated Vena8 Biochips at a shear rate of 20 dyn/cm^2, and stacks of Z-images were recorded. Analysis of the acetylated proteins in platelets and study of early GPVI signalling events was investigated by immunoblot analysis.
Results: Seven HDACs were identified in human platelets. Using an inhibitor for HDAC classes I, II and IV (SAHA), and a class III Sirtuin inhibitor (splitomicin), the potential involvement of HDACs in the regulation of platelet aggregation, dense and α-granule secretion were explored. Both inhibitors caused a reduction in collagen- and CRP-stimulated platelet aggregation, implicating HDACs in GPVI-stimulated signalling mechanisms. Splitomicin and SAHA were accompanied by inhibition of fibrinogen and P-Selectin. Accordingly, thrombus formation *in vitro* also inhibited.
Early GPVI signalling events were studied; neither inhibitor affected CRP-stimulated SYK, LAT, BTK and PLCγ2 phosphorylation. Tubulin can modulate cell motility and shape change, and is indeed important in the regulation of platelet activation. We found that a-tubulin is acetylated in unstimulated platelets, but is rapidly deacylated upon collagen, or CRP stimulation. Stimulation of platelets in the presence of SAHA or splitomicin blocked deacetylation of α-tubulin.
Conclusions: Our data provide evidence of possible roles for protein acetylation/deacetylation in the regulation of platelet signalling and function.

Regulation of platelet GPCR receptor function by NHERF1 in mouse platelets

Pope R, Nisar SP, Cunningham MR, Williams CM, Savage JS, Harper MT, Goggs R and Mundell SJ
University of Bristol, Bristol, UK

Background: Recent studies investigating P2Y receptor (P2YR) function in cell lines have revealed a key regulatory role for Na^+/H^+ Exchange Regulatory Factor (NHERF) proteins (Nisar et al., 2012). ADP signaling via $P2Y_1$ and $P2Y_{12}$ plays a key role in platelet activation and haemostasis. We sought to investigate P2YR function in NHERF1 (−/−) mouse platelets and investigate the consequences of any changes in P2Y receptor traffic on platelet function both in isolated platelet preparations and in thrombus formation assays.
Aims: To characterize platelet responsiveness and thrombus formation in NHERF1 (−/−) mouse platelets.
Methods: Mouse platelets were isolated and prepared in either Tyrode's buffer as 'washed platelets' or in plasma as platelet rich plasma (PRP). Ligand binding was employed to determine P2YR surface expression and traffic. Aggregation responses, Ca^{2+} signaling and GTPase activity were measured in response to a number of platelet agonists and concentrations. Thrombosis formation *in vitro* (flow of blood over a collagen-coated surface) and *in vivo* (FeCl3-injured carotid arteries) were also measured.
Results: Ligand binding studies revealed that NHERF1 (−/−) mouse platelets have an increase in surface P2YR levels, a marked reduction in ADP-dependent P2YR internalization and a virtual absence of P2YR recycling following ADP removal. However these changes in receptor expression and traffic did not significantly alter ADP induced aggregation or ADP induced Ca^{2+} signaling.
Interestingly NHERF1 (−/−) platelets displayed reduced aggregatory responses to agonists at the PAR4 receptor (thrombin and PAR4 peptide) and the TP thromboxane receptor (arachidonic acid and U46619). No significant differences were observed however in Ca^{2+} signaling or GTPase activity following PAR4 receptor activation. The reductions in aggregation responses following PAR4 or TP thromboxane receptor activation did not however translate into significant changes in thrombus formation either in flow models or in whole animal intravital microscopy studies.
Summary: This study supports our recent findings in cell lines which show that NHERF1 proteins regulate P2YR traffic. However, alterations in P2YR traffic do not translate into significant changes in ADP-dependent platelet aggregation/activity in NHERF1 (−/−) mice.
Unexpectedly, we observed a reduction in TP thromboxane and PAR4 receptor responsiveness although PAR4-dependent Ca^{2+} signaling and GTPase activity remained unaltered. These findings suggest novel interactions between NHERF1 and PAR3/4 and TP thromboxane receptors in murine platelets Further studies investigating the association of PAR4 receptors and NHERF1 and other NHERF isoforms are currently underway.

Podoplanin overexpressed rat C6 glioma cells enhances platelet aggregation and lymphatic metastasis

Chong KY, Lin PY, Lu PS, Tseng CP and Chong KY
Chang Gung University, Kwei-Shan, Taiwan

Background: Tumor metastasis was considered as the major causes of death for cancer patients. Cancer cells acquire the ability to penetrate the walls of lymphatic and/or blood vessels for escape from the primary site. Recent studies demonstrated that lymphatic metastatic routes were controlled by specific gene alternation of tumor cells. Furthermore, podoplanin (pdpn), a membrane protein in tumor cells, is an endogenous ligand for platelet activation receptor CLEC-2 and facilitates tumor metastasis by inducing platelet aggregation. Recent studies indicated pdpn was involved in cancer development, lymphatic metastasis and poor prognosis a wide variety of cancer types. Our previous study, genetically modified rat C6 glioma cells (C6-LG) that elicit high procoagulant activity and express luciferase/GFP reporter gene were used for xenograft injection into nude mice to establish a metastatic model. The cancer cells colonized at lung were isolated for establishing a C6 subline (C6-lung). When the C6-lung cells were inoculated into nude mice subcutaneously, we found that it's enhancing *in vivo* metastatic potential and activity. Interestingly, we also noticed that the pdpn mRNA and protein was up-regulation in metastatic C6-lung cells. Therefore, we hypothesize the C6 glioma cell which overexpressed pdpn has potential of lymphatic metastasis.
Aims: To investigate whether pdpn overexpressed C6 glioma cells enhances platelet aggregation and facilitates lymphatic metastasis.
Results: Our results shown that compared with parental cells, the C6-lung cells exhibited significant decreasing in cell motility and cell growth rate, but had a greater migratory capacity. Furthermore, C6-lung cells activated platelet and induced platelet aggregation that is closely associated with their *in vivo* metastatic ability. The C6-Lung cells provided a strong chemoattractant signal which together induced the directional migration of human lymphatic endothelial cells (HLEC) through the micropores compared to the parental C6 cells. Furthermore, the real-time RT-PCR and Western blot results shown that endogenous pdpn mRNA and protein expression was significantly inhibited from stably pdpn shRNA expressed C6-lung clones. We also found that the podoplanin knockdown C6-LG subline reduced HLEC cell migration, and reduced metastatic ability *in vivo*.
Conclusion: We demonstrated that pdpn overexpression in C6-lung cells was associated with tumour lymphatic metastasis.

Does loss of insulin signalling lead to a hyperactive platelet phenotype? Studies on Pf4-Cre insulin receptor knock out mice

Moore SF, Williams CM, Aitken EW and Hers I
University of Bristol, Bristol, UK

Platelets from patients with obesity and type 2 diabetes mellitus (T2DM) have a hyperactive phenotype, which may contribute to the increased risk of cardiovascular events observed in these patients. Circulating insulin levels in obesity and T2DM are often increased due to peripheral insulin resistance. Previous work by other groups suggested that insulin inhibits platelet function and that the loss of insulin responsiveness of megakaryocytes/platelets from patients with diabetes contributes to a platelet hyperactive phenotype. In contrast, our group found that insulin and insulin-like growth factor do not inhibit, but increase platelet function.

To determine the role of the insulin receptor, insulin receptor signalling and platelet insulin resistance in platelet function, we used the *Pf4-Cre* system to generate megakaryocytic lineage specific insulin receptor knock out mice (*Insr*−/−). Western blot analysis of platelet lysate confirmed that the insulin receptor was present in wild type platelets, but not in *Insr*−/− platelets, whereas IGF receptor expression levels were unchanged. Insulin stimulation resulted in phosphorylation of the insulin receptor and the PI3K substrate Akt in wild type, but not *Insr*−/− platelets, demonstrating that this receptor is essential for insulin signalling.
PAR-4-mediated integrin activation and α-granule secretion were unchanged in *Insr*−/− platelets, indicating that 'insulin resistance' of megakaryocytes/platelets alone does not increase platelet function. Furthermore, both ATP secretion and PAR-4-mediated aggregation were slightly reduced in *Insr*−/− platelets, suggesting that insulin receptor activation may contribute to platelet function. Consistent with this, insulin induced an enhancement of PAR-4 mediated integrin activation and platelet aggregation, which was absent in *Insr*−/− platelets.
Together, these results demonstrate that insulin resistance of platelets/megakaryocytes does not lead to a platelet hyperactive phenotype. Furthermore, insulin enhances platelet aggregation and integrin activation, with the effect lost when the insulin receptor is absent.

Hemostasis and thrombosis in JAK2V617F-KI mice

Lamrani L[1], Lacout C[2], Ollivier V[1], Ho Tin Noe B[1], Vainchenker W[2], Villeval JL[2] and Jandrot-Perrus M[1]
[1]Inserm U698, Paris Cedex; [2]Inserm 1009, Villejuif, France

Background: Hemostasis disorders represent a leading cause of mortality and morbidity in patients suffering from myeloproliferative neoplasms (MPN) with a high incidence of thrombosis and a lower incidence of hemorrhagic disorders.
The pathophysiology of these anomalies is not known but some risk factors have been identified including the V617F mutation of JAK2 found in 95% and 60% of PV and TE patients, respectively. The specific effect of $JAK2^{V617F}$ on hemostasis deregulation is difficult to characterize in patients because of their heterogeneity in $JAK2^{V617F}$ allele burden and prophylactic treatments. Recently, animal models of MPN were developed as $JAK2^{V617F}$ transgenic and knock-in mice.
Aims: Our objective was to determine, the effect of the $JAK2^{V617F}$ mutation on the *in vitro* and *in vivo* hemostatic responses using $JAK2^{V617F}$mice.
Methods: We used two KI models, the Vav-Cre and Scl-CreERt/$JAK2^{V617F}$ KI that constitutively and upon tamoxifen induction express the mutation in hematopoietic cells, respectively. Both models mimic a PV-like disease with its evolution into secondary myelofibrosis. The effect of the mutation on platelets was analyzed *in vitro* by flow cytometry, and by measuring adhesion and aggregation in flow conditions on collagen-coated area. Hemostatic responses were assessed *in vivo* by measuring the tail bleeding time and FeCl3-induced thrombosis on mesenteric vessels.
Results: Platelets from Vav-Cre/$JAK2^{V617F}$ mice did not exhibit elevated CD62P level and had normal surface expressions of the major glycoproteins to the exception of GPVI that was significantly decreased ($P < 0.01$). Platelets adhesion and aggregation, in arterial flow conditions (1200/s) on immobilized collagen was profoundly impaired with a platelet surface decreased by up to 80% ($P < 0.01$). *In vivo*, Vav-Cre/$JAK2^{V617F}$ mice exhibited an enlargement of mesenteric vessels and have a prolonged tail bleeding time ($P < 0.01$). After FeCl3-induced injury, platelet aggregates formed rapidly but were highly unstable.
Interestingly, using Scl-CreERt/$JAK2^{V617F}$ mice, platelet GPVI deficiency, morphological vessel abnormalities, the increased tail bleeding time, and the *in vivo* accelerated rate of thrombosis with low thrombus stability, only appeared 2 months after induction of the mutation by the tamoxifen suggesting no direct link with it.

Secondary polycythemia induced by EPO-treatment of WT mice occurred without hemostasis disturbance; Thrombocytemia induced by retroviral expression of TPO in WT mice reproduced the GPVI deficiency, the prolonged bleeding time and the absence of *in vivo* occluding thrombi.

Conclusions: Our results in $JAK2^{V617F}$ mice are consistent with the complex hemostasis disorders observed in MPN patients i.e. thrombosis, embolism and hemorrhages. They seemed not directly associated with the mutation but rather with the development of MPN. Further work is needed to evaluate the cause and consequence of the GPVI and collagen adhesion deficit.

PA 1.03-5

Platelet activation and function during dengue virus infection

De Mast Q[1], Michels M[1], Bachti A[2], Puspita M[2], Rudiman PIF[2], Roest M[3], Fijnheer R[3], De Groot PH[3] and Van Der Ven A[1]

[1]Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands; [2]Hasan Sadikin Hospital, Padjadjaran University, Bandung, Indonesia; [3]University Medical Center Utrecht, Utrecht, The Netherlands

Background: Dengue is the most prevalent mosquito-borne viral disease and is characterized by thrombocytopenia. Bleeding and plasma leakage the most frequent complications and they typically occur around the time of defervescence which corresponds with platelet nadir. Platelets are important for preserving vascular integrity. Not only thrombocytopenia but also thrombocytopathy may contribute to plasma leakage. Because complications are often observed with platelet numbers above the level for spontaneous bleeding, we hypothesized that platelet hypo-responsiveness and storage pool disease may occur as consequence of prolonged platelet activation and/or megakaryocyte infection.

Aims: To investigate the prevalence of platelet activation, secondary platelet hypo-responsiveness and storage pool disease in Indonesian patients with dengue.

Methods: We performed a prospective cohort study on 75 adult dengue patients admitted to a referral hospital in Bandung, Indonesia and 30 healthy local controls. Whole-blood flow cytometry was performed in the four phases of dengue: febrile (n = 11, early stage of illness), critical (n = 63, time at which most complications occur), early recovery (n = 61, time at which platelet number starts to recover) and convalescence phase (n = 43, 2 weeks after hospital discharge). The expression of CD62P (alpha granule marker), CD63 (lysosomal marker) and changes in $\alpha_{II}\beta_3$ activation were measured without stimulation and following maximal platelet activation with the PAR-1 agonist TRAP. Furthermore, CD62P expression to increasing concentrations of TRAP was evaluated. Finally, intra-platelet and plasma concentrations of serotonin were measured to determine storage pool disease of dense bodies.

Results: The platelet count in the febrile and critical phase was 69 and 40 $\times$ 10^9/L, respectively. Increased CD62P, CD63 expression and $\alpha_{II}\beta_3$ activation was only found in a minority of dengue patients. There was no difference in marker expression between patients with severe (n = 11) and non-severe dengue (n = 64) or between patients with and without bleeding or plasma leakage. Expression of CD63 and $\alpha_{II}\beta_3$ activation after maximal platelet stimulation was, however, reduced in the critical phase. There was also a trend for reduced CD62P expression in response to increasing TRAP concentrations in the febrile and critical phase. While median serotonin plasma concentrations were below the detection limit of 0.3 ng/mL during dengue, intra-platelet serotonin concentrations (median, interquartile range) were significantly increased in the febrile (4.9; 4.2–7.7 μg/mL) and critical phase (5.0; 4.1–6.9 μg/mL) vs. convalescence (2.5; 2.3–2.7 μg/mL), all $P < 0.001$) and correlated inversely with platelet counts ($R_s = -0.65$, $P < 0.001$) in early dengue.

Summary/Conclusion: Increased expression of activation markers of unstimulated platelets was only found in a subset of dengue patients. However, maximally stimulated platelets show a reduced expression of CD63 and $\alpha_{II}\beta_3$ activation, while there was a trend for lower CD62P expression in response to increasing TRAP concentrations in the febrile and critical phase. These findings indicate that platelet activation with secondary hypo-responsiveness occurs in dengue. There was no secondary storage pool disease as platelet serotonin concentrations were higher during dengue. Increased uptake of serotonin per platelet in dengue is required to prevent serotonin-induced plasma leakage. Although significant changes in circulating platelets were noticed during dengue infection, no relation with severity of disease was observed.

PA 1.03-6

Platelet-mediated angiogenesis is independent of VEGF and fully inhibited by aspirin

Etulain J[1], Fondevila C[2], Negrotto S[1] and Schattner M[1]

[1]Institute of Experimental Medicine, CONICET-National Academy of Medicine; [2]Bazterrrica Clinic, Buenos Aires, Argentina

Background: Platelets are major players in every step of vessel development through the local delivery of angiogenesis-modulating factors. Among these factors, the proangiogenic vascular endothelial growth factor (VEGF) and the antiangiogenic endostatin have been the most studied and can be differentially released from alpha-granules upon platelet activation by different stimuli. Although thrombin is the most potent agonist and is highly elevated in angiogenesis-related diseases, studies regarding its action on the release of platelet angiogenic factors are scarce and controversial.

Aim: To investigate the role of thrombin not only in VEGF and endostatin release but also in the net platelet angiogenic activity.

Methods: Washed human platelets were stimulated with thrombin (5 min) in the presence of inhibitors of the main signaling pathways involved in platelet activation and supernatants/releasates were used to determine the levels of angiogenic molecules and to induce angiogenic responses (ANOVA. n = 4–5, $^*P < 0.05$).

Results: We found that thrombin (EC_{50}, 0.051 ± 0.005 U/mL) induced the secretion of both VEGF and endostatin (7.9 ± 0.5 and 2.5 ± 0.3 ng/mL, respectively) (ELISA); however, the overall effect of the releasates was proangiogenic as they promoted the formation of tubule-like structures (matrigel) and increased endothelial proliferation (2.3 ± 0.3* fold) (MTT). Both processes were independent of VEGF as they were only slightly suppressed by a VEGF receptor-neutralizing antibody (15 ± 2*% of inhibition). Pharmacological studies revealed that the formation of tubule-like structures and endothelial cell growth were partially inhibited by pretreatment of platelets with inhibitors of PKC (Gö6983, 1 μM), p38 (SB203580, 25 μM), ERK1/2 (U0126, 10 μM), Src kinases (PP1, 5 μM), or PI3K/Akt (Ly-294002, 10 μM) (60 ± 6*, 63 ± 4*, 60 ± 5*, 33 ± 7*, and 15 ± 9*% of inhibition, respectively) but fully suppressed by the blockade of the cyclooxygenase pathway with aspirin (96 ± 4*% of inhibition) (500 μM). Protein array analysis revealed that the pretreatment of platelets with the different drugs inhibited the release of IL-1-beta, IL-2, Angiopoietin-1, Angiopoietin-2, G-CSF, GM-CSF and TNF-alpha release, but not VEGF, with a similar inhibition pattern observed in the angiogenic functional responses.

Conclusions: Our data indicate that the proangiogenic activity of platelets is independent of VEGF and appears to be the result of the combined action of several molecules. Aspirin could be a promising therapeutic agent to treat angiogenesis-related diseases.

PA1.04 – Circulating Microparticles

PA 1.04-1

Increased levels of P-selectin glycoprotein ligand-1 positive microparticles in patients with unprovoked venous thromboembolism

Jamaly S, Starikova I, Sovershaev M and Hansen JB

Hematological Research Group, University of Tromsø, Tromsø, Norway

Background: Microparticles (MPs) are small circulating membrane vesicles, less that 1 μm in diameter, released from activated or apoptotic cells, and reported to play an important role in pathogenesis of thrombotic diseases. MPs are known to express the P-Selectin Glycoprotein Ligand 1 (PSGL-1) receptor. Experimental studies have shown that accumulation of active tissue factor (TF) in the developing thrombi *in vivo* is dependent upon interactions between PSGL-1 and P-selectin (P-sel). P-sel inhibitors have also been shown to be equally efficient as low molecular weight heparins to reopen venous occlusions in animal models.

Aims: The present study was undertaken to investigate whether patients with unprovoked venous thromboembolism (VTE) had higher circulating levels of MPs baring PSGL-1, and to explore the role of PSGL-1/P-sel interaction in thrombogenicity of these MPs.

Methods: A case-control study was performed in 20 patients with a history of incident unprovoked VTE 1–5 years prior of the study, and 20 age- and sex-matched healthy controls recruited from the general population. Plasma levels of PSGL-1-positive MPs were measured in total MPs preparations by immunostaining with phycoerythrine (PE)-conjugated monoclonal antibody (clone KLP-1, Santa Cruz Biotechnology) using a FACS Aria instrument (BD Biosciences). Cellular origins of PSGL-1-positive MPs were determined by immunostaining of total MP fraction with cyanine (PerCP-CY5.5)- conjugated anti-PSGL-1 antibody, coupled with immunostaining using PE-conjugated monoclonal antibodies specific to parental cell, namely CD14 for monocytes, CD41 for platelets and CD62E for endothelial cells (all from BD Biosciences). The presence and expression levels of PSGL-1 on circulating MPs were confirmed by confocal microscopy and western blotting. The impact of interaction between P-sel and PSGL-1-positive MPs on thrombogenicity of MPs was assessed by levels of TF protein expression and functional activity on the surface of MPs, along with the assessment of presentation of negatively charged phospholipids. Differences between groups were tested by a nonparametric test for paired samples (Wilcoxon). Values are medians with 25% and 75% percentiles in brackets. The study was approved by the regional committee for research ethics, and all participants gave their informed written consent to participate.

Results: VTE patients had significantly higher body mass index (BMI) (28.2 kg/m^2 (24.1, 31.6 kg/m^2) vs. 26.1 kg/m^2 (22.6, 30.3 kg/m^2), $P = 0.045$) and circulating levels of PSGL-1-positive MPs (94×10^3/mL (72, 137×10^3/mL) vs. 66×10^3/mL (55, 78×10^3/mL), $P = 0.002$) compared to healthy controls. PSGL-1-positive MPs were found positive for CD14 and CD62E, but not for CD41. The data from confocal microscopy and western blotting confirmed expression of PSGL-1 at the surface and lysates of isolated MPs. Interaction between PSGL-1-positive MPs and P-sel boosted TF functional procoagulant activity, as well as higher surface presentation of negatively charged phospholipids on MPs and several cell types.

Conclusions: We found elevated levels of PSGL-1 positive circulating MPs in patients with unprovoked VTE originating from monocytes and endothelial cells. Our findings indicate that the interaction between PSGL-1-positive MPs and P-sel augmented the thrombogenicity of MPs, suggesting that this receptor-ligand interaction is important for the role of MPs in the pathogenesis of VTE.

Microparticles from monocytes and CFTR?F508 mutated exocrine cells are deleterious for insulin secreting cells

Constantinescu AA[1], Gleizes C[1], Leclercq A[2], Zobairi F[1], Mitrea IL[3], Stoian G[4], Prevost G[5], Toti F[6] and Kessler LP[1]

[1]UR 7293, Stress Vaculaire et Tissulaire en Transplantation; [2]Hopitaux Universitaire de Strasbourg, UR 7293, Strasbourg, France; [3]University of Agricultural Sciences and Veterinary Medicine; [4]Univesity of Bucharest, Bucharest, Romania; [5]EA 7290 Virulence Bacterienne Precoce; [6]CNRS UMR 7213, Strasbourg, France

Background: Cystic fibrosis (CF) is a genetic disorder targeting CFTR channel, the most frequent mutation being CFTRΔF508. Cystic fibrosis-related diabetes is a particular form of diabetes detected in 50% of patients in the adult age. It is characterized by an early exocrine pancreas alteration followed by endocrine dysfunction. Chronic infections leading to major cytokine generation contribute to endocrine dysfunction by promoting insulin resistance. Microparticles (MPs) are plasma membrane fragments that are reliable markers of cell stress and act as cellular effectors.

Aims: Our aim was to study the role of MPs as effectors of cellular cross-talk between monocytes or exocrine cells and endocrine insulin secreting β-cells, in the context of CF and LPS infection.

Methods: Normal exocrine pancreatic cells (PANC-1) or with CFTRΔF508 mutation (CFPAC-1) and human monocytes (THP-1) submitted to CFTR inhibitor (CFTR(Inh)-172), were stimulated by LPS from *P. aeruginosa* to produce MPs. RIN-m5F rat ß-cells were targeted by 10 nM exocrine or monocyte MPs (18 h) or submitted to 25 μM CFTR(Inh)-172 thereby limiting expression of active CFTR at cell surface. PANC-1 and CFPAC-1 were targeted by monocyte MPs. NFkB activation induced by MPs was detected in HEK-Blue [TRADEMARK] reporter cells. Immunological labeling and Tenase activity probed the presence of Tissue Factor (TF) on MPs and cells. Cell apoptosis was quantified by cytometry and lysosomal activity by Neutral Red; MPs integration into target cell membrane was assessed by lipid PKH26 probe.

Results: LPS was increased apoptosis in the CFTR-inhibited RIN-m5F. LPS challenge in CFPAC-1 resulted in exaggerated apoptosis and enhanced release of TF-bearing MPs (13-fold increase compared to normal exocrine cells). After 18 h incubation, 98% of normal RIN-m5F target cells had captured PKH26-probed MPs. By restoring the decreased lysosomal activity caused by LPS ($n = 5$; $P < 0.01$), monocyte MPs exerted a cytoprotective effect on exocrine cells but were deleterious to endocrine cells by increasing apoptosis (12.5% vs. 3.8%; $n = 6$; $P < 0.0001$) and lowering lysosomal activity (−13%; $n = 5$; $P < 0.01$). MPs from THP-1 and CFPAC-1 delivered proinflammatory signal as demonstrated by NFkB activation in HEK reporter-cells, while MPs from PANC-1 did not. Addition of MPs from THP-1 and CFPAC-1 respectively generated a 33% and 40% decrease in insulin secretion ($n = 6$; $P < 0.0001$). Conversely, MPs from PANC-1 cells did not alter insulin secretion or lysosomal activity of RIN-m5F.

Conclusions: The exaggerated LPS susceptibility of CFTRΔF508 exocrine cells favors the shedding of MPs with high TF content, that are deleterious to normal endocrine cells. Similarly, MPs from monocyte and exocrine cells with defective membrane CFTR activity both deliver a proinflammatory and proapoptotic signal. In CF, TF-bearing MPs of exocrine and monocyte origin may contribute to early exocrine and endocrine pancreas dysfunction by reducing insulin secretion and ß cell survival.

PA 1.04-3

Circulating MPs show a prothrombotic phenotype in patients with long-life exposure to high LDL levels and directly associate with lipid-rich atherosclerotic plaque burden

Suades R[1], Padro T[1], Alonso R[2], Mata P[2] and Badimon L[1]

[1]Cardiovascular Research Center (CSIC-ICCC), IIBSantPau, Barcelona; [2]Jimenez Diaz Foundation, Madrid, Spain

High plasma cholesterol levels are a risk factor for atherothrombosis and cardiovascular disease. Familial hypercholesterolemia (FH) is a monogenic disorder characterized by a reduced expression of the LDL receptor that leads to life-time exposure to high levels of LDL and the development of premature coronary artery disease. Circulating microparticles (cMPs), released from various cell types of the vascular compartment, may play important roles in vascular function. High levels of cMPs have been associated with a variety of pathological conditions, including thrombosis, inflammation, and metabolic disorders. We hypothesize that cMPs could contribute to the increased atherothrombotic risk in heterozygous FH patients.

The present study aimed to investigate cell-associated thrombogenic markers in cMPs of patients with genetic diagnosis of FH and subclinical atherosclerosis detected by aortic magnetic resonance imaging (MRI) under lipid-lowering therapy (LLT). The control was an age/gender/treatment-matched group of non-FH patients treated with LLT for secondary hypercholesterolemia.

Clinically and genetically characterized FH patients and control subjects (n = 37/group) were from the SpAnish Familial hypErcHolEsterolaemiA cohoRT (SAFEHEART). Patients were treated as per guideline indication. This study was approved by the local ethics committee, was conducted according to the Declaration of Helsinki and a written informed consent was obtained from all participants prior to the study. cMPs were obtained by high speed centrifugation from citrated platelet-free plasma (PFP) and quantitatively analyzed by flow cytometry for a) annexin V (AV) binding; b) specific blood cell activation surface markers; and c) tissue factor. cMP-associated TF activity was measured by a functional assay determining the FVII-dependent FXa generation.

At the moment of blood collection LDL cholesterol levels were 145 and 134 mg/dL in FH and control patients, respectively. The total number of cMPs was significantly increased in FH patients compared with controls (2390 [1890–3416] vs. 1872 [1418–2274] cMPs/μL PFP, $P < 0.005$). cMPs positive for platelet activation markers ($PAC1^+$ and $PAC1^+/CD62P^+$) increased 2- and 4-fold, respectively in FH patients ($P < 0.0001$ for both markers). FH patients had significantly higher overall numbers of tissue factor-rich ($CD142^+$) cMPs than controls ($P < 0.0001$). TF-exposing cMPs exerted procoagulant activity showing that cMPs carry functional active TF. Furthermore, the presence of lipid-rich atherosclerotic plaques in the FH patients was significantly associated with total AV^+-cMP levels, activated AV^+-pMPs ($TSP1^+$) and TF-bearing AV^+-pMPs ($CD142^+/TSP1^+$) ($P < 0.05$ in all cases). Taking one time-point LDL level as co-variate gave similar results, indicating that long-term exposure to high LDL in FH increases activation of the cells of the vascular compartment. Levels of AV^+-cMPs, activated AV^+-pMPs ($TSP1^+$) and TF-bearing AV^+-cMPs ($CD142^+$) were significantly lower in FH patients with calcified plaques.

Circulating MPs showed a prothrombotic phenotype in patients with FH and directly associated with lipid-rich atherosclerotic plaque burden. Thus, the specific increase in $\alpha_{IIb}\beta_3$-integrin$^+$ and TF^+ microparticles indicate that cMPs are active contributors in the on-going atherothrombotic process in FH patients and highlights the potential of TF-rich cMPs as a biomarker of thrombotic risk and as attractive therapeutic target in FH patients.

PA 1.04-4

Plasmatic levels of leukocyte-derived microparticles predict unstable plaque in asymptomatic patients with high-grade carotid stenosis

Sabatier F[1], Sarlon-Bartoli G[2], Bennis Y[1], Lacroix R[1], Piercecchi-Marti M-D[2], Bartoli M[2], Leroyer A[1], Mancini J[2], Magnan PE[2] and Dignat-George F[1]

[1]Inserm UMR 1076, Aix Marseille University; [2]Assistance Publique Hopitaux de Marseille, Aix Marseille University, Marseille, France

Background: Preventive carotid surgery in asymptomatic patients is currently debated given the improvement of medical therapy. Therefore, non-invasive biomarkers that can predict plaque instability are needed. LMPs, originating from activated or apoptotic leukocytes, are the major microparticle subset in human carotid plaque extracts.

Aim: To analyze whether plasmatic levels of leukocyte-derived microparticles (LMPs) associate with unstable plaques in patients with high-grade carotid stenosis.

Methods: Forty-two patients with greater than 70% carotid stenosis were enrolled. Using a new standardized high-sensitivity flow cytometry assay allowing to measure low size microparticles, LMPs were measured before thromboendarterectomy. The removed plaques were characterized as stable or unstable using histological analysis according to the AHA criteria. LMP levels were analyzed according to the plaque morphology.

Results: The median LMP levels were significantly higher in patients with unstable plaque (n = 28, CD11bCD66b+MP/μl: 240 [147–394], and CD15+ MP/μl: 147 [60–335]) compared to those with stable plaque (16 [0–234] and 55 [36–157], $P < 0.001$ and $P < 0.01$, respectively). The increase in LMP levels was also significant when considering only the group of asymptomatic patients with unstable plaque (n = 10; CD11bCD66b+ MP/μl: 199 [153–410] and CD15+ MP/μl: 78 [56–258] compared to those with stable plaque (n = 14, 20 [0–251] and 55 [34–102], $P < 0.05$ and $P < 0.05$, respectively). After logistic regression, the neurologic symptoms (OR 48.7, 95% CI 3.0–788, $P < 0.01$) and the level of CD11bCD66b+ MPs (OR 24.4, 95% CI 2.4–245, $P < 0.01$) independently predicted plaque instability.

Conclusions: LMPs constitute a promising biomarker predicting plaque vulnerability in patients with high-grade carotid stenosis. These data provide clues for identifying asymptomatic subjects who may benefit the most from carotid surgery.

PA 1.04-5

Circulating microparticle plasma levels in obese patients

Campello E[1], Eva Z[2], Claudia M R[1], Luca S[1], Sabrina G[1], Barry W[3], Paolo P[1], Roberto V[2] and Paolo S[1]

[1]Department of Cardiologic, Throcacic and Vascular Science, University of Padua; [2]Department of Medical and Surgical Sciences, University of Padua, Padova, Italy; [3]HaemaCon Ltd, Bromley, UK

Background: Arterial and venous thromboembolic risks have been shown to increase in obese subjects. Obesity is associated with a hypercoagulable state with either increased levels of clotting factors or inhibition of the fibrinolytic pathways. The procoagulant state involves several plasma proteins such as tissue factor (TF), fibrinogen, FVII, FVIII and PAI. Obesity is further characterized by enhanced platelet response predisposing to thrombi formation. Adipose tissue may play a significant role in stimulating the up-regulation of TF production and platelet function by the production of proinflammatory cytokines (TNF-α) and adipokines (eg leptin and adiponectin).

Aim: To elucidate the hypercoagulable state that characterizes obesity, we evaluated procoagulant microparticles (MP), both type and activity, in patients with different degree of obesity.

Methods: We measured the plasma levels of annexin V-microparticles (AMP), platelet-MP (PMP), P-Selectin-bearing MP (P-Selectin+), endothelial activated MP (E-Selectin+), leukocyte-MP (LMP) and tissue factor-bearing MP (TF+), and the MP procoagulant activity (PPL) in 80 patients (of whom 20 were overweight [BMI = 25–29.9 kg/m^2], 20 with 1st degree obesity [BMI = 30–34.9 kg/m^2], 20 with 2nd degree obesity [BMI = 35–39.9 kg/m^2] and 20 with 3rd degree [BMI > 40 kg/m^2]), and in 80 age and gender-matched normal weight healthy individuals. MPs levels were assessed by flow-cytometry (Beckman Coulter, USA) and MPs procoagulant activity was measured using a FXa based clotting assay (Diagnostica Stago, France). The study was approved by the Ethical Committee of the University Hospital of Padua.
Results: A significant increase of MP levels (mean ± SD) was found in obese patients, with a gradual rise according to the degree of obesity. In particular, AMP and PMP levels (MPs/μL) were higher in patients with 2nd obesity degree (4029 ± 2465 and 2881 ± 926, respectively) and 3rd obesity degree (4948 ± 2254 and 3098 ± 1426, respectively) than in controls (AMP 1635 ± 897, $P < 0.01$ for both comparisons; PMP 402 ± 225, $P < 0.0001$ for both comparisons). P-Selectin+ and E-Selectin+ MP showed the same pattern. LMP and TF+ were higher in overweight patients (273 ± 83, P vs. controls < 0.01 and 162 ± 36, P vs. controls < 0.0001, respectively), 1st degree obesity (238 ± 98, P vs. controls < 0.01 and 163 ± 57, $P < 0.0001$, respectively), 2nd degree obesity (305 ± 63 and 127 ± 27, $P < 0.0001$ for both comparisons, respectively) and 3rd degree obesity (393 ± 183 and 182 ± 66, $P < 0.0001$ for both comparisons, respectively) than in controls (LMP 106 ± 54; TF+ 50 ± 35). The phospholipids clotting time was significantly shorter in 2nd obesity degree (51 ± 16 s) and in 3rd obesity degree (56 ± 13 s) than in controls (68 ± 9 s, $P < 0.05$ for both comparisons).
MP levels are found to correlate to BMI (r 0.41, $P < 0.001$), waist circumference (0.43, $P < 0.001$), HDL (r −0.27, P 0.004), TNFa (r 0.37, P 0.02), leptin (r 0.34, P 0.04). Diabetes and thyroid diseases were associated with increased MP levels.
Conclusions: Our study indicates that excessive adipose tissue may induce overproduction of different types of MP. These MP levels significantly correlated with degree of obesity and with proinflammatory cytokines. Further studies are needed to clarify the role of increased MP levels, if any, in thrombosis risk in obese patients.

PA 1.04-6
Variations of procoagulant microparticles during disseminated intravascular coagulopathy and septic shock: a prospective multicentre study

Delabranche X[1], Boisrame-Helms J[1], Berger A[1], Desprez D[1], Lanza F[2], Lavigne T[1], Asfar P[3], Toti F[4] and Meziani F[1]
[1]Les Hôpitaux Universitaires de Strasbourg; [2]UMR_S949 INSERM, Université de Strasbourg, EFS-Alsac, Strasbourg Cedex; [3]CHU d'Angers, Angers; [4]Université de Strasbourg, Strasbourg Cedex, France

Background: Septic shock remains a leading cause of death in intensive care units (ICU) despite care improvement during the past 20 years. Alteration in haemostatic balance and disseminated intravascular coagulopathy (DIC) contribute to multiple organ failure. Microparticles (MPs) are sub-micronic plasma membrane fragments released from stressed cells that expose procoagulant phospholipids (almost phosphatidylserine – PhtdSer).
Aims: Study of circulating MP variations as biomarkers of vascular competence and dysfuntion during septic shock.
Methods: One hundred patients with septic shock were enrolled and their haemostatic status evaluated at admission (D1), and at D2, D3 and D7. Routine and specific haemostasis parameters were measured. DIC was diagnosed according to JAAM 2006 criteria. To assess cellular injuries, total microparticles (PhtdSer-MPs), GPIb-MPs (platelets), CD11a-MPs (leucocytes), CD31− MPs (endothelial cells) were quantified by prothrombinase assay. Soluble (s)E-selectin, sP-selectin, t-PA, PAI-1, platelet glycoprotein V (sGPV) and prothrombin fragments 1 + 2 (F1 + 2) were quantified by ELISA. Repeated measures were analysed with ANOVA, linear mixed model and two-way ANOVA with post hoc analysis when recommended.
Results: Ninety-two patients were investigated. Early DIC (first 24 h after ICU admission) was diagnosed in 40 (43.5%) patients, 30 were diagnosed at D1, and 10 at D2. Early DIC was characterised by higher SAPS2 and SOFA scores (65 ± 20 vs. 52 ± 14 and 11.8 ± 3.0 vs. 8.5 ± 2.1 respectively, $P < 0.05$). Acute renal failure (82.5% vs. 36.5%) and renal replacement therapy (55.0% vs. 25.0%) were significantly more frequent. Bacteraemia was associated with a greater DIC occurrence (20.0% vs. 1.9%, $P = 0.01$) whereas pneumonia seemed to be protective (40.0% vs. 63.5%, $P = 0.03$).
PhtdSer-MPs were in the same range (15 nM eq. PhtdSer) in all patients and remained at high level on D7. GPIb-MPs were strongly correlated to platelet count ($r^2 = 0.24$, $P < 0.001$). Leucocyte count remained unchanged but leucocyte CD11a-MPs were increased in DIC, a higher MPs/leucocyte ratio suggesting leucocyte activation. In DIC CD11a-MPs/leucocytes returned to baseline overtime, with concomitant secondary hyperleucocytosis contributing to still important CD11a-MPs at D7 compared to patients without DIC. At D1, endothelial cell activation was evidenced in all patients with elevated CD31-MP that were at higher level in patients with no DIC. Antithrombin, protein C, F1 + 2, fibrin monomers, sE-selectin, sP-selectin, sGPV, t-PA and PAI-1 were not associated with DIC diagnosis in our study.
Summary/Conclusion: During septic shock, haemostasis is greatly activated and procoagulant MPs are thrice as high as in control. If MPs originates from platelets and endothelial cells in no DIC patients, DIC is associated with a phenotypic change where MPs originate from leucocytes and endothelial cells.

PA1.05 – Immune Thrombocytopenia Purpura – I

PA 1.05-1
CD8+ regulatory/suppressor T cells in primary immune thrombocytopenia

Li H, Zhang D and Yang R
Institution of hematology, Tianjin, China

Background: Primary immune thrombocytopenia (ITP) is an acquired disorder characterized by autoantibody-mediated platelet destruction and insufficient platelet production. Multiple factors have been implicated in ITP pathogenesis, including breakdown of immune tolerance. Regulatory/suppressor T cells, which have inhibitory functions on inflammation, play important roles in maintenance of peripheral immune tolerance. They include $CD4^+$ regulatory T cells, CD8+ regulatory T cells, $CD8^+$ suppressor cells, natural killer T cells and so on. It is reported that $CD4^+CD25^+$ regulatory T cells were reduced in active ITP patients with poor functions, but whether $CD8^+$ regulatory/suppressor T cells were involved in ITP is still unknown.
Aim: To elucidate the role of $CD8^+CD25^+CD127^-$ regulatory and $CD8^+CD28^-CD127^{low}$ suppressor T cells in pathogenesis of ITP.
Method: A total of 27 untreated active ITP patients, 23 ITP patients in remission and 34 age- and sex-matched healthy donors were enrolled in this study. The mRNA expression of transforming growth factor-β1 (TGF-β1), membrane cytotoxic T lymphocyte-associated antigen-4 (mCTLA-4), indoleamine-2,3-dioxygenase (IDO) and forkhead box protein 3 (FoxP3) in peripheral blood mononuclear cells (PBMCs) were detected by real-time PCR. The serum concentration of TGF-β1 and soluble CTLA-4 were measured by ELISA. In addition, flow cytometric analysis was carried out to detect the percent of $CD8^+CD25^+CD127^-$ regulatory and $CD8^+CD28^-CD127^{low}$ suppressor T cells in peripheral blood from ITP patients and healthy controls. This study was approved

by the hospital-based ethics committee and informed consents were obtained from the patients or their parents as appreciate.
Results: (i) The mRNA expressions of mCTLA-4 and TGF-β1 were significantly decreased in PBMCs from ITP patients compared with those of normal controls ($P < 0.05$). In addition, although the mRNA expressions of IDO and FoxP3 were decreased in PBMCs from ITP patients, it did not reach the statistic difference ($P = 0.126$, $P = 0.175$ respectively). (ii) The serum concentration of TGF-β1 was down-regulated but sCTLA-4 was up-regulated in ITP patients than those of healthy controls ($P < 0.01$). We speculated that these increased sCTLA-4 can act as a competitor of mCTLA4 to bind CD80 or CD86, thereby interfering the inhibitory function of regulatory T cells. In addition, the down-expression of multiple inhibitory molecules indicated that the dysfunctions of immune negative regulations played an important role in ITP etiology. (iii) The percent of $CD8^+CD25^+CD127^-$ regulatory and $CD8^+CD28^-CD127^{low}$ suppressor T cells in peripheral blood from active ITP patients were lower than those of ITP patients in remission and healthy controls, but there was no difference between ITP patients in remission and healthy controls.
Conclusion: The down-regulation of $CD8^+CD25^+CD127^-$ regulatory cells, $CD8^+CD28^-CD127^{low}$ suppressor T cells and multiple inhibitory molecules indicated that breakdown of immune tolerance is a key defect in ITP patients. In addition, considering the association between the number of $CD8^+$ regulatory/suppressor T cells and disease progression, the treatment targeted to $CD8^+$ regulatory/suppressor T cells will be a candidate strategy for ITP therapy.

PA 1.05-2
Defective proliferation and the immunosuppressive function of bone marrow-derived mesenchymal stem cells in patients with primary immune thrombocytopenia

Zhang D, Li H, Ma L, Zhang X, Zhou Z, Yang S and Yang R
Institute of Hematology & Blood Diseases Hospital, Tianjin, China

Background: Primary immune thrombocytopenia (ITP) is an acquired autoimmune disease characterized by decreased platelet count resulting from increased platelet destruction and insufficient platelet production. Both the development of autoantibodies against platelet glycoproteins and the cellular mechanisms of immune modulation are involved in the pathogenesis of ITP. Bone marrow-derived mesenchymal stem cells (BM-MSCs) are key components of the hematopoietic microenvironment and provide support to hematopoiesis. At the same time, BM-MSCs are also being considered as potential therapeutic agents in various inflammatory autoimmune diseases for their tissue-repair and anti-inflammatory properties.
Aims: The qualitative properties and immune modulation capacity of MSCs derived from ITP patients in Chinese population is unclear. The aim of this study is to further characterize phenotypically and functionally BM-MSCs from ITP patients in Chinese population.
Methods: *In vitro* cultures of BM-MSCs from patients with ITP ($n = 12$) and age-and sex-matched healthy individuals ($n = 9$) were established and characterized by their differentiation potential into adipocytes and osteoblasts, and phenotype by flow cytometry. BM-MSCs (irradiated) from healthy and ITP patients were tested for their ability to suppress the *in vitro* proliferation of allogeneic peripheral blood mononuclear cells (PBMC) (from healthy donors) stimulated with PHA.
Results: Our results showed that BM-MSCs from ITP patients and normal controls can be successfully culture-expanded, but the BM-MSCs from ITP grew more slowly than those of normal controls ($P < 0.05$). Cells from both groups were positive for CD73, CD90 and CD105, and negative for CD11b, CD19, CD14, CD34, CD45 and HLA-DR. ITP BM-MSCs were shown to have a similar capacities to differentiate along adipogenic and osteogenic lineages as those of healthy donor BM-MSCs. Both the BM-MSCs from healthy donors and ITP patients could reduce the proliferation of allogeneic PBMCs, inhibit the secretion of IFN-γ and TNF-α, and promote the secretion of IL-10 in a cell dose-dependent fashion. MSC-mediated suppression of PHA-induced PBMCs proliferation was significantly lower in the ITP group than the healthy cohort, when the ratio of PBMC/MSC was 10:1 ($P = 0.003$).
Summary/Conclusions: These results showed that BM-MSCs from patients with ITP under the described culture conditions exhibited the same phenotype and differentiation potential as healthy counterparts. The proliferation of MSC and the ability to downregulate PHA-induced PBMC priming is deficient in patients with ITP. BM-MSCs may play an important role in the ITP pathogenesis.

PA 1.05-3
Detection of circulating B cells producing anti-GPIb autoantibodies in patients with immune thrombocytopenia

Kuwana M[1], Okazaki Y[1] and Ikeda Y[2]
[1]Keio University; [2]Waseda University, Tokyo, Japan

Background: Immune thrombocytopenia (ITP) is an autoimmune disease caused by IgG anti-platelet autoantibodies. This condition is seen in patients with various diseases, such as systemic lupus erythematosus (SLE), and can also occur without an underlying disease. Production of IgG autoantibodies to platelet surface glycoproteins, such as GPIIb/IIIa and GPIb, is the hallmark of the disease. We previously reported that an enzyme-linked immunospot (ELISPOT) assay for detection of B cells secreting anti-GPIIb/IIIa antibodies was a sensitive method for identifying ITP patients.
Aims: To assess potential usefulness of measuring circulating anti-GPIb antibody-producing B cells for diagnosis of ITP and evaluation of anti-platelet autoantibody profiles.
Methods: We examined 114 patients with primary ITP, 94 with various conditions potentially causing secondary ITP, including 25 with SLE, 30 with liver cirrhosis (LC), and 39 with post-hematopoietic stem cell transplantation (post-HSCT), and 18 with aplastic anemia or myelodysplastic syndrome (AA/MDS). All patients had a platelet count $< 50 \times 10^9$/L at blood collection. Thirty-two healthy individuals without thrombocytopenia were used as a control. All samples were obtained after the subjects gave their written informed consent as approved by the Institutional Review Board. B cells producing IgG anti-GPIIb/IIIa and anti-GPIb antibodies were simultaneously measured using ELISPOT assay. The antigens used included GPIIb/IIIa affinity-purified from human platelets and a recombinant protein encoding an extracellular domain of GPIb. Results represented the mean of 10 values and were expressed as the number per 10^5 peripheral blood mononuclear cells.
Results: Circulating anti-GPIb antibody-producing B cells were significantly greater in patients with primary ITP, SLE, LC, and post-HSCT than in healthy controls (3.0 ± 3.3, 10.5 ± 25.6, 4.8 ± 5.2, and 3.4 ± 6.2 vs. 0.4 ± 0.4; $P < 0.01$ for all comparisons). When a cutoff level was set at five standard deviations above the mean of healthy controls, a positive result was detected in 44% of primary ITP, 48% of SLE, 50% of LC, 44% of post-HSCT, 17% of AA/MDS, and none of healthy controls. Anti-GPIb ELISPOT assay for the diagnosis of primary ITP had sensitivity of 44% and specificity of 83%, whereas anti-GPIIb/IIIa ELISPOT assay had sensitivity of 86% and specificity of 72%. When two tests were combined together, sensitivity was improved to 90%. Interestingly, frequencies of anti-GPIb and anti-GPIIb/IIIa antibody-producing B cells in circulation were correlated each other. The frequency of anti-GPIIb/IIIa antibody-producing cells exceeded the frequency of anti-GPIb antibody-producing B cells in patients with primary ITP, LC, and post-HSCT, but anti-GPIb antibody-producing B cell frequency predominated in SLE patients. Serial measurement revealed decrease of anti-GPIb and anti-GPIIb/IIIa antibody-producing B cells in parallel with platelet count recovery after therapeutic intervention, including corticosteroids, splenectomy, and eradication of *Helicobacter pylori*.

Conclusions: The ELISPOT assay for detection of anti-GPIb antibody-secreting B cells is useful for identifying patients with primary ITP and various forms of secondary ITP. In addition, anti-platelet autoantibody repertoire may be different among conditions accounting for ITP.

PA 1.05-4

Is the total 2 g/kg of intravenous immunoglobulin G optimal dose for acute immune thrombocytopenic purpura in childhood?

Lee KS and Kim UH

Kyungpook National University Hospital, Daegu, South-Korea

Background: Immune thrombocytopenic purpura (ITP) is the most common bleeding disorder in children. High dose intravenous immunoglobulin G (IVIG) has been used for treatment of ITP since 1981 by Imbach, and now several methods of IVIG infusion are used. But total doses were 2 g/kg for almost patients, uniformly. Since 1983, we have done short-term IVIG therapy according to the individual patient's response.

Aims: Through this study, we showed that low dose IVIG therapy according to the individual patient's response is reasonable and cost-effective in childhood acute ITP.

Methods: Daily 200 mg/kg of IVIG was given until platelet count reached over 50,000/mm^3 in 75 childhood acute ITP who were newly diagnosed at the Department of Pediatrics, Kyungpook National University Hospital from September, 2006 to December, 2012. We evaluated the time to reach desired platelet counts (50,000/mm3), relapse rate and changes of neutrophil count after treatment of IVIG.

Results: The median age was 2.7 years (1 month–15 years), male to female ratio was 1.5:1 and median follow up duration was 14.8 months (0.5–67 months). The median platelet count was 10,787/mm^3 (2000–37,000/mm^3) at diagnosis. The platelet count increased to 22,920/mm^3 (3000–103,000/mm^3) after one dose, 46,507/mm^3 (3000–185,000/mm^3) after two doses, 51,155/mm^3 (2000–282,000/mm^3) after three doses and 52,833/mm^3 (4000–294,000/mm^3) after four doses of IVIG therapy. The median duration of IVIG therapy was 3.8 days and median total dose of IVIG therapy was 900 mg/kg. Sixteen patients (21.3%) were relapsed (< 50,000and median interval to relapse was 26 days (15–44 days) after first diagnosis. Among 49 patients followed up over 6 months, nine patients (18.4%) were eventually diagnosed as chronic ITP. All chronic ITP was observed only in relapse patients. Forty-one patients (54.7%) showed neutropenia after IVIG treatment, and the neutropenia had resolved spontaneously in all patient after median 31.1 days (2–135 days). No serious complications were observed.

Summary/Conclusion: Compared to the previous our data (Low-dose and short term therapy of IVIG for childhood acute ITP: in Korean Journal of Hematology, 2001, 36:3241–6, 247–52), this very low-dose and short term therapy of IVIG (200 mg/kg/day) has similar effect on treating acute ITP in response and relapse rate. Total dosage of IVIG has no association with neutropenia in frequency and severity. The short-term very-low dose IVIG therapy (200 mg/kg/day) according to the individual response is resonable for effect, cost-effectiveness and safety in childhood ITP.

PA 1.05-5

Successfully sparing splenectomy in immune thrombocytopenia purpura (ITP)

Choi PY[1] and Chong BH[2]

[1]UNSW, St George Clinical School; [2]SEALS St George Hospital, Kogarah, NSW, Australia

The hallmark of primary ITP is the development of an isolated thrombocytopenia in the absence of a recognised secondary cause. Some of the earliest experiments to elucidate the pathogenesis of ITP demonstrated that an asplenic state could abrogate the platelet destruction seen with ITP serum. Since then, the role of splenectomy has been inextricably linked with the management of this condition. However, the recent analysis of our single centre experience with the management of ITP demonstrated a significant disparity between most accepted international guidelines and our current practice: splenectomy has not been performed for newly diagnosed patients with primary ITP over the last 8 years.

We aimed to investigate the reasons why our current practices were so divergent from conventional guidelines on the role of splenectomy.

We performed a subanalysis on a recent retrospective observational study on thrombocytopenia in a single Australian centre. All patients with newly diagnosed primary ITP between 2005 and June 2010 were investigated after obtaining local ethics approval. Updated information was then obtained from clinical files and via correspondence with treating physicians to elaborate their decision making processes.

Fifty-one adult patients were newly diagnosed with primary ITP during the study period. Seven have been reclassified due to clinical evolution as secondary ITP (autoimmune pancreatitis, SLE, drug-induced), congenital thrombocytopenia in two, myelodysplasia and cirrhosis. One patient was lost to follow-up abroad. One other patient developed pancreatic carcinoma and was treated with chemotherapy.

Forty-two patients were therefore evaluable for the potential role of splenectomy. 19/42 required no treatment at any point. Of the 23 who did require treatment, 10 eventually required second-line therapy. Four patients were successfully re-treated with first-line therapy for relapsed but responsive disease.

4/10 patients requiring second-line therapy were unfit for surgery: three with primarily refractory ITP and one elderly male with multiple medical co-morbidities. Six patients were potential candidates for splenectomy: four patients refused and two were not offered by the clinician as steroid-sparing agents were successfully introduced within 4 weeks of initial presentation (azathioprine and danazol).

Of the four patients who refused splenectomy, three received thrombopoietin agonist therapy. All three have maintained a response to this therapy, one of whom is in an enduring complete remission off all therapy. One patient who refused splenectomy was unable to obtain compassionate access to thrombopoietin agonists and intermittently requires steroids and danazol without significant adverse effects.

This small analysis of consecutive patients newly diagnosed with primary ITP between 2005 and 2010 demonstrates several salient features. Despite recent refinements in the classification of ITP, the clinical diagnosis still encompasses a broad clinicopathological range of patients with diverse outcomes. As a diagnosis of exclusion, primary ITP is reclassified in at least approximately 15% of cases after a median follow-up of 18 months. Owing to patient preferences and the dearth of steroid-sparing and splenectomy-sparing options, surgery is infrequently required in newly diagnosed patients with primary ITP. Although splenectomy is not obsolete, it is an unpopular option in this Australian tertiary referral centre.

Cell-based haemostasis assessment to improve disseminated intravascular coagulopathy (DIC) diagnosis during septic shock

Delabranche X[1], Boisramé-Helms J[1], Asfar P[2], Berger A[3], Mootien Y[4], Lavigne T[3], Zobairi F[5], Grunebaum L[3], Lanza F[6], Gachet C[6], Freyssinet JM[7], Toti F[8] and Meziani F[3]

[1]Service de Réanimation Médicale, Nouvel Hôpital Civil, Hôpitaux Universitaires, Strasbourg; [2]CHU d'Angers, Angers; [3]Les Hôpitaux Universitaires de Strasbourg, Strasbourg Cedex; [4]CH de Mulhouse, Mulhouse; [5]UMR 7213 CNRS, Faculté de Pharmacie, Université de Strasbourg, Illkirch; [6]UMR-S949 Inserm, Université de Strasbourg, EFS-Alsace 10, Strasbourg; [7]U770 INSERM, Faculté de Médecine, Université Paris-Sud, Le Kremlin-Bicêtre; [8]Université de Strasbourg, Strasbourg Cedex, France

Background: Cell-free plasma routine tests failed to predict thrombotic or haemorrhagic tendency during septic shock and large randomised clinical trials aiming at anticoagulation were not relevant. *Post-hoc* tests highlighted patients' survival improvement only when DIC was present.

Aims: To improve DIC diagnosis during septic shock time-course and assess vessel cells activation using circulating microparticles (MPs) and truly soluble membrane proteins as vascular cell surrogates.

Methods: One hundred patients with septic shock were enrolled and their haemostatic status evaluated at admission (D1), D2, D3 and D7. Circulating MPs were isolated, quantified by prothrombinase assay and their cellular origin determined after capture onto specific antibodies. Soluble proteins were measured by ELISA. Cell markers of endothelial cells were sE-selectin, sP-selectin, t-PA, PAI-1, CD31-MPs (apoptosis) and CD105-MPs (activation); sP-selectin, sGPV and GPIb-MPs accounted for platelets; IL-6, IL-10, TNFa, MCP-1 and CD11a-MPs for leucocytes. Thrombin formation was assessed by prothrombin fragments 1 + 2 (F1 + 2), fibrin formation by fibrin monomers (FM) and fibrinolysis by D-dimers (DDi). DIC score was established according to JAAM 2006 criteria. (NCT #01604551)

Results: Forty patients had DIC during the first 24 h. Compared to no DIC, they were characterised by higher multiple organ failure especially acute renal failure (82.5% vs. 36.5%). Haemostasis activation was obvious in all patients with sustained thrombin generation and fibrinolysis over time. Delayed AT and PC restoration was observed in DIC patients ($P < 0.05$ for time-course D1–D7).

Regardless DIC diagnosis, septic shock induced high level of total MPs. CD31-MPs, t-PA and PAI-1 were increased but not differently in DIC vs. no DIC patients. t-PA and PAI-1 returned to baseline at D7 ($P = 0.04$, $P < 0.01$, respectively) with delayed improvement when DIC was present while CD31-MPs were stable. CD105-MPs were significantly increased at D1 only in patients having early DIC. CD105-MPs and sE-selectin were greatly increased prior DIC diagnosis and significantly tended to return to baseline at the end of the follow-up period ($P < 0.05$). Leucocyte activation was enhanced in all DIC patients (CD11a-MPs/leucocyte ratio, MCP-1 and IL-10) whereas platelet activation (sGPV/platelet and sP-selectin/platelet ratios) was increased only once DIC was present. Interestingly, sGPV/platelet and sP-selectin/platelet ratios were increased at D3 then returned to baseline. GPIb-MPs mirrored platelet count. In multiple logistic regression analysis, CD105-MPs (OR 6.55 [2.54–16.92], $P < 0.01$), CD31-MPs (OR 0.49 [0.26–0.94], $P = 0.03$) and FV (OR 0.97 [0.95–0.99], $P = 0.02$) were strongly associated to DIC, while FM ($P = 0.06$) and prothrombin F1 + 2 ($P = 0.09$) were tightly associated.

Using our global approach of individual vascular competence, we identified three different profiles: (i) no DIC – low grade, controlled injury, (ii) pre DIC – obvious vascular injury but still-controlled thrombin generation, and (iii) DIC – uncontrolled thrombin and fibrin formation.

Summary/conclusion: According to cell-based haemostasis assessment, the initial activation of endothelial cells and leucocytes in septic shock prompts thrombin generation followed by platelet activation. MPs and soluble selectins are vascular cells activation surrogates that could improve early stratification for anticoagulant therapy during septic shock.

Key words: disseminated intravascular coagulopathy, microparticles, septic shock, cell-based haemostasis.

Identification of a novel, nanobody-induced, mechanism of TAFI inactivation and its *in vivo* application

Hendrickx ML[1], Zatloukalova M[1], Hassanzadeh-Ghassabeh G[2], Muyldermans S[2], Gils A[1] and Declerck PJ[1]

[1]KU Leuven, Leuven; [2]Vrije Universiteit Brussel, Brussels, Belgium

Background: Down regulation of fibrinolysis due to cleavage of C-terminal lysine residues from partially degraded fibrin is mainly exerted by the carboxypeptidase activity of activated thrombin-activatable fibrinolysis inhibitor (TAFIa). Some intrinsic carboxypeptidase activity (= zymogen activity) for the pro-enzyme TAFI, has been reported.

Aims: The aim is to identify and characterize *in vitro* nanobodies (single-domain fragments derived from heavy-chain-only antibodies) that affect the pro-enzyme properties of mouse TAFI (mTAFI). Then, their applicability will be evaluated in an *in vivo* mouse thromboembolism model.

Methods and Results: Screening of a library of nanobodies towards mTAFI revealed one nanobody (VHH-mTAFI-i49) significantly stimulating the zymogen activity of mTAFI to 4.4 U/mg (at a 16-fold molar ratio over mTAFI, $P < 0.0001$ compared to no addition of nanobody). The stimulated zymogen activity is unstable at 37 °C, with a half-life of 8.1 ± 0.8 min. More importantly, incubation of mTAFI with VHH-mTAFI-i49 reveals a time-dependent reduced activatability (by thrombin/thrombomodulin) of mTAFI: 47%, 71% and 89% reduced activatability after incubation at 37 °C for 15, 30 and 60 min, respectively. *In vitro* clot lysis experiments were performed by pre-incubation of mouse plasma with VHH-mTAFI-i49 for 60 min followed by $CaCl_2$ triggered clot formation and t-PA induced lysis. VHH-mTAFI-i49 induced a dose-dependent reduction of the 50% clot lysis time, < i.e. 28 ± 7 min in the presence of a 16-fold molar excess of the nanobody over TAFI vs. 80 ± 4 min in the absence of the nanobody. Extensive analysis during *in vitro* clot lysis experiments revealed that the enhanced lysis was associated with a reduced activatability of TAFI to TAFIa, through transient zymogen stimulation. The affinity (K_A) of VHH-mTAFI-i49 for TAFI, as determined by surface plasmon resonance (Biacore®), is $4.2 \pm 1.2 \times 10^7$/M. *In vivo* application of VHH-mTAFI-i49 (2.6 mg/kg) in a tissue factor-induced mouse thromboembolism model significantly decreases the fibrin deposition in the lungs (20 ± 6.9 and 114 ± 20 μg/mL for VHH-mTAFI-i49 and buffer respectively). Epitope mapping discloses that Arg^{227} and Lys^{212} are important for the nanobody/mTAFI interaction and suggests that the zymogen stimulation and subsequent destabilization of TAFI may be the result of translocation of the activation peptide, thereby disrupting the stabilizing interaction between activation peptide and the dynamic flap region.

Conclusion: The nanobody-induced, reduced activatability of mTAFI, results in a very potent enhancement of *in vitro* clot lysis. Evaluation

of this nanobody in an *in vivo* mouse thromboembolism model illustrates that this novel way of interfering with the generation of TAFIa results in a strong profibrinolytic effect.

PA 1.06-2

Alpha2-antiplasmin is a potential regulator of neuronal morphology

Kawashita E[1], Kanno Y[1], Asayama H[1], Okada K[2], Ueshima S[3], Matsuo O[2] and Matsuno H[1]

[1]Faculty of Pharmaceutical Science, Doshisha Women's College of Liberal Arts, Kyo-Tanabe; [2]Kinki University School of Medicine, Osaka; [3]Faculty of Agriculture, Kinki University, Nara, Japan

Background: α2-Antiplasmin (α2AP), a member of the serine protease inhibitor (serpin) family, is a principal physiological plasmin inhibitor. On the other hand, α2AP regulates cell differentiation without the mediation of plasmin, suggesting that α2AP is a possible regulatory factor of cellular functions in a plasmin-dependent or plasmin-independent manner. α2AP is mainly produced by the liver and kidneys, but it is also expressed in the brain, particularly at a higher level in the hippocampus than in the cortex, hypothalamus and cerebellum. Hence α2AP might play an important role in hippocampal neuronal functions. However, no study thus far has addressed the role of α2AP in the neurons.

Neurons have a unique morphology characterized by dendrites and a long axon. During neuronal maturation, MAP2 and tau, which are abundant microtubule-associated proteins in neurons, segregate into dendrites and axon, respectively, and form cross-bridges between microtubules to regulate the development and stabilization of axon and dendrites. Transforming growth factor (TGF-β) is a key factor to promote neuronal maturation, neurites sprouging and axonal development. α2AP regulates the expression of TGF-β, thereby suggesting that α2AP could be a potential regulator of neuronal morphology.

Aims: This study investigated whether α2AP regulated the neuronal morphology, including dendritic and axonal growth, and also whether TGF-β was involved in the regulation. In addition, the mechanisms underlying the morphological regulation by α2AP were determined.

Methods: Primary hippocampal neurons were obtained from $\alpha 2AP^{+/+}$ [wild-type (WT)], $\alpha 2AP^{-/-}$mice and plasminogen$^{-/-}$ mice, and treated with α2AP, TGF-β or aprotinin. Immunocytostaining and phalloidin staining were performed, and then the length, the number of tips, and the branching of the neurites were measured. The expression of MAP2, tau1 and TGF-β in the neurons was analyzed by Western blotting.

Results: α2AP was intensely expressed in mature neurons, but not in immature neurons. Exogenous treatment with α2AP increased the length, the number of tips, and the branching of the neurites, and enhanced the expression of MAP2 and tau1 in both WT and $\alpha 2AP^{-/-}$ mice. Aprotinin, another plasmin inhibitor, had little effect on the expression of MAP2 and tau1 in the neurons from WT mice, and furthermore, α2AP induced the expression of MAP2 and tau1 in the neurons from plasminogen$^{-/-}$ mice. In addition, the activation of p38 MAPK, but not ERK and JNK, was involved in the induction. α2AP also induced the TGF-β expression in the neurons, and TGF-β signaling mediated the α2AP-induced expression of MAP2 and tau1.

Conclusion: α2AP induces TGF-β expression to regulate dendritic and axonal growth through activation of p38 MAPK without the mediation of plasmin, thus providing new insights into the role of α2AP in the neuron.

Generation and characterization of homozygous plasminogen-Tochigi mutant mice bearing reduced fibrinolytic activity

Tashima Y, Banno F, Kita T, Matsuda Y, Yanamoto H and Miyata T

National Cerebral and Cardiovascular Center, Suita, Japan

Plasminogen (Plg) is a precursor of a serine protease, plasmin that degrades fibrin fiber composed of blood clot. Fibrinolysis is an important event to dissolve unfavorable clot in blood vessel. Deficiency of Plg causes thrombosis, fibrin deposition, and delay of wound healing. Plg-A620T mutation previously named as Plg-Tochigi mutation is positioned close to the enzymatic active site and decreases the proteolytic activity of plasmin. Plg-Tochigi mutation has not been found in Caucasian but observed in Chinese and Japanese with an estimated prevalence of 4% in the general Japanese population. We suspected that Plg-Tochigi mutation is a potential risk factor for Asian to cause thrombosis because of the low fibrinolytic activity. In fact, Plg-Tochigi mutation was originally found in Japanese patients of deep vein thrombosis (DVT). However, our recent analysis proved that heterozygous Plg-Tochigi mutation is not a genetic risk factor for DVT. Herein, we focus on homozygotes of Plg-Tochigi mutation and investigate whether the homozygous Plg-Tochigi mutation in mice causes serious thrombosis.

We generated the Plg-A622T (Plg-Tochigi) knock-in mice corresponding to human Plg-A620T. The homozygous Plg-Tochigi mutant mice did not show any abnormality in birth, growth, and fertility. The urokinase-induced amidolytic activity of Plg in homozygous Plg-Tochigi mutant mice was reduced by about 25% of those in wild-type mice. Unexpectedly, delay of wound healing was not observed in Plg-Tochigi mutant mice unlike Plg-knockout mice previously reported. We compared artery and vein thrombogenesis between Plg-Tochigi mutant and wild-type mice using three different experimental thrombosis models. In a middle cerebral artery occlusion model of ischemia-reperfusion injury, we did not find any difference, indicating that the Plg-Tochigi mutation did not significantly affect the severity of ischemic artery diseases. Next, we induced acute pulmonary embolism by injection of recombinant human tissue factor via inferior vena cava (IVC). The survival rate of Plg-Tochigi mutant mice during 20 min after the injection was as same as wild-type mice although the degree of vascular occlusion in the lung of Plg-Tochigi mutant mice was a little severer than wild-type mice. We also induced IVC thrombosis by electrolytic stimulation of IVC at a current of 250 μAm for 15 min. Plg-Tochigi mutant mice tended to form slightly larger thrombi than wild-type mice but there were no significant differences in the thrombus weight.

In conclusion, homozygous Plg-Tochigi mutation showed reduced enzymatic activity of plasmin but did not cause severe thrombosis in mice. The potential of Plg-Tochigi mutation to modify thrombosis triggered by other genetic risk factors needs to be investigated.

PA 1.06-4

Enhanced t-PA-mediated fibrinolysis through co-administration of a TAFI-inhibiting nanobody

Hendrickx ML[1], Hassanzadeh-Ghassabeh G[2], Muyldermans S[2], Gils A[1] and Declerck PJ[1]

[1]KU Leuven, Leuven; [2]Vrije Universiteit Brussel, Brussels, Belgium

Background: One of the main disadvantages of current t-PA thrombolytic treatment is the increased bleeding risk. Upon activation, Thrombin Activatable Fibrinolysis Inhibitor (TAFI) is a very powerful antifibrinolytic enzyme. Therefore, co-administration of a TAFI inhibitor during thrombolysis could reduce the t-PA dose, thereby decreasing bleeding risks without compromising the efficacy.

Aim: The aim is to generate and characterize inhibitory nanobodies (single-domain fragments derived from heavy-chain-only antibodies) towards rat TAFI (rTAFI) and evaluate their profibrinolytic properties *in vitro* and *in vivo*.
Methods and Results: Nanobody VHH-rTAFI-i81 inhibits (at a 16-fold molar ratio nanobody over TAFI) the thrombin/thrombomodulin (T/TM) mediated activation of rTAFI by 83 ± 1.8% with an IC_{50} of 0.46 (molar ratio nanobody over TAFI). The affinity (K_A) of VHH-rTAFI-i81 for rTAFI, as determined by surface plasmon resonance (Biacore®), is 2.5 ± 0.2 × 10^{10}/M and illustrates a very strong binding. VHH-rTAFI-81 was also found to interact with mTAFI: 78 ± 2.6% inhibition of T/TM mediated mTAFI activation with an IC_{50} of 0.59 and an affinity (K_A) of 6.9 ± 1.2 × 10^9/M. *In vitro,* a dose-response curve of the profibrinolytic effect of VHH-rTAFI-i81 in rat plasma, in the presence of 1000 pM t-PA, shows a strong, maximal profibrinolytic effect already at an equimolar ratio of nanobody over rTAFI. A dose-response curve of the fibrinolytic effect of t-PA, in the presence and absence of VHH-rTAFI-i81 at a two-fold molar ratio over rTAFI, indicates that (i) in the absence of VHH-rTAFI-i81 lysis remains limited even at the highest concentration of t-PA (900 pM), whereas in the presence of VHH-rTAFI-i81, full lysis is achieved and (ii) in the presence of VHH-rTAFI-i81 the time to reach full lysis is 25 min whereas in the absence of VHH-rTAFI-i81, no full lysis is reached at 180 min. Epitope mapping discloses that Lys^{380} and Lys^{392} are of primary importance for the nanobody/rTAFI interaction besides minor contributions of Tyr^{175} and Glu^{183}. *In vivo* application of VHH-rTAFI-i81 (1.3 mg/kg) in a tissue factor-induced mouse thromboembolism model significantly decreases fibrin deposition in the lungs (8.0 ± 2.2 and 180 ± 27 μg/mL for VHH-rTAFI-i81 and buffer, respectively).
Conclusion: Nanobody VHH-rTAFI-i81 is a very potent inhibitor of TAFI activation. Co-administration of this nanobody and t-PA enhances the fibrinolytic efficacy. In an *in vivo* mouse thromboembolism, application of VHH-rTAFI-i81 reduces fibrin deposition in the lungs.

PA 1.06-5
Clots formed from y′-fibrinogen are more resistant to lysis than those formed from? A-fibrinogen because of delayed plasminogen activation by tissue plasminogen activator

Kim PY, Vu T, Leslie BA, Stafford AR, Fredenburgh JC and Weitz JI
Thrombosis and Atherosclerosis Research Institute and McMaster University, Hamilton, ON, Canada

Background: About 15% of circulating fibrinogen (Fg) contains a γ-chain variant with an extended C-terminus and is designated γ'-Fg. Fibrin (Fn) clots formed from γ'-Fg are more resistant to lysis by tissue plasminogen activator (tPA) than those prepared from the predominant γA-Fg. Because release of fibrinopeptide (FP) B is purported to expose a cryptic plasminogen (Pg) binding site, we speculated that the resistance to lysis may reflect delayed release of FPB from γ'-Fg.
Aim: To determine whether resistance of γ'-Fn clots to lysis relative to γA-Fn clots reflects impaired FPB release.
Methods: Samples containing γA- or γ'-Fg at various concentrations, Pg, tPA, and a_2-antiplasmin were incubated at 37 °C with thrombin, which releases FPA and FPB, or with batroxobin, which only releases FPA. Turbidity was monitored at 400 nm and the time to half maximal decrease was designated as the lysis time. To compare the cofactor activities of γA- and γ'-Fn, experiments were repeated (a) in the presence of S2251 so that kinetic parameters for Pg activation by tPA and the time to initiation of Pg activation relative to that of clot formation could be determined, and (b) using plasmin in place of Pg and tPA so that the Pg activation step could be bypassed. Finally, to explore the impact of FPB release on the Pg/Fn interaction, immobilized γA- or γ'-Fg was converted to Fn with thrombin or with batroxobin and surface plasmon resonance (SPR) was used to quantify Pg binding.
Results: With tPA, lysis times of γ'-Fn clots were longer than those of γA-Fn clots; a difference that reached 30% with increasing Fg concentrations. Substitution of batroxobin for thrombin or plasmin for Pg/tPA abolished the difference, suggesting that it is related to an effect of FPB release on Pg activation. Although Fg isoform and the use of thrombin vs. batroxobin to clot the Fg had no effect on the individual kinetic parameters for Pg activation by tPA, the time to initiation of Pg activation with γ'-Fn clots was delayed by 95.0 ± 15.6 s compared with γA-Fn when clots were formed with thrombin, but not with batroxobin; findings that also implicate FPB release. In support of this concept, based on the SPR data, 2-fold more Pg bound to Fn lacking both FPA and FPB compared with Fn lacking only FPA.
Conclusion: Our findings suggest that the capacity of Fn to promote Pg activation by tPA is accelerated by FPB release, which promotes Pg binding. Therefore, slower lysis of γ'-Fn likely reflects delayed FPB release rather than impaired plasminogen activation or resistance to plasmin-mediated Fn degradation. Thus, these studies provide additional insights into the mechanism by which Fn promotes Pg activation by tPA, and why incorporation of γ'-Fg into Fn clots may render them resistant to lysis.

Structural and biochemical studies of naturally occurring antiplasmin variants

Horvath AJ, Lu B, Encarnacao JA, Zhang QW, Whisstock J, Coughlin PB and Law RHP
Monash University, Melbourne, Australia

Antiplasmin(AP) is a highly effective inhibitor of plasmin and its deficiency often results in a variable, often severe, bleeding disorder. Two AP mutations that cause bleeding disorders have been identified. AP *Enschede* involves an insertion of an alanine residue in the RCL (353A-A-A-A357). Although the variant is normally expressed, it is a substrate rather than an inhibitor of plasmin. A second mutation, V372M is located just C-terminal to the RCL on the first strand of the C-sheet and results in deficiency through an as yet uncharacterized mechanism. To understand how these mutations alter AP function we generated recombinant forms of human and mouse AP *Enschede* and mouse V372M variant and investigated their structural and biophysical properties. The X-ray crystal structures of murine AP *Enschede* and V372M were solved at 2.8 Å and 4.0 Å resolution, respectively. The structural data reveals that both variants are in a native conformation and that the serpin fold is not perturbed by the mutations. No electron density was observed for the RCL of either protein. The biophysical properties of recombinant human and mouse AP *Enschede* were unaltered by the mutation despite both proteins demonstrating substrate like inhibitory activity. In contrast, the recombinant mouse V372M variant had inhibitory properties similar to wild-type mouse AP and no differences in polymerization and biophysical characteristics were observed. This suggests that the V372M mutation alone does not alter the native fold of the serpin or its inhibitory efficiency. The human V372M variant could not be expressed in *E. coli* and may indicate malfolding or structural instability in the human V372M protein.

Antiplasmin, but not amiloride, prevents synovitis and cartilage destruction following hemarthrosis in hemophilic mice

Nieuwenhuizen L, Roosendaal G, Coeleveld K, Biesma DH, Lafeber PJG and Schutgens REG

University Medical Center Utrecht, Utrecht, The Netherlands

Background and Aims: Blood-induced joint damage in hemophilia is characterized by synovitis and cartilage destruction. Recently, we demonstrated that a joint bleeding in hemophilic mice results in alterations in the fibrinolytic system with an increase in synovial cells expressing urokinase-type plasminogen activator (uPA), an increase in synovial levels of uPA and plasmin, and in plasmin-mediated cartilage destruction. In this study, we evaluate the alterations in synovitis and cartilage destruction following the induction of a joint bleeding in hemophilic mice treated with placebo, amiloride (a specific inhibitor of uPA), or antiplasmin.

Methods: The right knees of hemophilic mice were punctured to induce hemarthrosis. Subsequently, mice were randomized between daily oral treatment with amiloride or control, while other mice were randomized between weekly intra-articular treatment of the right knee joint with amiloride, antiplasmin, or control. After 5 weeks of treatment, the mice were sacrificed, knee joints were isolated, sectioned for histology, and stained with hematoxylin-eosin (synovitis) or safranin O (cartilage destruction). Hemophilic synovitis and cartilage destruction were determined by two blinded observers according to Valentino and Glasson. An increase in Valentino and Glasson score represents an increase in hemophilic synovitis and cartilage destruction, respectively. Treatment with amiloride or antiplasmin was compared with control. Categorical data were analyzed by loglinear analysis and Pearson Chi-Square.

Results: No significant alterations in synovitis and cartilage destruction were found when comparing the oral amiloride group with the oral control group, and when comparing the intra-articular amiloride group with the intra-articular control group. In contrast, intra-articular treatment with antiplasmin resulted in a statistical significant ($P < 0.01$) reduction in synovitis, as assessed by the Valentino score, when comparing the intra-articular control group to the intra-articular antiplasmin group: 1 (0% vs. 11.1%), 2 (4.2% vs. 11.1%), 3 (16.7% vs. 61.1%), 4 (29.2% vs. 5.6%), 5 (20.8% vs. 11.1%), 6 (8.3% vs. 7.7%), 7 (8.3% vs. 0%), and 8 (12.5% vs. 0%). In addition, treatment with intra-articular antiplasmin resulted in a statistically significant ($P < 0.01$) reduction in cartilage destruction, as assessed by the Glasson score, when comparing the intra-articular control group to the intra-articular antiplasmin group: 2 (8.3% vs. 10%), 3 (12.5% vs. 50%), 4 (33.3% vs. 30%), 5 (33.3% vs. 10%), 6 (12.5% vs. 0%), and 7 (4.2% vs. 0%).

Conclusions: Intra-articular treatment with antiplasmin following the induction of a joint bleeding prevented synovitis and cartilage destruction in hemophilic mice. Oral and intra-articular treatment with amiloride failed to attenuate synovitis and cartilage destruction. Given that complete prevention of joint bleeds in hemophilia is not feasible at the moment despite the prophylactic use of factor replacement, the data presented herein offer promise for the use of antiplasmin as a new therapeutic intervention.

A single intra-articular injection with IL-4 plus IL-10 ameliorates blood-induced cartilage degeneration in haemophilic mice

Van Meegeren E[1], Roosendaal G[2], Coeleveld K[2], Nieuwenhuizen L[2], Van Vulpen F[2], Mastbergen SC[2] and Lafeber PJG[2]

[1]UMC Utrecht; [2]University Medical Centre Utrecht, Utrecht, The Netherlands

Background: Blood-induced joint damage is still a major cause of morbidity amongst haemophilia patients, despite the increased use of prophylaxis. IL-4 and IL-10 are modulatory cytokines and candidates for stopping the progress of this blood-induced joint damage. It has been shown previously that combination of interleukin (IL)-4 and IL-10 protects against blood-induced cartilage damage *in vitro*.

Aims: The present study investigated whether a single intra-articular injection of IL-4 plus IL-10 immediately after a joint bleed limits cartilage damage in an *in vivo* haemophilia mouse model of blood-induced joint damage.

Methods: Factor VIII knockout mice with severe haemophilia A were punctured once with a needle below the patella to induce a joint haemorrhage. Subsequently IL-4 plus IL-10 ($n = 24$) or vehicle ($n = 24$) was injected intra-articularly. After 35 days, the time needed for development of detectable joint degeneration, knee joints were examined for cartilage damage by macroscopic and microscopic evaluation.

Results: A single intra-articular injection of IL-4 plus IL-10 ameliorated progression of cartilage degeneration caused by a single joint bleed to a certain extent. No effect on inflammation was observed at this time point.

Summary/Conclusions: A single intra-articular injection of IL-4 plus IL-10 directly after a single joint bleed limits progression of cartilage degeneration over time. Improved bioavailability (half-life) of both cytokines might improve their protective ability in the development of cartilage degeneration, and probably also inflammation.

Structure of a cyclic peptide binding to Kunitz domain 1 and 2 inhibiting tissue factor pathway inhibitor (TFPI)

Dockal M[1], Hartmann R[1], Fries M[1], Prohaska K[1], Pachlinger R[1], Polakowski T[2], Brandstetter H[3] and Scheiflinger F[1]

[1]Baxter Innovations GmbH, Vienna, Austria; [2]3B Pharmaceuticals, Berlin, Germany; [3]University of Salzburg, Salzburg, Austria

Background: TFPI is a potent inhibitor of tissue factor (TF)-induced blood coagulation. It is composed of three consecutive and flexible linked Kunitz-type domains (K) where K1 and K2 are involved in efficient inhibition of TF/FVIIa and FXa. TFPI inhibition has been shown to promote coagulation and hemostasis in hemophilia models *in vitro* and *in vivo*.

Aim: We solved the co-crystal structure of a TFPI construct comprising K1-K2 in complex with a cyclic TFPI inhibitory peptide (JBT-B5) to reveal molecular details of its inhibitory mode of action.

Methods: Recombinant K1-K2 (residues 22–150) produced by *E. coli* and complexed to JBT-B5, a cyclic peptide composed of 23 amino acids, was co-crystalized in 20% w/v PEG6000 and 50 mM imidazole, pH8.0. JBT-B5 binding to TFPI was verified by biomolecular interaction analysis (BiaCore). Functional inhibition of TFPI by JBT-B5 was tested in model assays including TFPI inhibition of FXa and FX activation by TF/FVIIa, and by global hemostatic assays including calibrated automated thrombography in FVIII-inhibited plasma and rotational thromboelastometry using FVIII-inhibited whole blood.

Inhibition of cell surface TFPI was analyzed in a FX activation assay performed on HUVECs.

Results: A co-crystal structure of TFPI K1-K2 bound to JBT-B5 was solved at 1.95 Å resolution. This is the first structure of TFPI consisting of K1, K2 and their linker. The K1-K2 structure is defined in the electron density from Met22 through Gly150. Both domains show a Kunitz-type structure, where only approximately 1/3 of the structure is engaged in secondary structure elements. These elements form the framework that is stabilized by the three canonical disulfide bonds in each of the Ks. The 23mer JBT-B5 assumes a β-hairpin-like structure which can be segmented into (i) a two-stranded β sheet comprising Tyr2-Ala8 and Thr17-Phe23; (ii) and a β-turn comprising Asp11-Thr15. The β-sheet is stabilized by a disulfide bridge (Cys7 and Cys18) and a hydrophobic zipper comprising the side chains of Tyr3, Trp5 and Trp20. JBT-B5 is sandwiched between K1 and K2 and locks them in a distinct conformational state bringing the reactive center loops (RCL) to opposite sides. The interaction between K1-K2 and JBT-B5 is mediated by a hydrophobic anchor in JBT-B5, forming more than 2/3 of the interaction surface (1340 Å2). In addition, several polar interactions stabilize the K1-K2/JBT-B5 complex, explaining JBT-B5′s exlusive binding to human TFPI. Interaction studies revealed high affinity binding to TFPI (K_D: 0.5 nM). The highly complex and extensive interaction of JBT-B5 with TFPI translates to a highly efficient inhibition of TFPI as demonstrated in model assays on FXa (EC_{50}: 1.3 nM), FXa generation by TF/FVIIa (EC_{50}: 0.2 nM), HUVE cell-based FX activation and global hemostasis assays, such as thrombin generation in hemophilia plasma (EC_{50}: 4 nM) and ROTEM in FVIII-inhibited whole blood.

Summary/Conclusions: For the first time, a structure of TFPI comprising K1, K2 and their linker in complex with a TFPI- inhibitory cyclic peptide was solved. This structure provides atomic details explaining the inhibitory mode of action of this highly efficient TFPI antagonist, and will guide its improvement for use as a hemophilia therapeutic.

The effect of a novel TFPI inhibitory fusion peptide on TFPI clearance

Dockal M, Hartmann R, Redl C, Panholzer E, Kolm A, Höllriegl W and Scheiflinger F

Baxter Innovations GmbH, Vienna, Austria

Recently, a hemophilia phase 1 clinical trial with the aptamer BAX 499 targeting human full length (hfl)-TFPI was stopped due to an increase in bleeding events – a consequence of considerably elevated hfl-TFPI plasma levels and only partial inhibition of TFPI by the aptamer. This rise in hfl-TFPI was mainly caused by a number of interrelated events including BAX 499 effects on receptor mediated clearance of TFPI. We developed a fusion peptide of a linear and a cyclic peptide, which was shown to be a full inhibitor of TFPI even at highly elevated TFPI levels.

The goal was to show the absence of any impact of the fusion peptide on TFPI clearance in *in vitro* test systems as well as *in vivo*.

The interference of the fusion peptide with low density lipoprotein receptor-related protein 1 (LRP1) and asialoglycoprotein receptor (ASGPR), two TFPI clearance receptors, was assessed using Biacore. Biotinylated recombinant human LRP-1 cluster II Fc chimera protein was bound to the surface via biotin after neutravidin immobilization to a series S sensor chip C1. Then hfl-TFPI or recombinant TFPI1-160 were injected in a single concentration of 10 nM. ASGPR was immobilized to a series S sensor chip CM5 using standard amine coupling chemistry. Hfl-TFPI or TFPI1-160 was injected in the single cycle analysis mode at concentrations ranging from 3.84 to 150 nM. Subsequently, hfl-TFPI was dissociated by changing the flow to running buffer conditions. When the interaction of hfl-TFPI with clearance receptors was assessed in the presence of the fusion peptide, 1 μM final concentration of peptide was added to the hfl-TFPI.

A possible impact of the fusion peptide on the pharmacokinetics of hfl-TFPI *in vivo* was studied in mice. C57Bl/6 mice were treated with hfl-TFPI (775 nM, 5 mL/kg i.v.) or hfl-TFPI complexed to a 10-fold molar excess of peptide. Human TFPI was monitored over 35 min using an ELISA.

Hfl-TFPI interacted efficiently with immobilized LRP and ASGPR with fast on- and off-rates via its K3-C-terminus region as was verified with a TFPI construct devoided of C-terminal parts (TFPI 1-160). When bound to the fusion peptide, hfl-TFPI interacted with LRP and ASGPR with a slightly increased response, which might be explained by the increased molecular weight of the complex. Unchanged association and dissociation kinetics of receptor-TFPI interaction with and without the fusion peptide corroborates that binding of hfl-TFPI to the clearance receptors is unaffected. Pharmacokinetic studies of hfl-TFPI in mice further supported the *in vitro* results. TFPI had a short half-life and a poor *in vivo* recovery. Recovery and half-life of hfl-TFPI remained unchanged when hfl-TFPI was administered in complex with the linear peptide-part of the fusion peptide. This experiment indicates that the peptide does not influence the clearance of TFPI.

The data suggest minimal effects of the fusion peptide on the fl-TFPI plasma level after peptide administration. Fusion peptide binding to hfl-TFPI does not affect binding of hfl-TFPI to the studied clearance receptors and the *in vivo* experiment showed an unaffected circulation time of hfl-TFPI.

Deferasirox prevents cartilage destruction following hemarthrosis in hemophilic mice

Nieuwenhuizen L, Roosendaal G, Coeleveld K, Biesma DH, Lafeber PJG and Schutgens REG

University Medical Center Utrecht, Utrecht, The Netherlands

Background and Aims: Joint bleedings in hemophilia result in iron-mediated synovitis and cartilage destruction. It was evaluated whether deferasirox, an iron chelator, was able to prevent the development of hemophilic synovitis and cartilage destruction.

Methods: Hemophilic mice were randomly assigned to oral treatment with deferasirox (30 mg/kg) or its vehicle (control) (30 mg/kg). After 2 months of pretreatment, the right knees of hemophilic mice were punctured to induce hemarthrosis. The mice were sacrificed after another 5 weeks of treatment. Post-mortem, knee joints were isolated and sectioned for histology. Hemophilic synovitis and cartilage destruction were determined by two blinded observers according to Valentino and Glasson respectively. For hemophilic synovitis, sections of tissue were stained with hematoxylin-eosin and scored for evidence of synovial hyperplasia, vascular hyperplasia, hemosiderin depositions, intra-articular erythrocytes, and synovial villi. For cartilage destruction, sections of tissue were stained with safranin O and the intensity of safranin O staining was scored according to Glasson, which is directly proportional to the proteoglycan content in the cartilage, which is a measure of cartilage destruction. The maximum score of the Valentino score is 10, and the maximum score of the Glasson score is 6. An increase in Valentino and Glasson score, represents an increase in hemophilic synovitis and cartilage destruction, respectively. Treatment with deferasirox was compared with control. Categorical data data were analyzed by loglinear analysis and Pearson Chi-Square.

Results: Treatment with deferasirox (823 ± 56 ng/mL) resulted in a statistically significant ($P < 0.01$) decrease in plasma ferritin levels as compared to the control group (1220 ± 114 ng/mL). The presence of hemosiderin was statistically lower ($P = 0.04$) in the deferasirox group compared to the control group. Signs of hemophilic synovitis, as assessed by the Valentino score, were not different ($P = 0.52$) when comparing the control group to the deferasirox group: 1 (12.4% vs. 7.7%), 2 (16.7% vs. 11.5%), 3 (12.5% vs. 38.5%), 4 (29.2% vs. 19.2%), 5 (16.7% vs. 11.5%), 6 (4.2% vs. 7.7%), and 8 (8.3% vs. 3.8%). Deferasirox treatment resulted in a statistically significant ($P < 0.01$) reduction in cartilage destruction, as assessed by the Glas-

son score, when comparing the control group to the deferasirox group: 2 (4.2% vs. 65.4%), 3 (4.2% vs. 26.9%), 4 (20.8% vs. 7.7%), 5 (54.2% vs. 0%), 6 (12.5% vs. 0%), and 7 (4.2% vs. 0%).
Conclusion: Treatment with deferasirox prevented cartilage destruction following the induction of hemarthrosis in hemophilic mice. The data presented herein support the need for further investigation of the potential role for iron chelation in the treatment of joint bleedings in hemophilia. This is in particular of interest in the event of a hemarthrosis despite prophylactic treatment with factor replacement.

In vivo blood loss in a FVIII-inhibited rabbit model and its correlation with global hemostatic assays *ex vivo*

Dockal M, Knappe S, Leidenmüller P, Resch M, Tippl S, Verdino D, Bauer KA, Scheiflinger F, Muchitsch M and Höllriegl W
Baxter Innovations GmbH, Vienna, Austria

Background: Hemophilia A is a bleeding disorder caused by mutations in the factor VIII (FVIII) gene. Treatment consists of intravenous infusions with recombinant or plasma-derived FVIII concentrates. In case of inhibitory antibody development, bleeds are treated with bypass therapy. For development of new therapeutic options, hemophilia animal models are crucial. Unlike in human clinical studies, global hemostasis *ex vivo* assays are not commonly included in preclinical studies.
Aim: We used an antibody-induced hemophilia A rabbit bleeding model to correlate *in vivo* blood loss with *ex vivo* parameters generated in two global hemostasis assays. We also present an example for efficacy assessment in this model.
Methods: Forty-two rabbits were injected with high titer FVIII-inhibitor plasma. After 45 min incubation, nail clipping was performed, and blood loss by weight determined over 30 min. Normal and FVIII-inhibited rabbit blood was measured by thromboelastography (TEG) triggered with very low concentrations of tissue factor. Thrombin generation was assessed by calibrated automated thrombography (CAT) under conditions optimized for rabbit plasma. We correlated blood loss (mg), CAT and TEG parameters of FVIII-inhibited blood/plasma using Spearman rank order analysis. We also evaluated the FVIII-sensitivity of the *ex vivo* parameters. For further model validation, the acute efficacy of 75 U/kg activated prothrombin complex concentrate (APCC), compared to a vehicle treated group, was demonstrated in six rabbits by monitoring the blood loss from the same wound for another 30 min.
Results: Peak thrombin, ETP (CAT), R-time, K-time and angle (TEG) were identified as the most FVIII-sensitive parameters in rabbit plasma or blood. For example, peak thrombin and ETP in normal plasma was consistently 2- to 3-fold higher than in FVIII-inhibited plasma. Strong correlations were also seen between CAT and TEG values, e.g. peak thrombin/ETP vs. R-time ($R = -0.6$, $P = 2\times10^{-7}$). Absolute blood loss in FVIII-inhibited rabbits was a highly variable parameter, ranging from 121 to 5043 mg (average 1066 mg). Blood loss did not correlate with CAT or TEG parameters. This demonstrates that absolute blood loss does not merely depend on the hemostatic status of the animal plasma/blood, but likely is influenced by other factors, such as the inflicted cut. Therefore, normalization of the bleeding parameter is indispensable. In our model, this was achieved by calculating relative blood loss (mg blood after treatment/mg blood before × 100%) for the APCC-treated group (average 2%) and vehicle group (average 173%). The difference between these groups was statistically significant. The high procoagulant activity of 75 U/kg APCC was also reflected by global hemostasis assay parameters.
Conclusions: Our results support the wider use of global hemostatic assays in hemophilia preclinical research and drug development. *Ex vivo* assays such as CAT and TEG can add value to the naturally more variable *in vivo* data. We also show the importance of well-controlled bleeding models to obtain meaningful data as accomplished by normalization. Continuous optimization of hemophilia animal models can help to improve data quality, possibly reduce the number of required experimental animals and support the realization of new hemophilia therapies.

A recurrent Gly43Asp substitution of coagulation Factor X rigidifies its catalytic pocket and impairs catalytic activity and intracellular trafficking

Menegatti M[1], De Cristofaro R[2], Vangone A[3], Palla R[1], Milano G[3], Cavallo L[3], Oliva R[4] and Peyvandi F[5]
[1]A. Bianchi Bonomi Hemophilia and Thrombosis Center, Milan; [2]Institute of Internal Medicine and Geriatrics, Catholic University of Medicine, Rome; [3]University of Salerno, Fisciano, Salerno; [4]University 'Parthenope' of Naples, Centro Direzionale Isola C4, Naples; [5]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy

Background: Coagulation Factor X (FX) deficiency is one of the most severe among inherited bleeding disorders. The homozygous Gly43Asp mutation (chymotrypsinogen numbering) was found in 15 patients, from the border area between Turkey and Iran, with severe FX deficiency (FX:C < 1%). Previous *in vitro* expression studies showed that the introduction of a charged hydrophilic Asp residue instead of a neutral Gly into the protein core caused a secretion defect.
Aim: To thoroughly study the pathogenic mechanisms of the Gly43Asp substitution, by extensively characterizing both the wild-type (WT) and mutant (FX43Asp) FX on a functional and structural basis.
Methods: Kinetic studies were performed on both WT and FX43Asp recombinant FX expressed in HEK293 cells. Molecular dynamics (MD) simulations were performed on the wild-type and mutant FXa with GROMACS ver. 4.5.4 and the AMBER99SB force-field. Four different 60 ns long NPT MD simulations for each system were performed assigning different initial velocities. Continuum Poisson-Boltzmann electrostatic potentials were calculated using the APBS program.
Results: FX43Asp showed a 2–3 folds reduced activation rate by RVV-X and FVIIa/TF, while the amidolytic activity showed a 11-fold reduction of the apparent k_{cat}/K_m, compared to WT, being k_{cat} severely (1.1 vs. 14.6/s) and K_m modestly (26 vs. 40 mM) reduced. Catalytic activity of the FXa43Asp, measured by the prothrombin hydrolysis, was markedly impaired, showing a 30-fold reduction of k_{cat}/K_m, being k_{cat} unchanged and K_m increased (V_{max} 2.69×10^{-5}, K_m 509 ± 86.7 vs. 145.4 ± 22.35 nM) compared to WT. From the MD analysis, it is apparent that the Gly43Asp mutation does not dramatically affect the FXa structure, neither globally nor locally. Analysis of the protein H-bonds during the simulations, however, showed that the mutation modifies the H-bonds network around the catalytic residues, by thickening it. As a possible consequence, the backbone-backbone H-bond between residue 43 and the catalytic Ser195(verystable in the wild type protein: occupancy 98.7%), becomes weaker in the mutant (66.2%). The continuum Poisson-Boltzmann electrostatic potentials calculated for the two systems resulted to be predominantly negative for both along the crevice. However, in the mutant, the electrostatic potential of the binding site, around the oxyanion hole, is reversed from the positive values of the wild type to negative ones.
Conclusion: MD simulations indicate that the Gly43Asp mutation neither disrupts nor destabilizes the FXa native structure, but makes it more rigid. Therefore, by compromising the FXa flexibility, the mutation may also compromise the catalytic efficiency of the enzyme. The increased rigidity of the mutant FX might also affect the molecular recognition by chaperones inside the cell, causing the retention and defective secretion. Altogether, the defects of FX43Asp explain the severe bleeding symptoms in patients with the mutation and outline

the relevance of the plasticity in the FXa catalytic pocket for maintenance of its catalytic competence.

PA 1.08-2

Mapping of inhibitory antibodies directed to the carboxy-terminus of FVIIa in severe FVII deficiency with elongated C-terminal variant (p.A354V-p.P464Hfs†)

Branchini A[1], Baroni M[1], Pfeiffer C[2], Batorova A[3], Giansily-Blaizot M[2], Mariani G[4], Pinotti M[1] and Bernardi F[1]

[1]University of Ferrara, Ferrara, Italy; [2]CHU of Montpellier, Montpellier, France; [3]Institute of Haematology and Blood Transfusion, University Hospital, Bratislava, Slovakia; [4]University of L'Aquila, L'Aquila, Italy

Background: The relationship between the development of inhibitory antibodies and gene defects, extensively investigated in Hemophilia patients, is still an open issue. We studied inhibitory antibodies in severe factor VII (FVII) deficiency, a rare bleeding disorder characterized by a low incidence of this complication.
Aim: To correlate the *F7* gene mutation to major epitopes of anti-FVII inhibitory antibodies developed after replacement therapy.
Patient and Methods: The proposita (female, 59 years old) has been treated with plasma derived FVII (pdFVII) and recombinant activated FVII (rFVIIa) and developed high titers of anti-FVII inhibitory antibodies. The patient displayed very low circulating FVII protein levels (FVII:Ag 1.2%) and undetectable FVII activity (FVII:C < 1%), in accordance with the homozygous condition for the *F7* p.A354V-p.P464Hfs† mutation.
Functional assays were performed in plasma samples and in FVII-deficient plasma upon addition of rFVIIa or engineered FVII recombinant variants. The affinity of antibodies in patient's plasma for rFVIIa, pdFVII and recombinant variants was evaluated by binding and competition studies, using ELISA-based assays and Bio-Plex technology.
Results: Isotypic analysis showed a large prevalence of IgG subtype 1 in patient's plasma and functional assays indicated a type II kinetics. Activated factor X (FXa) and thrombin generation activity assays showed a major impact of inhibitory antibodies on the coagulation initiation phase, leading to prolonged lag times. Binding assays revealed a 1.5 fold higher affinity of the antibody for rFVIIa than for pdFVII. Noticeably, once activated pdFVII was recognized similarly to rFVIIa in competition assays.
The p.A354V-p.P464Hfs† mutation causes frameshift from residue 464 and predicts an elongated carboxy-terminal region (491 vs. 466 residues in FVII-wt). The inferred structural differences between the elongated FVII molecules circulating in patient and the infused factors led us to hypothesize the carboxy-terminal region as bearing a candidate epitope for the antibodies. Binding assays demonstrated that denatured and reduced FVII was not recognized by antibodies, thus supporting the presence of a tridimensional epitope.
To assess whether the carboxy-terminal region contributed to shape the major antibody epitopes we performed functional assays (i) in plasma from a patient homozygous for the p.R462X nonsense mutation, which produces low circulating levels of a truncated FVII with increased specific activity (Branchini et al, 2011) and (ii) by deletion scanning leading to the truncated recombinant FVII-466X, FVII-465X and FVII-464X variants, displaying normal specific activity. Strikingly, functional assays showed that the natural FVII-462X was less inhibited than FVII in pooled normal plasma. Moreover, studies with the truncated recombinant variants demonstrated that the carboxy-terminus length was related to the inhibition rate, being the shortest rFVII-464X the least inhibited variant, as indicated by a significant difference ($P < 0.0001$) in lag time prolongation in FXa generation assays. Accordingly, binding assays on the Bio-plex platform indicated that the rFVII-464X was the least recognized variant by the inhibitory antibodies.
Conclusions: Taken together our findings, which represent the first characterization of an anti-FVII inhibitor, indicated that antibodies were directed toward the carboxy-terminal region of infused FVII molecules. Data may suggest a relation between the *F7* mutation and major inhibitor epitopes.

PA 1.08-3

Association between thrombin generation and bleeding severity in 41 patients with coagulation factor VII deficiency

Lotta LA[1], Siboni SM[2], Lemma L[2], Clerici M[2], Menegatti M[2] and Peyvandi F[2]

[1]Angelo Bianchi Bonomi Hemophilia and Thrombosis Center; [2]Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico, Milan, Italy

Background: Coagulation factor VII (FVII) deficiency is a rare bleeding disorder with autosomal recessive inheritance. The association between levels of FVII (FVII:C) and bleeding severity in FVII deficiency is weak, although patients with levels below 25% have been reported to generally diplay more severe symptoms (J Thromb Haemost. 2012;10:615–21). Measuring FVII:C may therefore provide little information on the bleeding tendency of patients with this condition, hampering the development of optimal management strategies. Measurement of thrombin generation may provide a better method for quantifying the combined effect of procoagulant and anticoagulant factors in determining the bleeding predisposition of a patient.
Aims: To study the association of thrombin generation with bleeding severity in patients with FVII deficiency.
Methods: Between 2009 and 2011, patients with FVII deficiency (i.e. FVII:C below 62%) who had been visited at the Rare Bleeding Disorders Outpatient Clinic of the Angelo Bianchi Bonomi Hemophilia and Thrombosis Center (Milan, Italy) were recalled to the center for a follow-up clinical visit. Bleeding tendency was measured by a tailored bleeding severity score (BSS), compiled by the same physician (S.M.S.) on all participants. Thrombin generation was measured within 2 h of collection on freshly-prepared platelet-rich plasma, with the addition of 1 pM recombinant tromboplastin (IL, Orangeburg, NY, USA). Assay parameters that were used to quantify thrombin generation and their range of normal values (i.e. the 5th and 95th percentiles of the distribution in 43 normal subjects) were: lag-time (5–8 min), endogenous thrombin potential (1699–2937 nM/min), peak level of thrombin generation (137–252 nM), time-to-peak (10–15 min). The association of thrombin generation assay parameters with BSS was assessed by linear regression analysis adjusting for age and sex.
Results: A total of 41 patients with FVII deficiency were included in the study. Patients had a meadian age at enrollment of 40 years (interquartile range [IQR]: 21–49 years), were equally distributed between sexes (21 females, 20 males) and displayed mild to moderate bleeding symptoms (median BSS: 5; IQR: 2–9). Median FVII:C was 23% (IQR: 5–34%). Patients with FVII:C below 25% had higher BSS than patients with activity above 25% (median 8.5 vs. 3.0; difference 5.5, 95% confidence interval [CI]: 0–12). Thrombin generation results were as follows: lag-time, median: 8, IQR: 7–11 min; endogenous thrombin potential, median: 1848, IQR: 1632–2100 nM/min; peak, median: 182, IQR: 145–202 nM; time-to-peak, median 13, IQR: 12–15 min. Thrombin generation was inversely associated with bleeding tendency. Longer lag-time and time-to-peak were associated with higher BSS (lag-time, beta: 0.8; 95% CI: 0.0–1.6; $P = 0.046$; time-to-peak, beta: 0.7; 95%CI: 0.0–1.4; $P = 0.040$) and higher endogenous thrombin potential was associated with lower BSS (per 100 nM/min increase, beta: 0.6; 95% CI: 1.2–0.0; $P = 0.050$). Peak levels were not associated with BSS (beta: 0.0; 95% CI: −0.1 to 0.0; $P = 0.542$).
Summary/Conclusions: In patients with FVII deficiency, increased thrombin generation is associated with milder bleeding tendency.

PA 1.08-4

Characterization of a primary hemostasis abnormality in patients with OCRL1 gene mutations (Lowe syndrome)

Egot M[1], Lasne D[2], Baujat G[3], Payrastre B[4], Gratacap M-P[4], Mirault T[5], Elie C[6], Baruch D[7] and Bachelot-Loza C[7]

[1]Inserm UMR_S765; [2]Necker hospital, Assistance Publique Hopitaux de Paris (AP-HP); [3]AP-HP Génétique Pédiatrique, Hôpital Necker, Paris; [4]Inserm/UPS UMR 1048, Toulouse; [5]Inserm UMR_S765, Université Paris Descartes, Hôpital Européen Georges Pompidou; [6]Unité de Recherche Clinique, Université Paris Descartes, Hôpital Necker; [7]Inserm UMR_S765, Université Paris Descartes, Sorbonne Paris Cité, Paris, France

Background: The Lowe oculo-cerebro-renal syndrome (OCRL) is a rare X-linked disorder characterized by congenital cataracts, cognitive disability, and proximal tubular dysfunction. This syndrome results from loss-of-function mutations in the *OCRL1* gene, which encodes OCRL protein. OCRL is a type II phosphatidylinositol bisphosphate 5-phosphatase that contains a Rho-GAP and clathrin domains. Patients with Lowe syndrome often require surgical procedures and an abnormal rate of hemorrhagic events occurring per-or post-surgery have been reported, suggesting clot instability. In a preliminary study, we found that all patients ($n = 6$) had normal coagulation tests excepted for elevated levels of plasma fibrinogen and von Willebrand factor (VWF), but a prolonged closure time in the PFA-100® system.

Aim: The aim of this study was to characterize platelet functions of Lowe syndrome patients compared to controls.

Methods: Fourteen patients and 14 controls were enrolled in a 1-year prospective study. For each patient and control, a bleeding score (BS), derived from VW disease bleeding score, was calculated. Platelet function evaluation was performed using (i) light-transmission aggregation in the presence of various agonists (ii) flow-cytometry assays to quantify platelet membrane glycoprotein level (CD41, CD42, CD62 and CD63) at rest and after activation (iii) lysosome secretion by colorimetric quantification of *N*-acetyl-β-D-glucosaminidase, and (iv) platelet adhesion on collagen under flow. Finally, we studied clot retraction in platelet rich plasma (PRP) and in washed platelets (WP) in the presence of fibrinogen. Clots were formed by adding thrombin and calcium then, at various time points, clots were photographed and clot size was quantified. Clots were solubilized for western blotting analyses. The intensity of Myosin Light Chain (MLC) phosphorylation during clot retraction was evaluated using imageJ. Data presented are median [range] and statistical analysis used paired Wilcoxon tests.

Results: Median patient bleeding score was 3[0–11] (nine patients had positive BS ≥ 3) compared to 0 [(-3)-1] for controls ($P = 0.004$). We confirmed the prolonged PFA-epinephrin closure time in nine out of patients (162 s [126–300] vs. 120 s [97–174], $P < 0.0003$), with no abnormality in platelet aggregation, glycoprotein level or secretion assays. Although no significant difference was denoted in platelet adhesion level on collagen under flow, the size of platelet aggregates was significantly smaller in patients compared to controls 1874 μm^2 [114–5139] vs. 4169 μm^2 [1012–7188] ($P < 0.001$). We also found an abnormal kinetics of clot retraction in Lowe's patients; the PRP-clot retraction was 40% [11.3–71] in patients vs. 60% [30–89] in controls after 20 min ($P < 0.001$). This difference was also observed in WP (63% [27.5–92.5] vs. 70.5% [48–96.2], $P = 0.007$). Moreover, we evidenced a deregulation of MLC phosphorylation during clot retraction in patients compared to controls.

Summary/Conclusions: This study confirms a hemostasis defect in Lowe's patients, especially regarding abnormal clot retraction observed both in PRP and washed platelets. This defect is associated with a decrease of MLC activity, pointing to a deregulation of 'outside-in' signaling pathway. In conclusion, we provide for the first time that loss of OCRL protein is associated with an abnormal MLC signaling pathway during clot retraction. Abnormal clot retraction is in line with the observed re-bleeding events reported in patients.

Measurement of the 5- and 7-carbon aglycone vitamin K metabolites in term and preterm neonatal faecal matter using HPLC with electrochemical detection

Huisjes HR[1], Card DJ[1], Few K[2], Clarke P[2], Flesch FM[3] and Harrington DJ[1]

[1]GSTS Pathology, London; [2]Norfolk and Norwich University Hospitals NHS Foundation Trust, Norwich, UK; [3]Utrecht University, Utrecht, The Netherlands

Background: Vitamin K deficiency bleeding (VKDB) is a rare, but potentially life-threatening disease of the newborn. Prophylactic administration of vitamin K_1 at birth is protective, though further dose optimization remains desirable. Urinary excretion of vitamin K metabolites reflects vitamin K status in newborns, but the relationship between vitamin K exposure and vitamin K metabolite excretion in neonatal faecal matter is not yet understood.

Aim: Our aim was to develop a non-invasive method for measurement of the 5C- and 7C-aglycone metabolites of vitamin K in neonatal faecal matter using HPLC with electrochemical detection.

Methods: Faecal samples collected from term and preterm neonates were dried for 48 h at 37 °C and weighed to determine dry mass. Samples were then deconjugated overnight with methanolic HCl. The suspended faecal matter was pelleted by centrifugation and the methanolic HCl decanted. The metabolites were then extracted twice by Bligh and Dyer liquid-liquid extraction and dried under nitrogen. Stabilisation of the metabolites was achieved by conversion to the methyl ester derivatives using MNNG. Further purification was carried out by normal phase, solid phase extraction prior to a final drying stage under nitrogen. The extracts were then reconstituted in methanol and injected to the HPLC-ECD system. A Thermo Betasil C_{18} 100 × 4.6 mm column (3 μm) was used with a mobile phase of 37% polished, deionized water with a sodium acetate buffer (50 mM, pH = 3) and EDTA (0.1%) in methanol. The metabolites were first reduced using an ESA 5011A cell (−1.2 V) controlled by an ESA Coulochem II and subsequently detected using a HyRef VT-03 Electrochemical Flow Cell (+0.3 V, oxidative) controlled by a Decade II. Quantification was achieved using standards made from the pure methyl ester derivatives of the metabolites. LC-MS/MS was used to confirm the identities of the metabolites in the faecal extracts.

Results: Repeat extraction of the faecal matter indicated efficient extraction of the metabolites. The on-column lower limits of qualification (LLOQ) were 3.2 and 10.4 μg/g for the 5C- and 7C-metabolites respectively. The estimated total 5C- and 7C-metabolite excretory half-life values were 12.3 days in a 27-week gestation pre-term infant and 7.3 days in a 39-week gestation term infant, broadly consistent with previously published values for vitamin K_1 clearance in term neonates of 1.1–8.0 days (median 3.2 days). The relative quantity of 7C-metabolite in the preterm neonate declined from 60% of total metabolite excretion to 30% in 25 days (adults ≈ 25%), whereas this ratio was maintained at around 30% in the term neonate. Based on the mass of the parent and daughter ions, LC-MS/MS confirmed the identities of the methyl-ester metabolite derivatives.

Summary/Conclusion: These data provide proof of principle that the 5C- and 7C-metabolites of vitamin K can be detected and quantified in the faecal matter of term and preterm neonates. This method may help provide insight into post-prophylactic vitamin K metabolism in neonates. Further validation experiments are required to determine assay precision, accuracy, and recovery.

Novel homozygous mutation Met362Thr identified as a cause of cross-reacticting material reduced factor X deficiency in Japanese brother patients

Chikasawa Y, Shinozawa K, Amano K, Ogata K, Hagiwara T, Suzuki T, Inaba H and Fukutake K

Tokyo Medical University Hospital, Tokyo, Japan

Introduction: Factor X (FX) deficiency is a rare bleeding disorder inherited as an autosomal recessive trait. In this study, we diagnosed a new Japanese patient with congenital FX deficiency and identified a novel missense mutation in the FX gene (*F10*). We performed a recombinant mutant protein expression study to investigate the molecular basis of the genetic defects of the mutant.

Methods: FX activity was determined using a one-stage clotting assay based upon prothrombin time (PT), and FX antigen level was measured with a sandwich enzyme-linked immunoadsorbent assay (ELISA). After receiving informed consent, we obtained blood samples from the patient and his brother, and genomic DNA was extracted. Coding regions and exon/intron boundaries in *F10* were amplified by polymerase chain reaction (PCR). The PCR products were purified and direct sequenced with a 3730 DNA Analyzer (Applied Biosystems). We constructed an FX wild-type plasmid using the *F10* cDNA and the pcDNAtm 3.2 expression vector (Invitrogen). The identified mutation was introduced into the wild-type/pcDNAtm 3.2 plasmid with a QuikChange Site-Directed Mutagenesis Kit (Stratagene). Vectors expressing wild-type and mutant FX proteins were transfected into HEK293 cells with Lipofectamine reagent. Culture media and cells were harvested 60 h later, and culture media were concentrated using Amicon Ultra-15 centrifugal filter units (Millipore).

Patient and Results: The patient, a Japanese man in his early 40s, presented with gingival and nasal hemorrhage. His PT was 51.9 s (control, 11.7 s) and activated partial thromboplastin time (aPTT) was 74.7 s (control, 28.1 s). His younger brother had a past history of postoperative hemorrhage without prior spontaneous bleeding. Other family members had no significant bleeding symptoms. FX activities of the patient and his brother were both < 1%, and their FX antigens were 11% and 12%, respectively. A homozygous missense mutation, Met362Thr (HGVS names: c.1205 t>c, p.Met402Thr), was identified in *F10* from the patient and brother using direct sequencing. A Met362Thr mutation was not detected in the *F10* gene of 82 unrelated normal Japanese individuals. Study of recombinant protein expression revealed that the quantity of secreted FX antigen of the mutant and the wild-type were 1.4 and 4.5 μg/mL in concentrated conditioned media, respectively. It was suggesting that the secreted antigen level of the mutant was about 30% of the wild type. Therefore FX specific activity of the mutant was 19% of the wild-type.

Discussion: The patients were identified as having cross-reacting material reduced (CRM^{RED}) FX deficiency because of the existing of a certain amount of FX antigen with very low activity. Results of the recombinant protein expression study suggested that the mutant would cause a secretion defect and a molecular abnormality of FX.

Conclusion: We identified a novel homozygous Met362Thr mutation located in the catalytic domain of the FX protein as a causative mutation of CRM^{RED} FX deficiency. We will use this FX-Met362Thr mutant protein in our future studies of functional analysis.

Cysteine 584 is required for correct von Willebrand factor multimerization

Daidone V, Gallinaro L, Pontara E, Cattini GM, Zampese E, Pizzo P, Barbon G, Bertomoro A and Casonato A

University of Padua, Padova, Italy

Background: Cysteines have a key role in the dimerization and multimerization of von Willebrand factor (VWF), and their loss may have a great impact on the structure and function of VWF. There are 64 cysteines in the VWF propeptide (VWFpp), some of them involved in favoring interchain disulfide bonds at the N-terminus of VWF.

Aims: The present work describes a new VWF mutation (C584F) located in the VWFpp, reporting the effects of this mutation and using our findings to help explain the physiological process underlying the multimerization of VWF.

Methods: Three type 3 VWD patients were investigated, establishing their phenotype by analyzing their VWF antigen (VWF:Ag), VWF collagen binding (VWF:CB) activity, VWF ristocetin cofactor (VWF:RCo) activity, factor VIII (FVIII), platelet VWF content and multimer pattern. VWF gene mutations were identified by amplifying and sequencing all 52 exons of the VWF gene. Recombinant normal and mutated VWF was produced by transient transfection of HEK293T cells, using pSVvWF vectors. C584F-VWF trafficking was explored in BHK cells by co-expressing VWF and a Green Fluorescent Protein localized in the endoplasmic reticulum (ER) or Golgi apparatus.

Results: Plasma and platelet VWF:Ag were found at almost undetectable levels, as were VWF:CB and VWF:RCo, while FVIII levels were below 10 U/dL. Multimer analysis of plasma VWF revealed no multimers apart from the first oligomer, which was slightly represented. On high-resolution gel electrophoresis (2.2%) the protomer was resolved as a dimer running as the slow- and fast-running satellite of the triplet occurring in the normal counterpart. Genetic analysis showed that the patients were carrying two mutations: a deletion of seven nucleotides in exon 7 (c.729_735del) and the new C584F missense mutation, located in the propeptide of VWF. The C584F mutation was transiently expressed in the HEK293T cells, showing that C584F-VWF was virtually absent from the conditioned medium at homozygous levels. Multimer analysis demonstrated the absence of any multimers in the conditioned medium, except for the slightly represented first oligomer. Conversely, the intracellular VWF content was higher than normal, both when C584F was co-expressed with wild-type VWF, and when C584F-VWF alone was expressed. VWF:CB and its ratio (VWF:CB/VWF:Ag), which are parameters expecially sensitive to large VWF multimer representation, were found much reduced, suggesting that C584F-VWF is synthesized, but not multimerized.

The trafficking of rC584F-VWF showed a normal ER content of C584F-VWF, suggestive of a normal synthesis and dimerization of C584F-VWF, but a reduced localization in the Golgi apparatus, probably due to a defective transport of C584F-VWF from ER and/or its retention in the ER.

Conclusions: We conclude that the C584F mutation abolishes multimerization, but not dimerization, thus interfering with the storage and secretion of VWF. These findings suggest that C584F might be involved in the formation of the intermediate propeptide-dependent species during the VWF multimerization process.

PA 1.09-2

Von Willebrand factor activity determination using new assay principle ristocetin-free for reliable von Willebrand disease diagnosis

Caron C[1], Rugeri L[2], Rauch A[3], Susen S[4] and Goudemand J[4]
[1]*Laboratoire d'Hématologie, Lille;* [2]*Haematology Department, CHU, Lyon;* [3]*University Lille Nord de France, Faculté de Médecine;* [4]*Haematology and Transfusion Department, CHU, Lille, France*

Background: VWF:RCo assay is the reference method for VWD diagnosis despite its poor precision and sensitivity to low VWF activity. Last years, alternative platelets and/or ristocetin free methods have emerged to improve or replace the VWF:RCo assay. The Innovance® VWF Ac Assay (Siemens) is an automated immunoturbidimetric assay using polystyrene particles coated with rGPIb with two gain-of-function mutations avoiding requirement of ristocetin.

Aim and Methods: The aim of the study was to evaluate the performance of this new assay in screening and identification of the various type and subtypes VWD. Results of VWF:Ac, performed in two laboratories on Siemens analysers (Sysmex® CA-1500 and BCS) were compared to VWF:RCo performed using BC von Willebrand reagent on agregometer (SD Medical) or BCS.

Frozen plasma from 43 controls (21 blood group O and 22 non O) and from 172 VWD patients (67 type 1, 101 type 2 and four type 3) phenotypically and genotypically characterized (n = 108) were evaluated.

The two laboratories used the same bath of Standard Human Plasma (Siemens) for the calibration, and same batches of VWF:Ac and VWF:RCo reagents. The sensitivity of the method was evaluated on type 3 VWD samples using a low calibration curve and the imprecision using a normal and pathological control plasma (Siemens).

Type 1, type 3 carriers and type 2N have been grouped in Group A and type 2A, 2B and 2M grouped in group B for results analysis.

Statistical analysis was performed using t test comparison in paired series, Pearson linear regression and agreement estimation according Bland & Altman graphic representation plotting difference vs. mean.

Results: Sensitivity of VWF:Ac was lower than 4%, and lower compared to VWF:RCo methods (5% on agregometry and 10% on BCS). The imprecision was lower than 5% for VWF:Ac while VWF:RCo imprecision was respectively 14% (agregometry) and 15% (BCS).

In controls, a significant correlation between the two methods (r = 0.837, $P < 0.0001$) was observed with an estimated bias +3.5%. In O blood group, VWF:Ac and VWF:RCo means were 65.6 and 65.3 IU/dL respectively. In non O blood group, means were 98.8 and 92.1 IU/dL.

In VWD patients, a very good correlation (r = 0.965, slope = 1.04, $P < 0.0001$) was observed.

VWF:Ac and VWF:RCo means were 33.6 and 33.3 IU/dL respectively in group A, 19.8 and 16.4 IU/dL in group B (mean bias of +2.5% in group A and – 2% in group B).

Discrepant results were observed in only 7/168 samples (type 3 excluded).

In group A, VWF:Ac < VWF:RCo was found in two samples (2N, 1) and VWF:Ac>VWF:RCo in one (2N): [VWF:Ac – VWF:RCo] out of bias ± 2SD, i.e. [+17%; −12%].

In group B, VWF:Ac < VWF:RCo was found in three samples (2A, 2B, 2M/2Alike) and VWF:Ac>VWF:RCo in one (2M/2Alike): bias ± 2SD, i.e. [+7%; −11%].

Conclusion: Despite rare discrepant results (4%), Innovance® VWF Ac assay provides a simple sensitive and reliable test for diagnosing of VWD which seems as good as the reference method.

PA 1.09-3

Identification of VWF gene deletions in nine VWD families using multiplex ligation-dependent probe amplification (MLPA)

Theophilus BD[1], Baugh ML[1], Guilliatt AM[1], Wilde T[2], Motwani J[1] and Williams MD[1]
[1]*Birmingham Childrens Hospital;* [2]*Queen Elizabeth Hospital, Birmingham, UK*

The current classification of von Willebrand Disease (VWD) is based on quantitative (type 1 and 3) or qualitative (type 2) deficiencies of von Willebrand factor (VWF). VWD has a heterogenous mutational basis, but about 10% of severe VWD are caused by either single or multiple exon deletions in heterozygous or homozygous form. Exon deletions in homozygous patients with VWD can be detected by an absence of PCR products of the deleted fragment. However, the detection of deletions in heterozygous form is more difficult because of the presence of the normal allele. Multiplex ligation-dependent probe amplification (MLPA) is a method for the relative quantitation of exonic sequences of a gene in a single reaction. MLPA is a rapid, sensitive and reproducible method based on the ligation and amplification of sequence-specific probes. We have used MLPA to investigate nine families with VWD in whom mutations were either not detected by DNA sequencing, or in whom a second mutation was suspected because of the VWD phenotype. A number of novel abnormalities have been detected using this technique.

In family 1, we identified a novel deletion of exons 4–52 in a male with type 3 disease, in compound heterozygous form with a previously reported single base duplication in exon 14. In family 2, we identified a novel deletion of exons 19–52 in heterozygous form in a male with type 3 disease, in compound heterozygous form with a novel point mutation in exon 14. In family 3, we identified a novel deletion of exon 22 in heterozygous form in a male with type 1 disease. In family 4, we identified a previously reported deletion of exons 33–34 in an individual with type 2 unclassified VWD and abnormal VWF:Ag multimer pattern. Deletion of *VWF* exons 4–5, previously reported to be recurrent among type 3 VWD and to underlie a proportion of dominant type 1 VWD was identifed in three individuals with type 1 VWD. In the remaining two cases, MLPA did not produce a signal for exon 7 in an individual with type 3 VWD, or for exon 45 in an individual with severe type 1 VWD. However, subsequent PCR and DNA sequencing revealed these results to be false postives arising from a novel 2 bp deletion and a novel nonsense mutation respectively in the respective MLPA probe binding sites.

MLPA is a useful addition to DNA sequencing and other screening methods for the identification of deletions, and potentially insertions, in VWF where the genotype determined by standard methods does not fully explain the VWD phenotype. This method facilitates genetic counselling to family members, but care should exercised in data interpretation, particularly with single exon deletions where a false positive may be generated by sequence changes in the probe binding site.

PA 1.09-4

Characterization of von Willebrand factor and ADAMTS13 in plasma derived factor concentrates

Konkle BA[1], Fletcher SN[1], Lannert KW[1], Johnsen JM[1], Bergman GEG[2] and Teramura G[1]
[1]*Puget Sound Blood Center, Seattle, WA;* [2]*Kedrion Biopharma, Fort Lee, NJ, USA*

Background: Prevention or treatment of bleeding in patients with von Willebrand disease (VWD) may require infusion of virally-inactivated plasma-derived von Willebrand factor (VWF)-containing concentrates. Three products are FDA approved in the US for treatment of patients with VWD; all contain VWF and factor (F) VIII. Koate®-DVI is a FVIII/VWF containing concentrate FDA licensed in the US for treatment of hemophilia A.

Aims: The aims of the study were to evaluate VWF and ADAMTS13 laboratory parameters in Koate®-DVI and compare to findings in the three FDA-licensed concentrates for treatment of VWD.
Methods: Koate®-DVI, provided by Kedrion Biopharma Inc. (nine lots), and three lots each of the other concentrates (noted as A, B and C), were purchased, and all reconstituted per the manufacturers' recommendations. For VWF and FVIII assays aliquots were diluted in VWF deficient plasma to a concentration of approximately 1 U/mL of FVIII for Koate®-DVI and approximately 1 U/mL of VWF for products A,B, and C. FVIII:C activity was measured by one stage assay (Siemens Actin FSL and deficient plasma), VWF antigen (VWF:Ag) by STA Liatest (Stago) and VWF ristocetin cofactor activity (VWF:RCof) by Siemens BC reagent on the BCS®XP coagulometer. VWF collagen binding (VWF:CB) and FVIII antigen (FVIII:Ag) were determined by ELISA (Technoclone and Affinity Biochemicals, respectively). VWF multimers were analyzed on 1% agarose gels. ADAMTS13 activity was measured in reconstituted concentrate using a FRET-based assay (GTI). Assays were performed in triplicate.
Results: Mean VWF parameters (given as ratios with ranges) for Koate®-DVI were VWF:RCof/VWF:Ag, 0.93 (0.82–1.02); VWF:CB/VWF:Ag, 1.05 (0.95–1.08); FVIII:C/VWF:Ag, 0.50 (0.43–0.55); and, FVIII:Ag/VWF:Ag, 0.45 (0.41–0.48). For concentrates: VWF:RCof/VWF:Ag: A = 0.66 (0.57–0.80), B = 0.53 (0.48–0.67), C = 0.65 (0.62–0.71); VWF:CB/VWF:Ag: A = 0.92 (0.91–0.93), B = 0.98 (0.96–1.0), C = 1.02 (0.92–1.05); FVIII:C/VWF:Ag: A = 0.42 (0.40–0.44), B = 0.67 (0.63–0.69), C = 0.94 (0.89–0.97); and, FVIII:Ag/VWF:Ag: A = 0.28 (0.26–0.32), B = 0.49 (0.47–0.52), C = 0.75 (0.70–0.83). All concentrates contained VWF intermediate-sized molecular weight multimers, defined as > 6–9 bands on the 1% agarose gel. Of the nine Koate®-DVI lots 7 (78%) contained high molecular weight multimers, defined as > 10 bands. This compared with 50% for concentrate B and 100% for concentrates A and C. Koate®-DVI contained more ADAMTS13 activity than the other concentrates, with two concentrates containing virtually no activity (Koate®-DVI: 577.1 ± 96.1; Concentrate A: 23.0 ± 10.4; Concentrate B: 140.1 ± 21.0; Concentrate C: 18.0 ± 4.4). ADAMTS13 activity per labeled FVIII activity for Koate®-DVI was 0.057 and per labeled VWF activity for the other concentrates was: A: 0.002, B: 0.013, C: 0.002.
Summary: Koate®-DVI contains approximately twice the VWF:Ag and activity as FVIII and has parallel VWF protein and functional measurements. VWF:CB was more consistent with the VWF:Ag measurement than was VWF:RCof in the other concentrates. Koate®-DVI contains more ADAMTS13 activity than found in the other concentrates; however, this was not associated with loss of high molecular weight multimers, and all concentrates have considerably less ADAMTS13 activity than labeled FVIII or VWF activity. These data should be of help to physicians treating patients with bleeding disorders.

PA 1.09-5
Development of the self-PBQ (Self-administered pediatric bleeding questionnaire): pre-testing and optimization

Rand ML[1], Tuttle AM[2], Grabell J[2], Moorehead PC[2], Deforest M[2], Wu J[3], Steele McG[4], Klaassen R[5], Silva M[2] and James PD[2]
[1]The Hospital for Sick Children, Toronto, ON; [2]Queens University, Kingston, ON; [3]The Child and Family Research Institute, Vancouver, BC; [4]Alberta Children's Hospital, Calgary, AB; [5]Children's Hospital of Eastern Ontario, Ottawa, ON, Canada

Background: Expert-administered bleeding assessment tools have been developed and prospectively validated for the diagnosis of von Willebrand disease (VWD).
Aim: To generate, pre-test and optimize a self-/parent-administered pediatric bleeding questionnaire.
Methods: The validated expert-administered Pediatric Bleeding Questionnaire (PBQ) (Bowman et al, JTH, 2009; 7:1418) was modified into the Self-PBQ Version #1 by simplifying the language to a Grade 4 reading level. Two groups of research subjects (< 18 years) were recruited: (i) children with known Type 1 VWD; and (ii) healthy control children. Parents completed the Self-PBQ for children < 12 years while children ≥ 12 years completed the Self-PBQ themselves if able to read at a Grade 4 reading level. The expert-administered PBQ was completed at a separate visit by face-to-face interview. All subjects completed the Self-PBQ and the expert-administered PBQ in random order at least 2 weeks apart, and the bleeding scores (BS) obtained from each were compared using the Interclass Correlation Coefficient (ICC). Focus groups were held following the second visit, and revisions made to the Self-PBQ based on feedback before subsequent recruitment.
Results: To date, a total of 36 subjects have been recruited; nine with Type 1 VWD and 27 controls; the Self-PBQ has undergone two revisions. The median age and gender distribution is similar between groups; 9.4 years in the affected group (range of 3–17) and 5.9 years in the control group (range of 9 months–17; $P = 0.078$), $n = 4$ female (44%) in the affected group and $n = 13$ female (48%) in the controls ($P = 1.00$). The mean BS in the affected group was 3 (range 0–7) from the Self-PBQ and 3.8 (range 1–9) from the expert-administered PBQ. The mean BS in the controls was 0.5 (range −1 to 2) from the Self-PBQ and 0.2 (range 0–1) from the expert-administered PBQ. For both the Self-PBQ and expert-administered PBQ the BS were significantly higher in the affected children compared with controls ($P = 0.015$ and $P = 0.003$ respectively). Four affected and 15 unaffected parents/children completed version #1 of the Self-PBQ. The ICC = 0.676, and the main concern during the focus group was the use of the word 'problem' in the question stems (ie: 'Has the research participant ever had a problem with nosebleeds?'), so this word was removed for Version #2. Four affected and eight unaffected parents/children completed Version #2; the ICC = 0.973. The focus group feedback resulted in the addition of the instruction at the beginning of the questionnaire 'If you are not sure whether the answer is yes or no (to each question about bleeding), answer yes' to Version #3. One affected and four unaffected children have been enrolled and are in the process of completing both study visits with Self-PBQ Version #3.
Conclusions: A self-/parent-administered pediatric bleeding questionnaire has been optimized and the BS obtained from its administration show a high degree of correlation with expert-administered BS. Future directions include prospective validation as a screening tool for children referred to Hematology for investigation of a bleeding disorder.

Genetic defect of von Willebrand disease in 30 Taiwanese patients

Chen YC[1], Cheng S-N[2], Hu SH[3] and Yiang YF[3]
[1]Divison of Hematology/Oncology, Hemophilia Care and Research Center; [2]Department of Pediatrics; [3]Hemophilia Care and Research Center, Taipei, Taiwan

Background: Von Willebrand disease (VWD) is the most common inherited bleeding disorder that results from quantitative and/or qualitative defects of the von Willebrand factor (VWF). Genetic study of VWF may provide information useful for VWD diagnosis, subtype classification and management.
Aim: To analyze the genetic defects in our cohort of VWD patients.
Methods: There were 30 patients (13 male and 17 female) from 25 unrelated families with VWD diagnosis enrolled from January 2008 to January 2013. The median age was 31 years with a rage of 14–56 years. Exon 28 of VWF gene was amplified using polymerase chain reaction followed by direct sequencing. Mutations in the other 51 exons were detected by Denaturing High-Performance Liquid Chromatography analysis.

Results: Of the 30 patients in the cohort, 21 had type 1 VWD, seven had type 2 VWD including six type2A and one 2N. Two patients had type 3 VWD. Eight of 30 (27%) patients were identified to have a VWF gene mutation. Four patients from two unrelated families with type2A VWD were found to have c3814T>G, C1272G and c4883T>C, I1628T, respectively. Three patients with type 1 VWD were revealed to have missense mutations including c.4499C>T, A1500V in two and c.7848T>A, S2516R in exon44 in one patient. One patient with type 3 VWD was identified to have IVS27+2T>C transition. Another 17 (57%) patients (16 type 1 and one type 2 VWD) of our 30 patients from 14 unrelated families were found to have polymorphisms of the VWF gene.
Conclusions: Our study demonstrated that around one third of VWD patients had a detectable genetic defect and there was also a high percentage of polymorphisms in our cohort.

Observed practice of bridging anticoagulation; guideline adherence and risk factors for perioperative bleeding

Eijgenraam P, Ten Cate H and Ten Cate-Hoek AJ
Maastricht University, Maastricht, The Netherlands

Background: Perioperative interruption of chronic anticoagulation harbors the risk of thromboembolism (TE). To minimize the risk for TE during the anticoagulant free interval, bridging therapy with low molecular weight heparins (LMWH) is applied. This introduces the risk of bleeding. Guidelines characterize patients at risk and strategies to be followed.
Aims: We conducted a search of two electronic patient data systems. Our primary goal was to delineate the features of bridging strategies applied in the region aroundMaastricht, theNetherlands. We intended to assess guideline-adherance and to document the incidence of bridging-related bleeding and TE. The secondary goal was to identify possible risk factors for bleeding during bridging therapy, both patient related risk factors and risk factors associated with the bridging strategy itself.
Methods: We searched from September 2010 until June 2012 the electronic patient data system of theMaastrichtanticoagulation service, which contains data of approximately 4200 patients in relation to anticoagulation therapy and treatment complications. Additional medical information for these patients was retrieved from the patient database of the Maastricht University Medical Centre (MUMC+). We identified 222 patients on chronic anticoagulation who received bridging therapy. We determined guideline-adherence and risk factors for major and overall bleeding. Guideline adherence was defined as low TE risk patients receiving prophylactic doses LMWH and intermediate to high TE risk patients receiving prophylactic or therapeutic doses. Patients without prior surgical bleedings undergoing low risk cataract operations, dental procedures, or dermatological procedures should not be bridged, and the duration of postoperative administration of LMWH should not exceed 7 days. Data were analyzed with SPSS version 19.0.0.
Results: In 27.9% of all cases bridging was installed for a procedure for which bridging was not indicated. The proportion of patients at low TE risk (n = 102) treated with therapeutic doses of LMWH was 84.3% (n = 86). The median duration of postoperative bridging with LMWH was 8 days (mean: 10.0, standard deviation: 6.7). The 30-day incidence of overall bleeding in the entire group (n = 222) was 19.8% (n = 44), the incidence of major bleeding 11.3% (n = 25). Two patients (0.90%) experienced a deep venous thrombosis. In univariable logistic regression analysis high TE risk (odds ratio (OR), 2.59; 95% confidence interval (CI), 1.11–6.04) and dental procedures (OR, 2.99; 95% CI, 1.45–6.13) were found to be risk factors for overall bleeding. Vitamin K administration (OR, 6.55; 95% CI, 1.01–42.52) and dental procedures (OR, 3.77; 95% CI, 1.60–8.86) were identified as independent predictors of overall bleeding, after adjusting for age, total duration of LMWH treatment, TE risk, creatinine clearance, and mitral valve replacement.
Conclusions: Guideline-adherence for bridging therapy was low, leading to prolonged bridging procedures, excess treatment of patients and overall high bleeding rates. The majority of patients had a low thromboembolic risk profile or underwent low risk procedures. The independent risk factor Vitamin K administration may be an indicator for perioperative elevated INR.

PA 1.10-2
The coagulation factor XIIa inhibitor rHA-Infestin-4 potently improves outcome after cerebral ischemia/reperfusion injury in rats

Krupka J[1], May F[1], Kaspereit F[1], Pragst I[1], Weimer T[1], Kleinschnitz C[2], Stoll G[2], Dickneite G[1] and Nolte MW[1]
[1]CSL Behring, Marburg; [2]University of Wuerzburg, Wuerzburg, Germany

Background: Ischemic stroke provokes initial brain damage and is still one of the most predominant diseases in industrialized countries with a high rate of mortality or severe disability, respectively. To reduce primary insults based on the main pathophysiological processes of vessel occlusion in the brain, restoration of blood flow is essential. Paradoxically, reperfusion of brain tissue triggers further pathophysiological mechanisms and results in a process termed ischemia/reperfusion injury (I/R injury). The coagulation factor XII (FXII)-driven contact activation system is widely discussed to play an important role within the processes of I/R injury.
Aims: The aim of the current studies was to assess the efficacy of the FXIIa-inhibitor rHA-Infestin-4 in a rat model of I/R injury in a prophylactic and a therapeutic medication.
Methods: Rats were randomly assigned to the treatment groups and all studies were performed in a blinded manner. Within prophylactic treatment, animals were treated intravenously with 100 mg/kg rHA-Infestin-4 or an equal volume of saline 15 min prior to transient middle cerebral artery occlusion (tMCAO). For therapeutic treatment, 100 mg/kg rHA' -Infestin-4 or an equal volume of saline was administered directly after start of reperfusion. tMCAO was induced using the filament technique. Occlusion held up for 90 min with subsequent reperfusion. Twenty-four hours after tMCAO, rats were tested for neurological deficits (Zea Longa score, a composite neurological score, rotarod assay and grip strength test). Thereafter, brains were removed and analyzed for infarct area and edema formation. Furthermore, blood was terminally withdrawn within the prophylactic treatment approach for additional coagulation assays.
Results: Compared to the control group, rHA-Infestin-4 significantly improved survival in both, the prophylactic as well as therapeutic treatment. Moreover, neurological deficits by means of Zea Longa score and a inhibition of FXIIa and aPTT prolongation were still prominent 24 h after tMCAO whilst PT was not affected.
Summary/Conclusions: Although beneficial effects were more prominent within the prophylactic treatment, rHA-Infestin-4 competently ameliorated outcome after acute ischemic stroke in rats. With regard to the central role of FXII-driven contact activation system in stroke, inhibition of FXIIa via rHA-Infestin' – 4 may represent a new and promising treatment approach for brain I/R injury.

Development of a clinical prediction model for an INR = 4.5 in hospitalized patients treated with vitamin K antagonists

Lindemans AD, Van Blijderveen JC, Kruip JHA, Vergouwe Y, Sturkenboom MCJM, Vulto AG and Van Den Bemt P

Erasmus MC, Rotterdam, The Netherlands

Background: Bleeding is a serious and frequently occurring complication in patients treated with vitamin K antagonists (VKAs). In the Netherlands, over 2.5% of the population is treated with VKAs. Treatment is usually monitored by measuring the clotting time, expressed as the international normalized ratio (INR). Optimal treatment depends on the indication but is normally in the range of 2.0–4.0. The risk of bleeding increases considerably at an INR above 4.5. Many other factors than dosage alone influence the INR. A few prediction models, based on these other factors for a high INR and/or bleeding complications can be found in literature. However, not all risk factors included in these models are readily available in daily practice, thereby limiting the usability of these models.

Aim: To develop a model designed to predict the risk of an INR $\geq$ 4.5 for hospitalized patients treated with VKAs, based on risk factors that are collected during routine care.

Methods: This is a retrospective cohort study conducted in a large university hospital in theNetherlands. Data on medication, laboratory results, admission and discharge dates are embedded in an electronic patient database (EPD).

We included admissions of adult patients in 2006–2009 during which a VKA was prescribed. Patients were followed from start of VKA treatment until their first INR $\geq$ 4.5, the end of treatment with a VKA, discharge, or until the end of the study, whichever came first.

Predictors included in the analysis were: age, sex, blood group, type of patient (surgical or medical), an INR $\geq$ 4.5 during an earlier admission (previous event), and at start of VKA therapy: the number of concomitantly used medicines, concomitant use of low molecular weight heparins (LWMHs) and/or amiodarone, and the laboratory values of liver enzymes: ALAT, ASAT, y-GT, LDH, albumin, haemoglobin, haematocrit, renal function, c-reactive protein (CRP), the number of thrombocytes and leucocytes. Obvious insignificant predictors (P-value > 0.2) were stepwise removed from the model.

Results: In 2006–2009 we included 4762 admissions of 3798 individual patients. We found 1128 admissions (23.7%) during which an INR $\geq$ 4.5 was found for 920 individual patients.

Strongly significant positive predictors were: age (odds ratio (OR) 1.01 per year, 95% confidence interval (CI) 1.004–1.014), being a medical patient (OR 1.56, 95% CI 1.29–1.89), concomitant use of amiodarone (OR 1.52, 95% CI 1.22–1.91), a previous event (OR 1.28, 95% CI 1.03–1.57) and the number of concomitantly use medicines (OR 1.15, 95% CI 1.06–1.25).

Predictors associated with a lower risk of an INR $\geq$ 4.5 were: male sex (OR 0.80; 95% CI 0.69–0.94) and the concomitant use of LMWHs (OR 0.625, 95% CI 0.503–0.776).

Summary/Conclusions: Ten predictors that positively contribute to the increased risk of an INR $\geq$ 4.5 were identified. The strongest predictors were: being a medical patient, concomitant use of amiodarone and an INR $\geq$ 4.5 during a previous hospital admission. The prediction model with routinely collected data can be used to identify high risk patients in every day practice, enabling targeted care by physicians and pharmacists

Inhibiting coagulation factor XIIa potently prevents thrombosis in a rabbit arteriovenous shunt model

Fries M[1], Krupka J[1], Kaspereit F[1], Rayzman V[2], Wilson MJ[2], Pragst I[1], Weimer T[1], Panousis K[2], Dickneite G[1] and Nolte MW[1]

[1]CSL Behring GmbH, Marburg, Germany; [2]CSL Limited, Parkville, Vic., Australia

Background: The intrinsic pathway of coagulation is initiated by contact activation of coagulation factor XII (FXII) at negatively charged surfaces, such as glass *in vitro* or platelet polyphosphates and collagen *in vivo*. Contact activation resulting from the exposure of blood to foreign surfaces from implanted prosthetics (e.g. artificial heart valves) or during invasive medical procedures such as cardiopulmonary bypass surgery can trigger life-threatening thrombotic processes and requires robust anticoagulation. However, anticoagulants are associated with an increased bleeding risk and need to be used cautiously. Interestingly, recent studies have demonstrated that FXII-deficient mice as well as rodents treated with FXIIa inhibitors display a robust antithrombotic efficacy without impairment of physiological hemostasis. These findings suggest that inhibiting FXIIa may serve as an ideal antithrombotic approach, especially in medical scenarios involving contact activation at foreign surfaces.

Aims: In the present study an arteriovenous (A/V) shunt model containing a procoagulant glass element was employed to assess the antithrombotic efficacy of two selective and potent inhibitors of FXIIa, i.e. rHA-Infestin-4, a recombinant protein derived from the hematophagus insect *Triatoma infestans*, and a fully human monoclonal antibody (anti-FXIIa MAb).

Methods: Female rabbits were randomly assigned to study groups and treated intravenously with either a single dose of 100 mg/kg rHA-Infestin-4 or 7 mg/kg anti-FXIIa MAb 10 min prior to the start of blood flow through the A/V shunt. Control groups received isotonic saline or 300 IU/kg heparin, respectively. Blood flow was monitored for 30 min in the rHA-Infestin-4 study whilst in the second study (anti-FXIIa MAb) the observation time was extended to 60 min. At the end of the observation period, thrombus weights and bleeding parameters (ear and kidney bleeding) were evaluated.

Results: In saline treated controls profound occlusion of the glass element in the A/V shunt was observed, whereas heparin treatment prevented thrombus formation as expected. Both rHA-Infestin-4 and anti-FXIIa MAb treatment potently inhibited thrombotic occlusion of the A/V shunt. Most notably and in sharp contrast to the increased bleeding observed with heparin treatment, neither ear bleeding time, nor time to hemostasis or blood loss after kidney incision were impaired by rHA-Infestin-4 or anti-FXIIa MAb.

Summary/Conclusion: The results of this study clearly demonstrate a potent antithrombotic efficacy of FXIIa inhibition by rHA-Infestin-4 and anti-FXIIa MAb in a rabbit arteriovenous shunt model where occlusive thrombus formation is initiated by contact activation on a glass surface. Importantly, inhibiting FXIIa had no effect on physiological hemostasis. Therefore, targeting FXIIa may represent a new approach for safe anticoagulation therapy in medical scenarios involving contact activation at foreign surfaces.

Treatment of acute VTE with rivaroxaban. updated results of the prospective Dresden NOAC registry (NCT01588119)

Beyer-Westendorf J, Ebertz F, Gelbricht V, Förster K, Köhler C and Werth S

Dresden University Hospital, Carl Gustav Carus, Dresden, Germany

Background: In the EINSTEIN program rivaroxaban has been found to be at least as effective and safe as warfarin in treatment of acute

venous thromboembolism (VTE), which lead to approval of rivaroxaban in many countries. However, patients in RCT's present a selected population treated under a strict protocol and followed for a short period of time. Consequently, efficacy and safety of new oral anticoagulants (NOAC) need to be confirmed in cohorts of unselected patients in daily care.

Aims: To evaluate the efficacy and safety of acute VTE treatment with rivaroxaban in daily care.

Patients and Methods: The Dresden NOAC registryis a prospective, non-interventional registry. A network of more than 230 physicians from private practice and hospitals enrol eligible patients, who are centrally followed by the registry office. Inclusion criteria are: 1) indication for therapeutic NOAC anticoagulation > 3 month; 2) age > 18 years; 3) written informed consent; 4) availability for follow-up. No Exclusion criteria apply. In the registry, up to 2000 patients will receive prospective follow up (FU) by phone visits at day 30 day and quarterly thereafter to collect efficacy and safety data. All events are centrally adjudicated based on copies of reports, patient charts, autopsy reports and death certificates and using standard definitions.

Results: Until December 31th 2012, 1665 patients were registered. Of these, 233 patients received rivaroxaban for acute VTE treatment (54.9% female). In our registry, the population receiving acute VTE treatment is older than the EINSTEIN population (63.5 vs. 55.8 years). Most patients were treated for DVT vs. PE (74.7% vs. 25.3%) and 28.3% had recurrent VTE.

During follow-up, no recurrent VTE event occurred, but one patient (0.48 per 100 patient years) had a major cardiovascular event (acute limb ischaemia). Furthermore, 71 patients (34 per 100 patient years) had bleeding complications, in eight cases (3.8 per 100 patient years) major bleeding according to ISTH definition, one of which was a fatal intracranial bleeding (0.48 per 100 patient years). Eight patients died (3.8 per 100 patient years) but none of acute thromboembolic or cardiovascular events (three terminal malignant disease, two chronic heart failure, two sepsis, one fatal bleeding).

At 6 month, 61.5% of patients were still taking rivaroxaban. The remaining patients had planned end of treatment (34.2%), were switched to other anticoagulants (4.3%, mostly for side effects or cost issues) or prematurely discontinued (4.3%). Therefore, unplanned discontinuation rate at 6 month was 8.6% (mostly side effects, cost issues, incompliance, malignant disease, unplanned surgery).

Conclusions: In unselected patients in daily care, acute VTE treatment with rivaroxaban is effective and safe with low rates of cardiovascular or bleeding events in the first 180 days of treatment. Overall, adherence to rivaroxaban therapy is over 90% and unplanned discontinuations occur in < 10% and equally because of side effects, cost issues or concomitant diseases.

For presentation at the ISTH meeting, updated results on demographic and clinical characteristics at baseline, cardiovascular and bleeding event rates will be provided.

The FXIIa inhibitor rHA-Infestin-4 safely protects from arterial and venous thrombosis in rodent and non-rodent species

May F[1], Krupka J[1], Thielmann I[2], Schenk S[1], Letmade P[1], Pragst I[1], Weimer T[1], Nieswandt B[2], Dickneite G[1] and Nolte MW[1]

[1]CSL Behring GmbH, Marburg; [2]University Hospital Wuerzburg and Rudolf Virchow Center, Wuerzburg, Germany

Background: Ischemic stroke provokes initial brain damage and is still one of the most predominant diseases in industrialized countries with a high rate of mortality or severe disability, respectively. To reduce primary insults based on the main pathophysiological processes of vessel occlusion in the brain, restoration of blood flow is essential. Paradoxically, reperfusion of brain tissue triggers further pathophysiological mechanisms and results in a process termed ischemia/reperfusion injury (I/R injury). The coagulation factor XII (FXII)-driven contact activation system is widely discussed to play an important role within the processes of I/R injury.

Aims: The aim of the current studies was to assess the efficacy of the FXIIa-inhibitor rHA-Infestin-4 in a rat model of I/R injury in a prophylactic and a therapeutic medication.

Methods: Rats were randomly assigned to the treatment groups and all studies were performed in a blinded manner. Within prophylactic treatment, animals were treated intravenously with 100 mg/kg rHA-Infestin-4 or an equal volume of saline 15 min prior to transient middle cerebral artery occlusion (tMCAO). For therapeutic treatment, 100 mg/kg rHA' -Infestin-4 or an equal volume of saline was administered directly after start of reperfusion. tMCAO was induced using the filament technique. Occlusion held up for 90 min with subsequent reperfusion. Twenty-four hours after tMCAO, rats were tested for neurological deficits (Zea Longa score, a composite neurological score, rotarod assay and grip strength test). Thereafter, brains were removed and analyzed for infarct area and edema formation. Furthermore, blood was terminally withdrawn within the prophylactic treatment approach for additional coagulation assays.

Results: Compared to the control group, rHA-Infestin-4 significantly improved survival in both, the prophylactic as well as therapeutic treatment. Moreover, neurological deficits by means of Zea Longa score and a composite neuroscore were significantly reduced after application ofrHA-Infestin-4 in both treatment approaches. In addition, prophylactic application of rHA-Infestin-4 significantly reduced infarct area and edema formation, and furthermore significantly improved performance in the rotarod assay and grip strength test. Using the therapeutic setting, a trend towards improvement in infarct area and edema formation was found whilst performance in the rotarod assay and grip strength test was unchanged between the groups. Following application ofrHA-Infestin-4, inhibition of FXIIa and aPTT prolongation were still prominent 24 h after tMCAO whilst PT was not affected.

Summary/Conclusions: Although beneficial effects were more prominent within the prophylactic treatment, rHA-Infestin-4 competently ameliorated outcome after acute ischemic stroke in rats. With regard to the central role of FXII-driven contact activation system in stroke, inhibition of FXIIa via rHA-Infestin' -4 may represent a new and promising treatment approach for brain I/R injury.

Activated Factor VII. Antithrombin Complex plasma concentration in subjects with or without angiographically demonstrated coronary artery disease and myocardial infarction

Tosi F[1], Martinelli N[1], Baroni M[2], Girelli D[1], Guarini P[1], Udali S[1], Branchini A[2], Woodhams B[3], Bernardi F[2] and Olivieri O[1]

[1]University of Verona, Verona; [2]University of Ferrara, Ferrara, Italy; [3]HaemaCon Ltd, Bromley, Kent, UK

Background: Plasma concentration of activated factor VII (FVIIa)-antithrombin (AT) complex has been recently proposed as a marker of intravascular exposure of tissue factor and, thus, of activation of the extrinsic pathway of coagulation cascade. However, the results of studies investigating the potential relationship between FVIIa-AT complex and cardiovascular disease are only preliminary so far.

Aims: The aim of this study was to investigate the relationship of FVIIa-AT complex plasma concentration with either coronary artery disease (CAD) or myocardial infarction (MI) in a case-control setting.

Methods: Within the framework of the Verona Heart Study (VHS), a regional survey aimed to search for new risk factors for CAD/MI in subjects with angiographic documentation of their coronary vessels, we selected a total of 686 subjects (546 CAD and 140 CAD-free), who

were not taking anticoagulant drugs and for whom plasma citrate samples for FVIIa-AT complex assay were available. Among CAD patients, 312 CAD had a history of previous MI. Plasma concentration of FVIIa-AT complex was determined by ELISA.

Results: There was no significant difference in plasma concentration of FVIIa-AT complex between CAD and CAD-free subjects (84.8 (80.6–88.2) vs. 83.9 (76.7–92.8) pM, respectively – $P = 0.949$). On the other hand, among CAD patients those with history of previous MI had lower FVIIa-AT complex levels than those without history of previous MI (79.8 (75.9–83.9) vs. 90.9 (85.6–97.5) pM, respectively – $P = 0.008$) and this association remained significant in a regression model also after adjustment for all the traditional cardiovascular risk factors.

Evaluating the potential relationships of FVIIa-AT complex with other clinical and laboratory variables in the whole study population, we found significant correlations with gender (higher in females), diabetes (higher in diabetic patients), body mass index (BMI), estimated glomerular filtration rate, total cholesterol, HDL-cholesterol, and triglycerides. In 305 subjects, for whom data about FVIIa levels and FVII genotype were available, a very strong direct correlation with FVIIa was found (beta coefficient = 0.533, $P < 0.001$). Moreover, FVII genotypes known to influence FVIIa levels (e.g. −323 A1/A2 and R353Q polymorphisms) were associated – in a concordant manner with FVIIa levels – also with significantly different concentrations of FVIIa-AT complex.

In a multiple adjusted linear regression model explaining the 34% of FVIIa-AT complex variability, FVIIa (beta coefficient = 0.464, $P < 0.001$), estimated glomerular filtration rate (beta coefficient = −0.131, $P = 0.044$), HDL-cholesterol (beta coefficient = 0.147, $P = 0.039$), and triglyceride (beta coefficient = 0.201, $P = 0.002$) remained significant predictors of FVIIa-AT plasma concentration. On the other hand, the statistical association of FVII genotypes with FVIIa-AT concentration appeared to be mediated by the influence on FVIIa levels.

Conclusions: In this case-control study FVIIa-AT complex plasma concentration was associated with some cardiovascular risk factors, like plasma lipids and renal function, as well as with FVIIa levels. There was no significant difference between subjects with or without CAD. On the other hand, the association of low levels with MI history among CAD subjects should be further investigated and could derive from some potential biases (e.g. survival-related bias). Additional studies are needed to clarify the role of FVIIa-AT complex in CAD and MI.

PA 1.11-2

The appearance of the second peak in platelet rich plasma thrombin generation curve can be provided by antiplatelet compounds: mechanism and possible applications

Ivan T[1], Artemenko E[1], Kopylov K[2], Kumskova M[2], Panteleev MA[1], Sinauridze E[2] and Ataullakhanov F[1]

[1]The Center for Theoretical Problems of Physicochemical Pharmacology RAS; [2]The National Centre for Hematology, Moscow, Russian Federation

Background: Measurement of thrombin generation in clotting blood plasma is now convenient and informative test to analyze a status of coagulation system. Usually the thrombin generation curve obtained in platelet poor plasma (PPP) has one peak. Here we show that this curve obtained in platelet rich plasma (PRP) can have two peaks in the presence of low doses of platelet inhibitors. Also we present the new modification of thrombin generation assay (TGA) based on this phenomenon which can correspond with the tendency of bleeding in severe hemophilia A (HA).

Aims: We explored the mechanism of the second peak appearance and investigated the ability of the new modification of TGA in PRP to determine the clinical phenotypes of severe HA.

Methods: Blood was collected from healthy donors and patients suffering from severe HA (FVIII < 1 IU/dL) by venipuncture. Eleven patients with mild phenotype and 10 with severe one took part in the study. All the donors signed the written inform consent which was approved by ethics committee. Tissue factor induced thrombin generation in PRP and PPP was monitored using continual measurement of hydrolysis rate for thrombin specific fluorogenic substrate Z-Gly-Gly-Arg-AMC. Phosphatidylserine (PS) and CD62P expression on the activated platelets in purified suspension were measured by flow cytometry using annexin' – V-RPE and antiCD62P-FITC staining.

Results: Addition of P_2Y_{12} receptor antagonist 2'-MeS-5'-AMP (160 μM), 83 nM prostaglandin E_1 (PGE_1) or 1.6% DMSO to healthy PRP caused the appearance of two peaks in the thrombin generation curve. All these compounds in used concentrations did not affect significantly endogenous thrombin potential. Supplementation of these agents to purified platelet suspension decreased PS exposure rate after activation with 35 nM of thrombin. However, these compounds did not affect CD62P expression. Decreasing the thrombin concentration to 0.545 nM led to the inhibition of CD62P expression by 830 nM of PGE_1. Supplementation of PRP containing 1.6% DMSO with 830 nM PGE_1 mediated the second peak disappearance and decreased the first peak amplitude. Increasing the platelet concentration in PRP promoted the arrangement of two peaks into one. To investigate the severe HA phenotypic heterogeneity we used TGA in PRP with 1.6% DMSO and the concentration of platelets was equal to 100,000 platelets/μL. HA patients with mild phenotype demonstrated significantly higher second peak amplitude in PRP than ones with severe bleeding tendency.

Conclusions: The second peak in the PRP thrombin generation curve can be mediated by reduced PS expression rate provided by platelet inhibitors. However, α-granules do not take part in the second peak appearance. The modified TGA can determine the bleeding tendency in HA. The possible mechanism of phenotypic heterogeneity is linked with thrombin generation mediated by PS-expressing platelets.

PA 1.11-3

Assessment of thrombin formation in patients with ulcerative colitis without a history of thrombotic events

Demir M, Halhalli S, Tezel A, Ustundag A, Can G and Umit E

Trakya University School of Medicine, Edirne, Turkey

Background: It is known that there is a strong relation between inflammation and hemostasis and inflammation causes tendency to the development of thrombosis. Ulcerative colitis (UC) is an inflammatory disease of the colon that follows a course of relapse and remission with a predisposition to thrombosis. The association between thrombin generation and inflammation in certain local and/or general inflammatory disorders with tendency to thrombosis such as ulcerative colitis remains unclear.

Aims: The aim of this study is to evaluate the pattern of thrombin generation tests along with the inflammatory markers in patients with active and inactive UC without a history of thrombotic event.

Methods: Sixty-one patients (age between 18 and 65 years) with UC diagnosed with clinical, endoscopic and histopathological findings and 36 age and gender matched healthy controls have been enrolled in the study. Thirty-three patients had active disease while 28 were in remission. Disease activity was scored using Mayo score of UC. Approval of the local ethical committee and informed consent of all the participants were obtained. Prothrombin time, activated partial thromboplastin time, fibrinogen, D-dimer (Diagnostica Stago), Thrombin Generation Assay (TGA; Thermo Electron Corporation, Flouroscan Ascent; 5 pM TF), Thrombin anti-thrombin complex (TAT; Assay-Max Human TAT), high sensitive C-reactive protein (hs-CRP; DRG CRP-HS, ELISA) tests were performed. The parameters of thrombin generation assay (lag time, thrombin peak, Endogen Thrombin

Potential-ETP, time thrombin peak, start tail) were compared with inflammatory markers. *P*-values < 0.05 were regarded as significant. Sensitivity and specificity values were determined by receiver operating characteristic (ROC) curve analysis for each parameter.
Results: Levels of fibrinogen (452.33 ± 126.97 mg/dL; $P = 0.000$), D-dimer (1.75 ± 3.46 mg/dL; $P = 0.000$) and hs-CRP (9.81 ± 3.23 mg/L; $P = 0.001$) were higher in patients with active disease compared to patients in remission and controls, while TAT values (1.23 ± 0.65 ng/mL; $P = 0.697$) were similar in all groups. Within the TGA, lag time was longer (3.93 ± 0.73 min; $P = 0.000$), thrombin peak higher (391.57 ± 62.94 nm; $P = 0.007$) and start tail was observed to be longer (24.18 ± 3.54 min; $P = 0.001$) in patients with active disease. Thus ETP (2191.42 ± 526.36 vs. 1974.89 ± 408.68 nm; $P = 0.296$) and time thrombin peak (6.21 ± 0.95 vs. 5.80 ± 0.91 min; $P = 0.112$) values were observed to be unchanged. As with the sensitivity and specificity values to distinguish active disease, values regarding fibrinogen (78.8%;70.1%), D-dimer (75.7%;74.1%), hs-CRP (75.8%;58.1%), lag time (75.6%;65.7%), thrombin peak (54.5%;73.4%), ETP (39.9%;82.8%), peak (54.5%;73.4%), tt peak (78.8%;42.1%) and start tail (75.6%;53.1%) were determined respectively.
Summary/Conclusions: Activity index was observed to be well correlated with the increased inflammatory markers (fibrinogen and hs-CRP). D-dimer and thrombin peak were observed to be useful as markers of thrombin generation since levels of D-dimer and TGA-thrombin peak was higher when TAT levels were unchanged. D-dimer and fibrinogen showed the highest sensitivity and specificity while thrombin peak and ETP showed low sensitivity thus highest specificity. According to the results of the study, D-dimer and thrombin peak are the best parameters to demonstrate dynamic nature thrombin generation in patients with ulcerative colitis.

PA 1.11-4

Simultaneous measurement of thrombin generation and fibrin formation in plasma and whole blood applying continuous flow

Kelchtermans H[1], Pelkmans L[2], Ninivaggi M[1], Al Dieri R[1], Hemker CH[1] and De Laat B[2]

[1]Synapse BV, Cardiovascular Research Institute Maastricht, Maastricht University; [2]Department of Biochemistry, Cardiovascular Research Institute Maastricht, Maastricht, The Netherlands

Background: Thrombin is the enzyme converting fibrinogen into fibrin. Assays measuring the thrombin generation and fibrin formation are often used separately in research and clinical settings. Recently it was shown that thrombin generation and fibrin formation do not always go hand in hand as factor XII independently of thrombin influences the crosslinking of fibrin and stability of the clot.
Aims: The development of an assay that is able to simultaneously measure thrombin generation and fibrin formation in plasma/whole blood.
Methods: We have redesigned an air-bearing rheometer, based on the plate and cone viscositor, rendering it sensitive enough to measure fibrin formation based on changes in viscosity. Placing a confocal fluorescent camera into the rheometer allows the measurement of thrombin generation based on the conversion of a thrombin-sensitive substrate, as in the Calibrated Automated Thrombogram (CAT) assay. Using this method, the endogenous thrombin potential (ETP), peak height and lag-time can be calculated. The measurement of fibrin formation results in the variables: lag-time, maximum clot strength and time to maximum clot strength. The rheometer further allows the application of different laminar flow conditions within the range of 50/s until 1200/s.
Results: For all variables related to fibrin formation and thrombin generation, the intra- and inter-assay variation were below 10% in platelet-poor and -rich plasma and whole blood. Increasing flow rates (100–1200/s) in platelet-poor plasma triggered with 5 pM TF resulted in reduced ETP and peak values in the thrombin generation (ETP 1113 nM/min [100/s]; 776 nM/min [1200/s] and peak 264 nM [100/s]; 209 nM [1200/s]). Accordingly, maximum fibrin clot strength was inversely related to increased flow rates (7.7 mPa/s [100/s]; 1.9 mPa/s [1200/s]). As the amount of fibrinogen influences both thrombin generation and clot strength we tested the effect of different fibrinogen concentrations (0–5 mg/mL) in our system, applying a shear rate of 300/s in the presence of 5 pM TF. As expected, an increase in fibrinogen was accompanied with dose-dependent elevated ETP (734 nM/min [0 mg/mL]; 1073 nM/min [5 mg/mL]), peak (199 nM [0 mg/mL]; 323 nM [5 mg/mL]) and maximum clot strength (0 mPa/s [0 mg/mL]; 4.7 mPa/s [5 mg/mL]). By simultaneously measuring the thrombin generation and fibrin formation, we calculated that only 1 nM of thrombin is sufficient to polymerize fibrin and cause a change in viscosity. Additionally, we confirmed that an increase in factor XII enhances the clot strength without influencing thrombin generation, when coagulation is initiated via the extrinsic pathway.
Conclusions: We have developed a new method capable of simultaneously measuring thrombin generation and fibrin formation in plasma and whole blood under continuous flow. Our method proved to be sensitive enough to detect differences in fibrinogen content and established that only a small amount of thrombin is necessary to initiate clot formation. Additionally, this technique allows to study the influence of venous vs. arterial flow rates on both thrombin generation and clot strength, bringing coagulation experiments one step closer to physiology.

PA 1.11-5

Preoperative thrombin generation is predictive for the risk of blood loss after cardiac surgery

Bosch YPJ[1], Al Dieri R[2], Bloemen S[2], De Laat B[2], Ten Cate H[1], Nelemans P[1], Hemker HCH[2], Weerwind PW[1], Maessen JG[1] and Mochtar B[1]

[1]Maastricht University Medical Center; [2]Synapse b.v., Maastricht, The Netherlands

Background: Bleeding after cardiopulmonary bypass is a major cause of morbidity and mortality. The contact of blood with the artificial surfaces of the extracorporeal circulation during cardiac surgery results in activation of coagulation, fibrinolysis and platelets that is recognized as potential reasons for increased bleeding tendency.
Aim: To investigate whether the calibrated automated thrombin generation (CAT) can be used as a predictive tool for blood loss after cardiac surgery with cardiopulmonary bypass (CPB) compared to the routine coagulation tests.
Methods: Thirty male patients undergoing first-time coronary artery bypass grafting were enrolled. Blood samples were taken pre-bypass before heparinization (T1) and 5 min after protamine administration (T2). TG was measured both in platelet-rich plasma (PRP) and in platelet-poor plasma (PPP) and the parameters of the CAT (ETP, peak, lag time and time to peak) were evaluated. Activated clotting time (ACT), hematocrit, hemoglobin, platelet number, fibrinogen, antithrombin, D-dimers, prothrombin time (PT) and activated partial thromboplastin time (aPTT) were also determined. Blood loss was measured and the amount of transfusion products was recorded postoperatively until 20 h after surgery. Patients were divided in two groups based on the median volume of postoperative blood loss (group 1: patients with median blood loss < 930 mL; group 2: patients with median blood loss ≥ 930 mL).
Results: Patients with blood loss > 930 mL had a significantly lower ETP and peak thrombin pre-bypass than patients with blood loss lower than 930 mL ($P = 0.000$ and $P = 0.004$ resp.) in PRP, as well as in PPP ($P = 0.004$ and $P = 0.014$). After bypass, ETP and peak thrombin remain significantly lower ($P = 0.011$ and $P = 0.010$) in patients of group 2, measured in PRP but not in PPP. Fibrinogen was higher both

pre- and postoperatively in group 1, but only statistically significant postoperatively ($P = 0.045$).
Platelet level was also significantly elevated in group 1 compared to group 2 ($P = 0.002$), pre- and after bypass. However, no significant difference between the two patient-groups was observed when blood loss was associated with the D-dimers levels or with the clotting time-dependent tests (ACT, aPTT and PT), pre and post-CPB.
Conclusions: This study clearly demonstrates that the thrombin generation assay when performed preoperatively in the absence and presence of platelets is a predictive tool for blood loss after cardiac surgery. The clotting time-dependent tests on the other hand do not show any significant association with bleeding after surgery.

Fibrin monomers improves CHA2DS2-VASc risk prediction in chronically anticoagulated atrial fibrillation patients

Gallego P[1], Romera M[2], Marín F[3], Valdés M[3], Lip GYH[4], Vicente V[2] and Roldán V[2]

[1]Centro Regional de Hemodonación, Hospital Morales Meseguer; [2]Centro Regional de Hemodonación, Hospital Morales Meseguer. UMU, IMIB; [3]Servicio de Cardiología Hospital Universitario Virgen Arrixaca, UMU, Murcia, Spain; [4]University of Birmingham Centre for Cardiovascular Sciences, City Hospital, Birmingham, UK

Atrial fibrillation (AF) is associated with abnormalities of haemostasis, endothelium and platelets, which is independent of structural heart disease and AF aetiology – suggesting that AF confers a prothrombotic or hypercoagulable state. To aid decisions for thromboprophylaxis, several risk stratification schemes have been developed using clinical characteristics, the most popular being the $CHADS_2$ score and more recently, the CHA_2DS_2-VASc score. There are limited data on the prognostic role of biomarkers patients taking oral anticoagulants (OAC). Soluble fibrin monomers, as markers of fibrin formation, have been studied as a risk marker in various situations related to a hypercoagulable state as deep vein thrombosis or disseminated intravascular coagulation.
The aim of our study was to analyze the prognostic role of FM in steady anticoagulated AF patients to set if it could refine clinical risk stratification
Methods: We studied 904 patients (50% male; median age 76) with paroxysmal/permanent AF who were stabilised (for at least 6 months) on oral anticoagulation (INRs 2.0–3.0). Plasma FM was measured by immunoturbidimetry using STA-LIATEST FM (Diagnostica Stago, France) at baseline. Patients were followed-up for up to 2 years, and adverse events (thrombotic and vascular events and mortality) were recorded. FM cut-off was assessed by ROC curves.
Results: Median (IQR) values of FM were 8.42 (3.53–12.18) pg/mL. Median follow-up was 955 (785–1096) days, and during this period, 95 (4.04%/year) died whilst 111 patients had an adverse cardiovascular event (4.70%/year), from them 40 were strokes (1.7%/year). On multivariate analysis, high FM (> 4.79 pg/mL) remained significantly associated with both stroke and vascular events even after adjusting for CHA_2DS_2-VASc score, with adjusted hazard ratios (HRs) of 2.66 (1.26–5.58, $P < 0.001$) for stroke and 2.64 (1.69–4.13, $P < 0.001$) for adverse vascular events. For all cause mortality, the adjusted HR was 1.61 (1.04–2.48, $P = 0.031$). Based on c-statistics, FM improved the prediction for stroke/systemic embolism using the CHA_2DS_2-VASc score (0.63 ± 0.04, $P = 0.005$–0.68 ± 0.04, $P < 0.001$).
Conclusion: In a large 'real world' cohort of anticoagulated AF patients, FM levels could provide complementary prognostic information to an established clinical risk score (CHA_2DS_2-VASc) for prediction of long-term stroke/systemic embolism, suggesting that this biomarker may potentially be used to refine clinical risk stratification in AF.

Quantitative whole body autoradiography (QWBA) study on the effect of albumin fusion on the biodistribution of recombinant factor rIX

Herzog E[1], Harris S[2], McEwen A[2], Pragst I[1], Dickneite G[1], Schulte S[1] and Zollner S[1]

[1]CSL Behring GmbH, Marburg, Germany; [2]Quotient Bioresearch, Rushden, UK

Background: The recombinant fusion protein linking the human coagulation factor IX (FIX) to recombinant human albumin (rIX-FP) is currently investigated in clinical phase II/III trials (PROLONG-9FP) for prophylaxis and on-demand treatment of bleeding in haemophilia B patients. However, to date, there is only limited information available on the tissue distribution of FIX products following intravenous administration.
Aim: The present study was designed to explore the biodistribution of recombinant Factor IX (rIX) and how albumin fusion may affect it.
Methods: [^{3}H]-rIX-FP, [^{3}H]-rFIX or [^{3}H]-albumin, labeled using the N-Succinimidyl [2,3,-^{3}H] propionate (NSP) method, were administered intravenously to male rats at a single radioactive dose of approximately 400 μCi/kg. Using quantititave whole-body autoradiography (QWBA), tissue radioactivity was determined over 24 ([^{3}H]-rFIX) or 240 ([^{3}H]-rIX-FP, [^{3}H]-albumin) h. In addition to full body sections, the hind limbs were separately subjected to QWBA to obtain more detailed information on the products' distribution within the bone marrow and knee joint region. In parallel, plasma, urine and feces were collected at several time points throughout the observation period to calculate excretion balance and assess physiological elimination pathways. The radioactivity associated with the [^{3}H]-labelled proteins was determined by quantitative radiochemical analysis (QRA) and high performance liquid chromatography (HPLC). The radioactivity associated with plasma, urine and feces samples was also determined using QRA. Biological activity of rFIX and rIX-FP after [^{3}H]-labeling was confirmed by a chromogenic assay *in vitro* followed by *in vivo* measurements of hemostasis in hemophilia B mice treated with 'cold'-labeled rIX-FP material.
Results: Elimination of [^{3}H]-rFIX and [^{3}H]-rIX-FP occurred primarily via the urine. Overall, 73% of radioactivity was recovered in urine (associated with only low molecular weight components), ≤ 5% eliminated in faeces and about 20% remained in tissues after 240 h. The tissue distribution of [^{3}H]-rIX-FP and [^{3}H]-rFIX was comparable, both penetrating predominantly into well vascularized tissues and/or excretion organs including the adrenal gland, spleen, lung, liver, kidney, myocardium and gastrointestinal mucosa. Both proteins were also rapidly present within bone marrow and synovial or mineralized regions of knee joint sections where they seemed to mostly localize to the zone of calcified cartilage within the growth plate regions of long bones. The longest retention times were observed for bone marrow and the endosteum of long bones. Overall, these results suggest similar tissue distribution profile of [^{3}H]-rIX-FP and [^{3}H]-rFIX independent of albumin fusion. In contrast, the biodistribution of [^{3}H]-albumin appeared to be different with only very low initial penetration of bone marrow and liver but rapid, homogeneous distribution throughout the whole body including muscle, skin and connective tissue. Intriguingly, both [^{3}H]-rIX-FP and [^{3}H]-albumin derived radioactivity was well detectable over 72 h, whereas comparable [^{3}H]-rFIX associated radioactivity was only detectable over 24 h, further supporting the notion of extended tissue half-life of [^{3}H]-rIX-FP due to albumin fusion.
Summary/Conclusion: The study indicates that rIX-FP exhibits equal biodistribution compared to other marketed rFIX products, but clearly distinguishes itself by an extended plasma half-life and tissue retention pointing towards a reduction in dosing frequency leading to increased therapeutic convenience and compliance.

PA 1.12-2

Expression and characterization of a novel recombinant factor IX molecule with enhanced clotting activity

Perot E, Enjolras N, Negrier C and Dargaud Y
University of Lyon 1, Lyon Cedex 08, France

Background: Hemophilia B is an inherited coagulation defect characterized by a deficiency in human factor IX (FIX). Patients with hemophilia B are commonly treated with FIX concentrates. Production of a recombinant human coagulation factor IX (rhFIX) with increased clotting activity is one of the current challenges for hemophilia B treatment. In addition, increasing potency of gene transfer vectors may improve their therapeutic index, as lower plasma concentrations may achieve therapeutic benefit following *in vivo* administration.
Aim: The purpose of our study was to obtain a rhFIX molecule with an increase of specific activity.
Methods: In order to improve the activity of FIX, we focused on an important amino acid sequence known to be potentially involved in the interface region between activated FIX (FIXa) and its cofactor, the activated factor VIII (FVIIIa).
Our group recently showed that the human hepatoma cell line HuH-7 represents an effective cellular system for production of rhFIX with improved posttranslational modifications and therefore significantly better specific activity. Using site-directed mutagenesis, we have developed and produced four mutated rhFIX produced by the HuH-7 cell line. These mutations correspond to the following substitutions on glutamate 410 (E410): rhFIX-E410H, rhFIX-E410A, rhFIX-E410L and rhFIX-E410N.
Results: The four recombinant FIX molecules were produced following stable transfection. Similar secretion rates were observed for both rhFIX-E410 and wild type rhFIX. Western blot analysis showed that the mutated rhFIX molecules presented the same molecular weight than wild type FIX. The activation time course of equimolar amounts of mutated rhFIX-E410 and wild type rhFIX cleaved by the activated factor XI or the activated factor VII – tissue factor complex was also very similar giving FIXa heavy and light chains which appeared within 2 min.
After purification using an ion exchange column, the concentration of rhFIX molecules was determined by ELISA assay. We assessed *in vitro* clotting activity of the rhFIX molecules and evaluated their procoagulant effect using thrombin generation test.
Our results showed that mutated rhFIX-E410 had 3–5 times increased procoagulant activity compared to wild type rhFIX produced in our laboratory using the same cell line. We also observed a significantly higher thrombin generating capacity specifically with rhFIX-E410H compared to wild type rhFIX. Thrombin peak induced by rhFIX-E410H was 4.5 times greater than wild type rhFIX.
Conclusion: Using HuH-7 cell line and mutations on amino acid 410, we produced a rhFIX molecule with significantly improved specific activity as demonstrated by aPTT (activated partial thromboplastine time) based FIX clotting assay and thrombin generation test. We hypothesized that the increased specific activity induced by E410 mutations might be explained by an enhanced affinity between of activated rhFIX towards FVIIIa. Further tests are currently carried in our laboratory to verify our hypothesis.

Pharmacokinetics of buccally and intravenously delivered transgenic recombinant and plasma derived Factor IX

Velander WH[1], Monahan PE[2], Morcol T[3], Nichols TC[2] and Vanderslice NC[1]
[1]University of Nebraska-Lincoln, Lincoln, NE; [2]University of North Carolina at Chapel Hill, Chapel Hill, NC; [3]CaPtivate Pharmaceuticals LLC, Doylestown, PA, USA

Introduction: Our previous studies showed that transgenic pig milk containing human Factor IX (tg-FIX) fed to hemophilia B (FIXKO) mice can correct the hemostatic defect in a tail transection model while achieving only low plasma tg-FIX levels. In the present studies we have examined the pharmacokinetics of non- and intravenously administered tg-FIX relative to plasma derived (pd-) FIX. Here, calcium phosphate (CaP:) microparticles of FIX were chosen as a buccal delivery vehicle for both tg-FIX purified from transgenic FIX pig milk and pd-FIX.
Buccal Administration in Mice: Due to the highly keratinized nature of the mouse mouth, relatively large amounts of FIX were buccally administered (10 mg FIX/kg body weight) to obtain changes in plasma FIX antigen levels. The plasma levels of human FIX antigen began to rise within 2 h after buccal delivery of CaP:pd-FIX in three of five normal mice (3/5). The peak values of FIX antigen ranged between 147 and 197 ng/mL and was undetected after about 48–72 h. We also examined the buccal administration of CaP:tg-FIX to hemophilic B mice expressing an inactive human FIX mutant (R333QhFIX). These R333QhFIX mice exhibited baseline levels of human FIX antigen of 100–600 ng/mL. Similarly to that of buccal delivery of CaP:pd-FIX in normal mice, five of seven mice (5/7), antigen levels rose > 200 ng/mL above baseline within 2 h after buccal delivery of CaP:tgFIX. One stage FIX activity values were at the limit of detectability. The low levels of coagulation activity relative to the rise in antigen level could be explained by displacement of inactive endogenous R333QhFIX from intravascular reservoirs by the buccally delivered tg-FIX. Therefore, we next examined the relative partitioning behavior of tg-FIX vs. that of pd-FIX by crossover intravenous infusion in hemophilic B dogs.
Vascular partitioning behavior of intravenously infused tg-FIX vs. pd-FIX in hemophilic B dog. We examined pharmacokinetic behavior of intravenously infused transgenic tg-FIX vs. pd-FIX in crossover studies done over a 7 day period in hemophilic B dogs at 50 IU/kg body weight. Large differences between the partitioning of tg-FIX and pd-FIX into extravascular reservoirs were observed. When the pd-FIX was infused first and then followed 2 days later by an infusion of tg-FIX, the mean residence times were 31.1 h for pd-FIX and 39.0 h for tg-FIX. When the crossover infusion was reversed with tg-FIX followed by pd-FIX, the mean residence time was 5.5 h for tg-FIX and 40.2 h for pd-FIX. Hence, the prior intravenous loading of either species resulted in the lengthening of the mean residence time of the latter infused species. This suggests a significant amount of extravascular reservoir occupation by the agent infused first.
Discussion and Conclusions: These studies of intravenous and buccal delivery of pd- and tg-FIX help to define the general bioavailability of the tg-FIX based upon its rapid extravascular partitioning. Due to the low bioavailability of buccally delivered FIX, transgenic livestock will likely be the only reasonable source of FIX.

PA 1.12-4

Detection of galactose-alpha-1,3-galactose (a-Gal) and *N*-glycolylneuraminic acid (NGNA) in recombinant and plasma derived FIX products

Zhang M, Lu Q, Mei B and Peters RT
Biogen Idec, Waltham, MA, USA

Background: Recombinant factor IXFc fusion protein (rFIXFc) is a recombinant fusion protein composed of a single molecule of FIX covalently linked to the human IgG1 Fc domain. It is a long lasting clotting factor that has been investigated in a clinical study in Hemophilia B patients. The commercially available FIX products are manufactured in either CHO cell lines or derived from human plasma. The rFIXFc is manufactured using the human cell line HEK293. Non-human glycosylation pattern has been observed in some recombinant proteins. The terminal galactose-alpha-1,3-galactose (α-Gal) antigen is produced by all mammals except humans, old world monkeys, and apes. Antibodies against this antigen constitute approximately 1% of all circulating antibodies in humans. It was reported that CHO cell lines possess the enzyme catalyzing α-Gal synthesis and α-Gal was found in CHO produced therapeutic proteins including FVIII. Another example is the sialic acid *N*-glycolylneuraminic acid (NGNA). Healthy humans are genetically unable to produce NGNA, and circulating anti-NGNA antibodies are present in most normal humans. Therefore, α-Gal and NGNA can be potentially immunogenic.
Aims: The goal of this study is to determine the presence or absence of α-Gal and NGNA in 3 FIX concentrates: Mononine (ZLB Behring), a plasma-derived concentrate; BeneFIX (Pfizer), a recombinant product produced in a CHO cell line, and rFIXFc, recombinant FIXFc fusion protein produced in HEK293 cells.
Methods: a-Gal measurement: the α-Gal moieties were released from FVIII by treating protein samples with α-(1-3,4,6)-galactosidase at 37 °C for 16 h. The α-Gal was labeled by 2-aminobenzoic acid (2-AA) and quantified by reversed-phase chromatography (RP-UPLC) coupled with fluorescence detector. Purified galactose was used to generate a calibration curve. The percentage mole α-Gal per mole of protein was calculated for all samples.
NGNA measurements: all protein samples were incubated with 50 mM sulfuric acid at 80 °C for an hour, and the released NGNA was then derivatized with DMB at 50 °C for 3 h. The DMB derivatized sample was analyzed by RP-UPLC with fluorescence detector. The NGNA standard was used to obtain the calibration curve. The percentage mole NGNA per mole of protein was calculated for all samples.
Results: α-Gal measurements: The limit of detection (LOD) and limit of quantitation (LOQ) were determined to be 0.3 pmol (0.9% for BeneFIX) and 0.1 pmol (0.3% for BeneFIX) respectively, and α-Gal was detected in BeneFIX (1.6%). As expected, no detectable α-Gal was found in either rFIXFc or Mononine (less than LOD of 0.3%).
NGNA measurements: The LOD and LOQ for NGNA were determined to be 2.5 fmol (0.1% for BeneFIX) and 4.5 fmol (0.25% for BeneFIX), respectively. No detectable NGNA was found in rFIXFc and Mononine, whereas NGNA was detected in BeneFIX ($0.27 \pm 0.02\%$).
Summary/Conclusions: The non-human glycosylation α-Gal and NGNA were detected in BeneFIX but not in rFIXFc and Mononine. Both α-Gal and NGNA have been reported to be responsible for generating immune responses in human, and therefore human glycosylation could result in lower immunogenicity, however, the impact of the presence of these antigens on the immunogenicity profile of FIX is not currently known.

PA 1.12-5

Impact of factor IXa content on function, safety and efficacy of recombinant factor IX products

Turecek PL, Auer W, Rottensteiner H, Schrenk G, Höllriegl W, Schiviz A, Scheiflinger F, Schwarz H-P and Muchitsch EM
Baxter Innovations GmbH, Vienna, Austria

Background: Baxter has developed BAX 326, a new recombinant factor IX (rFIX) product for the treatment of patients with hemophilia B.
Aims: The presented studies were designed to evaluate the function, safety and efficacy of BAX 326 and a commercially available rFIX with regard to differences in activated FIX (FIXa) content.
Methods: The FIXa concentration of BAX 326 was 0.009 IU/mL and that for the commercially available rFIX was 0.106 IU/mL. As control, BAX 326 samples with an increased FIXa content were prepared. Samples were analyzed *in vitro* by one-stage clotting assay, non-activated partial thromboplastin time assay and thrombin generation assay. The thrombogenic potential of BAX 326 was assessed *in vivo* using a modified Wessler Test in rabbits at 750 IU/kg (10-fold human clinical dose). Efficacy of the rFIX products was studied in hemophilia B (FIX ko) mice that received prophylactic treatment with 75 IU/kg of BAX 326 or the commercially available rFIX. Finally, FIX-deficient mice were treated with BAX 326 or commercial rFIX and analyzed in a carotid occlusion model and one using thrombelastography to study primary pharmacodynamics of the two products.
Results: In all three functional *in vitro* assays, spiking of FIX with FIXa caused an increase in the measured FIX activity, with thrombin generation assay being affected most. No thrombogenic potential was observed with BAX 326 (individual scores of 0), whereas the mean score for the commercially available rFIX was 0.5. After increasing the FIXa concentration of BAX 326 to equalize it with the commercially available rFIX, a mean score of 0.42 (individual scores 0–0.5) was determined. Efficacy was comparable for the two recombinant FIX products in both pharmacodynamic models.
Summary/Conclusions: The *in vitro* results revealed that FIXa interferes with potency assignment of FIX. The data in the thrombogenicity model strongly suggested that the differences in preclinical thrombogenicity were caused by the higher FIXa content of the commercially available rFIX, thereby confirming earlier findings. The efficacy studies demonstrated that despite its lower FIXa content, BAX 326 was as efficacious as a commercially available rFIX at 75 IU/kg ($P < 0.0076$), indicating that FIXa does not contribute to the efficacy of a FIX product. The gathered data thus indicate that rFIX products should preferentially contain a low FIXa content.

PA 1.12-6

Two phosphatidylserine-positive platelet subpopulations are major in binding of coagulation factor IXa

Kozlov A[1], Podoplelova NA[2], Ataullakhanov F[2] and Panteleev MA[3]
[1]Lomonosov Moscow State University; [2]Center For Theoretical Problems of Physicochemical Pharmacology; [3]National Research Center for Hematology, Moscow, Russian Federation

Background: The importance of membrane phase of proteolitic reactions on the activated platelets in the process of blood coagulation is known. Rate of these reactions if pass on the membrane increases by severalorders of magnitude. To achieve this the enzymatic complexes of protrombinase and intrinsic tenase areassembled on the membrane of activated platelets. Activated platelets include one PS-negative (PS-) non-procoagulant subopulation and two procoagulant phosphatidylserine-positive (PS+) subpopulations which strongly differ in the intracellular calcium concentration. The PS+ subpopulation with low intracellular calcium concentration became known only recently.

Aims: The aim of the study was to describe the properties of binding of the FIXa, a maincomponent of intrinsic tenase, to membranes of each of three known subpopulations of platelets.
Methods: FIXa was covalently labeled with fluorescein. Washed gel-filtered platelets were activatedat 2 × 108/mL with 100 nM thrombin in the presence of 2.5 mM CaCl2 for 15 min. Theywere incubated with different concentrations of fluorescein-labeled FIXa and analyzed witha FACS Calibur cytometer. The surface distribution of FIXa on the activated plateles wasalso imaged using confocal microscopy.
Results: The addition of different concentrations of labeled FIXa to the threesubpopulations demonstrated two types of binding with regard to the amount of bind factorper platelet. Two PS+ subpopulations showed insignificant difference (1.3-fold) in theirFIXa binding. Binding to the PS-negative subpopulation was approximately 12-fold smaller incomparison with the PS+ platelets. Generally, for both PS+ subpopulations thedependence of the bound factor quantity binding on the added FIXa concentration waslinear without any saturation up to very high concentrations of FIXa (2000 nM, which is byseveral orders of magnitude higher than the physiological value). Confocal microscopyshowed that FIXa localizes on the surface of the PS+ platelets to a some 'hat'-shapedformation. This localization could be important for additional acceleration of coagulationreactions.
Conclusions: Two PS+ subpopulations of platelets is better than the PS- in binding of FIXa by one orderof magnitude, their dependence of binding on the concentration of free FIXa is linear andwithout saturation. This suggests their major role in binding of FIXa during the clotting. Non-uniform, localized distribution of the FIXa on the surface of PS+ platelets, it's 'hat'-shaped formation, suggests that such a colocalization with other factors could workfor acceleration of coagulation reactions.

Residues within the BO2C11 epitope may participate in FVIII endocytosis by antigen presenting cells

Gangadharan B[1], Delignat S[2], Hegde P[3], Sharma M[3], Kaveri SV[2] and Lacroix-Desmazes S[2]

[1]2Université Pierre et Marie Curie-Paris 6,UMR S 872; [2]Inserm, UMR S 872; [3]Université Paris Descartes, Paris, France

Background: Twenty to 30% of severe hemophiliacs develop antibodies to therapeutic factor VIII (FVIII). Immune responses to FVIII require T-cell help and evoke class-switched antibodies that necessitate active antigen uptake and presentation. Currently, our understanding of immune recognition and cellular mechanisms involved in FVIII uptake is limited. Recently, membrane-binding residues within the C1 domain of FVIII (R2090, F2092 and L2093) have been implicated in the interaction with *low-density lipoprotein receptor*-related protein (LRP/CD91) receptor. Alanine substitutions of these residues inhibit LRP-dependent FVIII endocytosis by U87 cells. Conversely, endocytosis of FVIII by monocyte-derived human dendritic cells (MODC) or mouse bone marrow-derived dendritic cells is independent of LRP receptor and may involve other yet unidentified receptor(s). Interestingly, FVIII containing substitutions in the membrane binding residues of C1 domain exhibits diminished immunogenicity *in vivo*, thus possibly implicating the relevance of these residues in antigen uptake.
Aim: Similar to C1, the C2 domain of FVIII interacts with membrane surfaces and involves several basic residues. We targeted these residues with monoclonal antibody to investigate the possible inhibition of FVIII endocytosis by MODCs.
Methods: BO2C11 is a well-characterized human monoclonal antibody that targets C2 domain. It competes for FVIII binding with both phospholipids and VWF. As control, we used the commercially available C2 antibody ESH-8 that targets an epitope that does not compete for membrane binding or VWF interaction. MODCs were generated using standard differentiation protocols for 6 days. MODCs were verified for their immature phenotype by flow cytometry (FACS) and contained greater than 90% differentiated cells. For endocytosis, MODCs were incubated with 20 nM FVIII or FVIII pre-incubated with BO2C11 or ESH8 (20 nM) for 30 min at 37 °C, or at 4 °C as controls. In addition, endocytosis assays were performed using Fab fragments for BO2C11 and ESH8. Subsequently, cells were fixed using 3.7% formaldehyde, permeabilized and stained using FITC conjugated 77IP52 (LFB, Les Ulis, France), a murine anti-FVIII A2 antibody, and uptake was analyzed by FACS. The experiments were performed on 3–5 different donors and as duplicates per donor.
Results: BO2C11 completely inhibited FVIII endocytosis. Pre-incubation of FVIII containing two molar excess of BO2C11 Fab fragment (compensated for bivalency of antibody) also abrogated endocytosis. Surprisingly, ESH-8 interfered with endocytosis of FVIII albeit at diminished capacity as compared to BO2C11 (50% vs. no uptake). Fab fragments for ESH-8 only marginally reduced FVIII endocytosis. FVIII endocytosis was significantly decreased in the presence of both C2 antibodies, and was differentially reduced by the two antibodies, as assessed by one-way ANOVA followed by Newlan-keuls multiple comparisons.
Conclusions: The BO2C11 epitope includes residues involved in endocytosis of FVIII by MODCs. Hence, membrane-binding residues within C2 domain encompass an immunodominant epitope that overlaps with residues involved in its uptake. Currently, we are investigating the *in vivo* significance of this epitope. Identification of the specific C2 residues along with the C1 residues involved in FVIII uptake may help develop FVIII that potentially exhibits a lower immunogenic profile.

Bianchi Bonomi", Milano; [9]Centro Emofilia Di Padova, Padova; [10]U. O. di Angiologia e Malattie della Coagulazione "Marino Golinelli", Bologna; [11]Centro Emofilia e Trombosi, Sassari; [12]Bayer HealthCare, Milano, Italy

Background: Progressive arthropathy of large joints of the limbs causes morbidity and quality-of-life impairment in hemophiliac patients. While prophylaxis (primary or early secondary) started early in life has shown to prevent joint bleeding and deterioration and is now gold standard treatment in children, the benefits of late secondary prophylaxis (i.e. in adolescents or adults) are still controversial.
Aims: The POTTER study (Prophylaxis vs. On-demand Therapy Through Economic Report) evaluated clinical effects, economic burden and Health-Related Quality-of-Life (HRQoL) of long-term secondary prophylaxis, compared with on-demand treatment in Italian adolescents and adults (12–55 years) with severe haemophilia-A (factor VIII [FVIII] < 1%). Here we will focus on pharmaco-economic and HRQoL evaluations.
Methods: Patients receiving sucrose-formulated recombinant FVIII on secondary prophylaxis (20–30 IU/Kg three times weekly, $n = 27$) or on-demand ($n = 26$) were prospectively compared over a median

5.4 year-follow-up, being stratified in two age subgroups (12–25 and 26–55 years). Study outcomes included: joint bleedings/year (primary end-point); total bleedings/year, joint status (orthopaedic and radiologic scores), adverse events (AEs), economic assessment and HRQoL. The economic analysis estimated direct costs of treatment (FVIII consumption) and of other healthcare resource consumption (planned and emergency visits, physiotherapy, laboratory/instrumental tests, invasive procedures, hospitalizations) which were quantified with National tariffs (Euros) for the year 2011. Productivity loss assessment counted days lost from work/daily activities by patients/caregivers due to the disease. HRQoL was measured using generic (EQ-5D, SF-36) and disease-specific questionnaires (Haemo-A-Qol). Statistical differences from baseline were assessed by Mann-Whitney U test or paired Student t-test. HRQoL and patients' characteristics association was evaluated by multivariate linear regression analyses.

Results: Patients on prophylaxis showed high adherence to the prescribed regimen (median 93.6%) and achieved significantly better clinical outcomes in terms of joint and total bleedings (an approximately 8-fold lower annual rate) and joint status (reduction of orthopaedic scores and lower progression of radiologic scores) compared to those treated on-demand. Mean direct costs for prophylactic regimen vs. on-demand were respectively: €190,696.84 vs. €60,740.85 in the 12–25 year group and €205,387.35 vs. €103,460.80 in the 26–55 year group ($P < 0.0001$). The difference in costs was mainly due to higher use of FVIII in the prophylaxis arm. Patients treated on-demand showed higher FVIII consumption and costs due to surgery or reasons other than ordinary treatment. Mean days lost from work/daily life activities in the two regimens were: 10.62 vs. 42.99 for patients aged 12–25 years; 13.77 vs. 35.56 for 26–55 year patients ($P < 0.0001$). Patients on prophylaxis always showed statistically better scores in all HRQoL questionnaires and both in physical and mental dimensions ($P < 0.05$) throughout the study. At multivariate analysis, worse HRQoL was associated with higher frequency of bleedings whereas prophylaxis duration directly correlated with better HRQoL.

Summary/Conclusions: The POTTER study provides prospective evidence over the long-term that secondary prophylaxis can significantly improve joint status, HRQoL and social participation of adolescents/adults with severe haemophilia-A. These advantages may counterbalance considerable high treatment costs. Studies with even longer follow-up are needed to assess the full impact of such investment on overall costs of comprehensive care for adult and ageing hemophiliacs.

PA 1.13-3

MD simulation studies of the membrane binding process of the human blood coagulation factor VIII C domains

Du J, Wichapong K and Nicolaes GAF

Maastricht University, Maastricht, The Netherlands

Background: Blood coagulation factor VIII (FVIII) is the non-enzymatic cofactor of the FX-activating tenase complex. Human FVIII consists of 2332 amino acids and can be divided into five domains: A1-A2-B-A3-C1-C2 (from N to C terminus). The C1 and C2 domains of FVIII are the main membrane-binding region of the protein.

Aims: We aimed to study the membrane binding mechanism of the FVIII-C domains in near-atomistic detail. Via *in silico* simulation our goal was to identify residues that are of major importance to the membrane binding process and quantitate the contributions of individual residues. The potential cooperativity between the C1 and C2 domain with respect membrane binding is studied.

Methods: Coarse grained Molecular Dynamics (MD) simulations, employing the MARTINI force field, were performed of the C1 domain, the C2 domain and of the C1/C2 domain dimer of human FVIII in the presence of a 20/80 mol/mol PS/PC membrane. Protein-membrane interactions were analysed in terms of energies and individual residues were selected that play major roles during the membrane binding process.

Results: We succeeded in reproducibly performing *in silico* binding experiments for the spontaneous binding of C1, C2 and C1/C2 to PS/PC phospholipid membranes. A consistent mode of binding was observed for each of the experimental systems tested and we obtained novel information about the identity of residues buried in the membrane, of their mode of interaction and of the overall binding mode of individual domains. Overall, membrane binding is steered by hydrophobic spikes of the C domains and discrete phases can be distinguished in the binding process itself.

We observed a deeper burying of residues for the C2 domain as compared to the C1 domain and calculated a net highest binding energy for the C1/C2 dimer as compared to the two individual domains. Cooperativity in binding between C1 and C2 domains was quantitated and the binding mode of the dimer differs from that of the single domains, with the isolated C1 domain binding being most different.

Our simulation results are consistent with data in literature for individual residues such as R2090, H2155, R2159, R2163, V2223 which have previously been recognized as involved in membrane binding and/or causative mutations in hemophilia A. We identified additional residues that appear to be important to membrane binding. Moreover, *in silico* mutation of essential residues results in altered membrane binding or ultimately loss of membrane binding.

Conclusions: We have been able to reproducibly mimic membrane binding *in silico* and provide a method that is in agreement with data in literature. We observed strong interactions between the FVIII C domains and phosphatidylserine containing membranes during MD simulations. The binding of the C domain to the membrane appears to follow several discrete stages: a) approach by electrostatic attraction b) contact by interaction of hydrophobic spikes with the membrane in an upright position along the longitudinal axis of the C-domain, c) tilting of the C-domains to maximize the number of contacts between the domain and the membrane.

Light chain of coagulation factor VIII contains a site for low-density lipoprotein receptor

Kurasawa JH, Shestopal SA, Karnaukhova E, Struble EB, Lee TK and Sarafanov AG

U.S. Food and Drug Administration, Rockville, MD, USA

Background: The lifetime of blood coagulation factor FVIII (FVIII) in circulation depends on its clearance via hepatic receptors, and one of them was shown to be the low-density lipoprotein receptor (LDLR) (Bovenschen N., et al, 2005). The ligand-binding portion of LDLR is represented by a cluster of seven complement-type repeats (CRs), among which specific adjacent CRs were previously shown to form sites for such ligands as plasma lipoproteins ApoE and ApoB. In regard to FVIII, it was previously shown that its site for another clearance receptor, LDLR-related protein (LRP), is located on the light chain (LCh) (Lenting P., et al, 1998).

Aims: Considering similarity in structure of both receptors, in the present work, we investigated whether the binding site of FVIII for LDLR is also located on the LCh. On the receptor side, we aimed to map the interactive site.

Methods: Expression of recombinant proteins and their mutant forms in baculovirus system, purification of the proteins and performing binding assays in a purified system using surface plasmon resonance.

Results: In the binding assay, we found that FVIII interacted in similar fashion with the LDLR exodomain expressed in mammalian cells, and with the recombinant LDLR cluster of CRs expressed in insect cells. These data indicated that the LDLR site for FVIII is restricted within the CR cluster and not extended to a region beyond it. Next, FVIII was tested vs. a panel of CR doublets expressed in insect cells, overlapping the LDLR cluster. Three such doublets overlapping a four-CR region of the cluster were found positive for the binding. Specificity of these interactions was verified by site-directed mutagenesis of all positive binding LDLR fragments and by using an anti-FVIII antibody

fragment as competitor; both approaches resulted in strong inhibitory effects on FVIII binding. Finally, we tested the FVIII LCh, plasma- and insect cell-derived, for the binding with CR doublets and found that both preparations of the LCh bound to essentially the same receptor fragments as FVIII.
Summary/Conclusion: Thus, the LCh of FVIII contains a site for LDLR, and within the receptor, the LCh interacts with the second through fifth complement-type repeats. In turn, the fact that FVIII interacts with both LDLR and LRP via the LCh, indicates the similarity of these interactions.

Human liver sinusoidal endothelial cells but not hepatocytes contain FVIII

Jacquemin MG[1], Covens K[1], Jazouli N[2], Sokal E[3], Peerlinck K[4] and Shahani T[1]
[1]KU Leuven, Leuven; [2]UCL; [3]St Luc University Hospital, UCL, Brussels; [4]UZLeuven, KULeuven, Leuven, Belgium

Background: Although the liver is the major site of Factor VIII (FVIII) synthesis, the FVIII producing cell type within the liver is still unclear.
Aims: We therefore wanted to measure FVIII in extracts of primary liver sinusoidal endothelial cells (LSECs) and hepatocytes, thereby avoiding potential bias due to the modification of the cell phenotype during *in vitro* culture.
Methods: LSECs were purified by flow cytometry cell sorting based on the coexpression of Tie2 and CD32b and the strategy of purification controlled by RNA-Seq.
FVIII in extracts of purified cells was measured with a sensitive FVIII chromogenic assay. The specificity of each test was controlled by the neutralisation of FVIII activity with specific inhibitor antibodies.
Results: FVIII:C concentration in LSECs purified by cell sorting based on the coexpression of Tie2 and CD32b ranged from 0.3 to 2.8 nU/cell. On the contrary, FVIII:C remained undetectable in hepatocytes. The intracellular FVIII:C concentrations are therefore at least 10- to 100-fold higher in LSECs than in hepatocytes.
Summary/Conclusion: Our data demonstrate that LSECs but not hepatocytes contain measurable amounts of FVIII:C and suggest that the former is the main FVIII producing cell type in the human liver.

PA 1.13-6
Myeloid-derived cells a novel target for cell therapy in hemophilia A

Zanolini D[1], Merlin S[1], Feola M[1], Ranaldo G[1], Gherzi R[2], Valente G[1], Prat M[1] and Follenzi A[1]
[1]University of Piemonte Orientale "A.Avogadro"; [2]Azienda Ospedaliero Universitaria "Maggiore della Carità", Novara, Italy

Background: Identification of cells capable of synthesizing and releasing factor VIII (FVIII) is critical for developing therapeutic approaches in hemophilia A (HA). Hepatocytes and endothelial cells (EC), particularly liver sinusoidal endothelial cells (LSEC), express FVIII most in the body. However, recent studies of bone marrow (BM) transplantation suggested additional cell types could synthesize and release FVIII, and also correct bleeding in HA mice.
Aims: To establish the ability of myeloid blood-derived cells in expressing FVIII, we analyzed several murine and human hematopoietic cell types.
Methods: First, we generated polyclonal and monoclonal antibodies against recombinant human FVIII. The specificity of these anti-FVIII antibodies was established by western blotting and staining of lentivirally transduced fibroblasts from HA mice expressing human and mouse B domain-deleted FVIII. Human monocytes were obtained by adhesion from peripheral blood mononuclear cells (PBMC) and differentiated *in vitro* adding M-CSF to the medium for 7 days. Human hematopoietic stem cells (HSC) were isolated from cord blood mononuclear cells (CBMC) by immunomagnetic selection with anti-CD34 antibody. HSC were differentiated in macrophages and megakaryocytes through 2 weeks stimulation with IL-3, M-CSF, Flt-3 ligand, SCF and IL-6, IL-11, TPO respectively. In silico analysis to predict transcriptional factor consensus sequences on FVIII promoter was performed on the website: http://alggen.lsi.upc.edu/recerca/menu_recerca.html. Monocytes were isolated by CD11b immunopositive selection from CBMC and transplanted in NOD-SCID HA mice. Eleven mice were tail vein injected with 15 million cells. FVIII activity was analyzed by chromogenic assay 3 and 7 days after injection. As controls untreated NOD-SCID HA mice were used.
Results: FVIII was expressed in hematopoietic cells isolated from peripheral blood, BM and human cord blood (hCB). The identity of these cell types was verified by costaining for FVIII and cell type-specific markers for monocytes, dendritic cells and megakaryocytes. Moreover, FVIII expression in these cell types was verified by RT-PCR and western blot analysis. Antibody staining confirmed FVIII expression in normal human liver, including LSEC, Kupffer cells (KC), and hepatocytes. We detected FVIII expression in myeloid cells or EC in other organs, e.g., spleen, lymph nodes, lungs, BM and kidneys. Despite molecular progresses, little is reported about the transcriptional regulation of the factor VIII gene. In silico analysis of transcriptional factors (TF) consensus sequences of FVIII promoter predicted in addition of well-known hepatocytes specific TF, the presence of several myeloid-specific TF such as C/EBP and GR family, GATA1, IRF-2 and STAT1 and 4. In order to evaluate the ability of monocytes to release FVIII we performed injections of human CD11b+monocytes hCB-derived in NOD-SCID HA mice. Tissue analysis showed engraftment of CD11b+ monocytes in the mouse liver and spleen up to 1 week. Tail clip challenge of these mice showed bleeding correction in nine of 11 transplanted mice (82%) and plasma FVIII activity was detected in treated mice.
Conclusions: Besides hepatocytes and EC, FVIII is expressed in myeloid cells, offering further opportunities to understand mechanisms in FVIII synthesis and activity for cell therapy approaches.

PA 1.14-1
Kinetics and thermodynamics of knob-hole interactions in fibrin from dynamic force measurements in silico

Litvinov RI[1], Zhmurov A[2], Kononova O[2], Weisel JW[1] and Barsegov V[2]
[1]University of Pennsylvania, Philadelphia, PA; [2]University of Massachusetts, Lowell, MA, USA

Background: The physico-chemical properties of fibrin, the primary structural protein of blood clots and thrombi, are essential for hemostasis and wound healing. The polymerization of fibrin occurs primarily via intermolecular interaction between knobs 'A' and 'B' in the central nodule and holes 'a' and 'b' in the γ- and β-nodules.
Aims: To explore the mechanisms of A:a and B:b knob-hole interactions and compare the kinetics and thermodynamics of the forced dissociation of A:a and B:b knob-hole bonds under various solution conditions (pH and temperature).
Methods: Molecular Dynamics simulations of atomic structural models of the complexes of fragment D with peptides GPRP (mimicking knob 'A') and GHRP (mimicking knob 'B').
Results: We found that the main binding determinants in hole 'a' and 'b' are localized to residues in loop I (residues γ315–330 in hole 'a' and β383–398 in hole 'b'), interior region II (residues γ335–365 in hole 'a' and β404–434 in hole 'b'), and moveable flap III (residues γ295–305 in hole 'a' and β359–369 in hole 'b'). The A:a and B:b knob-hole bonds are roughly equally strong when tested mechanically. The average A:a and B:b bond lifetime decreases with increasing pulling force applied

to dissociate the bond, yet the dissociation kinetics are sensitive to pH and temperature variation. Both A:a and B:b interactions are not 'all-or-none' transitions – they occur through distinct pathways via populating intermediate states. This leads to formation of A:a and B:b knob-hole bonds of varying strength. We analyzed the time-dependent maps of residues in hole 'a' and hole 'b' forming binding contacts with their ligands and identified the most important residues critical for binding. The single-step unbinding transitions from the bound state *B* to the unbound state *U*, *B* -> *U*, correspond to longer interaction times, whereas the two-step sequential transitions, *B* -> *I* - > *U* (*I* is the partially bound intermediate state), which occur more frequently in an acidic environment (pH = 5), favor shorter bond lifetimes. There are similar structural changes in the holes 'a' and 'b', which accompany dissociation of the A:a and B:b knob-hole complexes: short 2–4 Å elongation of loop I, limited stretching of the interior region II by 2–4 Å, and large-amplitude 2–6 Å translocation of the moveable flap III. We profiled the binding free-energy as a function of the interaction range underlying the A:a and B:b non-covalent coupling. For pH = 7, the binding energy ΔE decreases from approximately 20 to 17 kcal/mol for the A:a bond, and from approximately 16 to 13 kcal/mol for the B:b bond when the temperature decreases from 35 to 25 °C. For pH = 5, ΔE increases from approximately 2 to 7 kcal/mol for the A:a bond, but decreases from approximately 10 to 8 kcal/mol for the B:b bond upon lowering temperature from 35 to 25 °C.

Summary/Conclusion: These results from equilibrium Molecular Dynamics simulations confirm and clarify the binding determinants from the static X-ray crystallography picture. The pulling simulations provide kinetic and thermodynamic information for the strongest and most significant non-covalent interactions for polymerization of fibrin.

Fibrinogen Birmingham II – a novel variant associated with hypodysfibrinogenemia, due to co-inheritance of Trp334Cys and Asn335Tyr in the fibrinogen Aa chain

Greenhalgh KA[1], Hill M[2], Gordon B[2], Ariëns R[1], Williams M[3], Dolan G[2] and Ajjan RA[1]

[1]University of Leeds, Leeds; [2]Nottingham University Hospitals, Nottingham; [3]Birmingham Children's Hospital, Birmingham, UK

Background: A patient presented with a strong history of thrombosis with paradoxical bleeding diathesis. There was a family history of hypodysfibrinogenemia associated with a range of clinical symptoms, which included thrombosis and/or bleeding, and asymptomatic individuals.

Aims: The aim of this work was to establish whether patient symptoms are due to abnormality in the fibrinogen molecule resulting in altered clot structure and/or lysis.

Methods: Genetic analysis was carried out by PCR and nucleotide sequencing of the entire coding regions/splice junctions of fibrinogen FGA, FGB and FGG genes. Fibrinogen was purified from plasma samples using affinity chromatography. Double mutation in the α-chain of fibrinogen was found in our patient, which was further studied in a recombinant system by site-directed mutagenesis and stable expression of fibrinogen variant in Chinese Hamster Ovary cells.

Clot maximum absorbance (MA) and lysis time (LT) were measured by a turbidimetric assay. Confocal and scanning electron microscopy were used to assess clot structure.

Results: The patient was found to have a novel fibrinogen variant (Birmingham II), consisting of co-inheritance of two previously unreported changes in the fibrinogen FGA gene; c.1002 G>T (p.Trp334Cys) and c.1003 A>T (p.Asn335Trp). Aα Trp334 and Asn335 are both highly conserved residues in the fibrinogen aC domain; there was no evidence that either change was polymorphic. SIFT analysis suggested both substitutions were deleterious (both score 0.03), Polyphen analysis predicted that these changes were 'possibly damaging' and benign' (score 0.85 and 0.41 respectively).

Clots made from plasma purified fibrinogen of our patient showed significantly lower MA compared with control (0.0065 ± 0.0005 and 0.065 ± 0.001 au, respectively; $P < 0.01$). Similar results were obtained in clots made from recombinant fibrinogen with and without the mutations (0.014 and 0.059 au, respectively; $P < 0.01$). These results suggest thinner fibrin fibres in the presence of the mutation, which was confirmed by scanning electron microscopy (32.47 ± 0.91 and 100.23 ± 2.75 nm, respectively for plasma; $P < 0.01$ and 45.40 ± 1.12 and 118.65 ± 3.53 nm, respectively for recombinant protein; $P < 0.01$).

In a purified system, LT was shorter in clots made from the patient compared with control (144 ± 15.49 and 308 ± 5.06 s, $P < 0.01$) with similar results for recombinant fibrinogen with and without the mutations (459 ± 38.69 and 882 ± 22.18 s, respectively; $P < 0.01$). Conversely, LT was longer with variant recombinant fibrinogen when added to fibrinogen depleted plasma (2356 ± 164.72 and 1590 ± 27.93 s, respectively; $P < 0.01$), indicating interactions between clot structure and plasma proteins.

Discussion: We report a novel fibrinogen variant due to co-inheritance of two missense mutations in αC domain (Aa p.Trp334Cys and Aa p.Asn335Trp). This variant is associated with thin fibrin fibres and resistance to fibrinolysis in a plasma environment. Our data using plasma-purified and recombinant fibrinogen confirm the mutations are directly responsible for the changes in clot structure and lysis. Moreover, these findings provide mechanistic explanations for the clinical presentation of our patient. The excessively low clot turbidity and thin fibres are consistent with less robust clots predisposing to bleeding, whereas impaired fibrinolysis may explain the increased thrombotic tendency.

PA 1.14-3

Fibrin structure in subjects with diabetes and aortic aneurysm

Mohd Izam MM, Ofosu-Adjei A, Cilia La Corte A, Johnson A, Sohrabi S, Scott J, Ariëns R and Kain K

LIGHT, MCRC, University of Leeds, Leeds, UK

Background: European men over 60 years have a high incidence of abdominal aortic aneurysm (AAA) (5%) and diabetes (12%). Cardiovascular morbidity and mortality is increased in both AAA (excessive and equivalent to that associated with coronary heart disease) and diabetes. Despite similar associations of diabetes and AAA with inflammation and arteriosclerosis, AAA is uncommon in patients with diabetes due to a thicker abdominal aortic wall causing reduction in wall stress and therefore appears protective against AAA. Patients with AAA form denser, smaller pored plasma clots that are more resistant to fibrinolysis and these characteristics correlate with aneurysm size. Clots formed by fibrinogen purified from diabetes subjects have a denser, less porous structure than those from control subjects.

Aims: To investigate fibrin structure, propensity to clot and resistance to clot breakdown in diabetes patients with AAA compared to those without.

Methods: Informed consent was obtained and the study was approved by a local medical ethics committee. Detailed medical history and blood samples were obtained only from patients diagnosed as diabetes as part of LEADS (a large population based study of AAA patients and matched controls recruited from the West Yorkshire) sub-study. Sixty patients had both diabetes and AAA as defined by aortic diameter ≥ 3.0 cm determined by ultrasound scan and 34 patients with diabetes had a normal aortic diameter < 3.0 cm. Turbidity or clot formation was measured using thrombin (5 U/mL) addition to plasma. Absorbency was read every 12 s at 350 nm for 1 h using Bio-Tek ELx 808 reader. Lysis or clot breakdown was measured by using tissue-plasminogen activator (85 ng/mL) to the turbidity assay. Absorbency was read every 120 s at 350 nm for 9 h.

Results: Although groups were sex-matched, diabetes subjects with AAA were older (78 vs. 73 years, $P < 0.001$) than those without. The

diabetes subjects with AAA had a lower prevalence of cardiovascular disease (75 vs. 97%, $P = 0.004$) and use of oral anti-glycaemic medications (3.3 vs. 29%, $P = 0.001$). There were no differences in low density lipoprotein, body mass index, hypertension, insulin or cardiovascular drugs usage. The diabetes subjects with AAA had shortened lag time (386 vs. 472 s, $P < 0.001$), increased clot rate (5.2×10^{-4} vs. 3.6×10^{-4} nm/s, $P < 0.001$) and decreased lysis rate (-9.6×10^{-5} vs. -150×10^{-5} nm/s, $P < 0.001$) than without AAA. Fibre thickness was similar in the two groups. Lag time ($P = 0.006$), clot rate ($P = 0.05$) and lysis rates ($P = 0.007$) remained significantly different (all $P \leq 0.05$) even after adjustment for age, oral anti-glycaemic medication and cardiovascular disease.

Conclusions: Patients with diabetes and AAA form clots, which are more pro-coagulant and resistant to fibrinolysis hence increasing the risk of cardiovascular disease. There are differences in medial wall pathology in diabetes (obliterating arteriosclerosis which causes more occlusion) and AAA (dilating arteriosclerosis which might be protective) hence possibly the cardiovascular disease is decreased in our study in subjects with both diabetes and AAA. Further prospective studies on fibrin clot structure and function in apparently healthy subjects with measure of medial wall changes and follow up for development of diabetes or aneurysm and cardiovascular disease are required.

PA 1.14-4

Prothrombotic plasma fibrin clot phenotype is predictive of recurrent venous thromboembolism following discontinuation of anticoagulant therapy

Undas A[1], Ciesla-Dul M[2], Drazkiewicz T[2] and Sadowski J[1]

[1]Jagiellonian University Medical College; [2]John Paul II Hospital, Krakow, Poland

Background: Prothrombotic fibrin clot phenotype, including reduced clot permeability and susceptibility to lysis, has been shown to be associated with idiopathic venous thromboembolism (VTE).

Aims: We evaluated the relation of plasma fibrin clot characteristics to risk of recurrent VTE.

Methods: In a prospective cohort study of 162 consecutive VTE patients aged 18–65 years, plasma fibrin clot characteristics were measured following discontinuation of anticoagulation. Recurrent VTE events were assessed during a median follow-up of 30 months.

Results: There were 41 VTE recurrences after 8.2 ± 4.5 months since discontinuation of anticoagulation. Idiopathic index event was associated with increased risk of VTE recurrence (hazard ratio [HR] 3.53, 95% confidence interval [CI] 1.61–7.76). Patients with recurrent VTE had lower K_s, longer $t_{50\%}$, shorter *lag phase* indicating faster fibrin formation, and greater ΔAb_{max}, indicating thicker fibrin fibers. Relative to the middle and upper tertile of clot permeability (K_s) and the rate of D-dimer release from clots ($D\text{-}D_{rate}$), the HRs of recurrent VTE for those from the lowest tertile were 3.68 (95%CI 1.72–7.84, $P = 0.001$) and 2.17 (95%CI 1.07–4.43, $P < 0.001$), $P = 0.003$), respectively. Similar associations were noted for the upper tertile of clot lysis time (HR 3.17, 95%CI 1.46–6.86, $P = 0.032$) and plasma D-dimer following anticoagulation cessation (HR 5.04, 95%CI 2.19–11.61, $P = 0.003$). In ROC analysis ΔAb_{max} has the highest area under the curve (AUC) of 0.784. Its cut-off point of 0.805 had sensitivity of 0.854 and specificity of 0.661. The presence of factor V Leiden mutation and/or prothrombin 20210A mutation were not associated with altered fibrin clot phenotype or recurrent VTE.

Conclusion: Unfavorably altered fibrin clot characteristics measured following discontinuation of anticoagulant therapy can help identify patients at risk for recurrent VTE.

PA 1.14-5

The impact of diabetes duration on plasma fibrin clot properties in type 2 diabetic patients

Undas A[1], Konieczynska M[2], Fil K[2] and Bazanek M[2]

[1]Jagiellonian University Medical College; [2]John Paul II Hospital, Krakow, Poland

Background: It is well known that hyperglycemia is associated with abnormal fibrin clot phenotype. It has been shown that fibrin clots made from fibrinogen obtained from type 2 diabetic patients have more compact fiber networks associated with reduced permeability and impaired fibrinolysis compared with healthy controls. Mechanisms underlying abnormal fibrin clot properties in diabetic patients remain unclear. It has been demonstrated that the level of glycated hemoglobin (HbA1c) is associated with worse fibrin clot phenotype and fibrinogen glycation is a major mechanisms of those alterations.

Aims: We investigate the impact of diabetes duration on plasma fibrin clot characteristics in a cohort of type 2 diabetic patients.

Methods: We studied 156 consecutive patients with type 2 diabetes (87 men, 69 women, aged 66.0 ± 8.5 years, mean disease duration 7.3 years, HbA1c levels from 5.2% to 12.6%). The patients were at high cardiovascular risk, i.e. 149 (95.5%) had hypertension, 126 (80.8%) had dyslipidemia, 103 (66%) were obese, 14 (9.0%) were current smokers, 41 (26.3%) had family history of cardiovascular disease (CVD). *Ex vivo* plasma fibrin clot permeation, turbidity, and efficiency of fibrinolysis using three different assays with various final recombinant tissue plasminogen activator concentrations, along with peak thrombin generation and fibrinolytic proteins were investigated.

Results: There were more patients with obesity, with documented CVD, diagnosed neuropathy and treated with insulin in the group with diabetes duration above 5 years ($n = 68$). There were no differences in laboratory parameters including fibrinogen between the groups with longer and shorter diabetes duration. Five percent lower clot permeability (*Ks*; $P < 0.0001$), 8.2% prolonged clot lysis time (CLT; $P = 0.017$) and 7.8% prolonged half-lysis time ($t_{50\%}$; $P < 0.0001$) were observed in patients with longer diabetes duration. Maximum D-dimer levels released from clots were (+4.5%, $P = 0.011$) higher and D-D rate was (2.8%, $P = 0.002$) lower compared to patients with shorter diabetes duration. Maximum absorbance of a fibrin gel, was (+3.6%, $P = 0.004$) higher, while lag phase was (4%, $P = 0.01$) shorter in patients with longer diabetes duration. Those patients had higher peak thrombin generation (+17.5%), plasminogen activator inhibitor-1 (PAI-1) antigen (+13%), tissue plasminogen activator (tPA) antigen (+17.9%, all $P < 0.001$) and antiplasmin (+7.2%, $P = 0.04$). Thrombin activatable fibrinolysis inhibitor (TAFI) and soluble thrombomodulin tended to be higher in patients with longer diabetes duration ($P < 0.1$). Comparison of patients with worse and better glycemic control (cut-off, HbA1c 6.5%), who did not differ with regard to fibrinogen, showed no differences in thrombin generation and fibrinolysis parameters. Fibrin clots obtained from plasma of patients with HbA1c>6.5% had 5% lower *Ks* ($P = 0.002$), 6.5% prolonged CLT ($P = 0.02$) and $t_{50\%}$ ($P = 0.0002$). Maximum D-dimer levels released from clot in the HbA1c>6.5% group were higher (+4.5%, $P = 0.026$) and Lag phase was (4.5%, $P = 0.027$) shorter in this group. Cardiovascular events and macrovascular diabetic complications as well as cardiovascular risk factors were not associated with less favorable fibrin clot variables.

Conclusions: Prolonged duration of type 2 diabetes is associated with more prothrombotic fibrin clot phenotype, including impaired fibrinolysis and those alterations are largely driven by increased thrombin generation and PAI-1 levels.

PA 1.14-6

Fluid and solute transport in thrombi as function of platelet and fibrin density

Wufsus AR and Neeves KB

Colorado School of Mines, Golden, CO, USA

Background: There is growing evidence that fluid and solute transport within the interstitial spaces of thrombi plays a role in thrombus growth, arrest, and dissolution [Stalker et al., *Blood*, in press, 2013]. However, there is a paucity of data on the physical properties, such as the permeability of fluid and diffusivity of solutes, that dictate these phenomena. The data that does exist has been collected at fibrin and platelet concentrations that are orders of magnitude less than what has been reported in thrombi formed *in vivo*. [Wysokinski et al., *J Thromb Haemost,* 2, 2004; Silvain et al., *J Am Coll Cardiol*, 57, 2011]

Aims: The objective of this work was to measure the hydraulic permeability and solute diffusivity in model thrombi as a function of platelet and fibrin density over the range of fibrinogen and platelets concentrations found in thrombi formed *in vivo*.

Methods: A series of thrombi were formed by adding 10 nM α-thrombin to solutions containing 3–156 mg/mL of fibrinogen and 0–5×10^7 platelets/μL. To measure permeability, both fibrin gels and platelet rich clots were formed in 3 mL syringes, which served as a permeation chamber. The flow rate of Tris buffer saline (TBS) through these clots at a constant pressure was used to calculate the permeability using Darcy's law. Fluorescence recovery after photobleaching (FRAP) was used to measure diffusion coefficients of FITC-labeled dextrans of 12, 29, and 54 nm in diameter in fibrin gels and platelet rich clots.

Results: Fibrin formed with fibrinogen concentrations from 3 to 156 mg/mL resulted in gels with a fiber volume fraction of 0.02–0.54 and permeabilities of 1.2×10^{-1}–1.5×10^{-4} μm^2. Platelet rich clots with a platelet volume fraction of 0.01–0.61 and a fibrin volume fraction of 0.03 had permeabilities over a range of 1.1×10^{-2}–1.5×10^{-5} μm^2. Preliminary results from FRAP studies show that diffusion was hindered in fibrin gels compared to free solution. We observed 60%, 66% and 85% reductions of diffusion coefficients for 12, 29, 54 nm probes, respectively, in fibrin gels (100 mg/mL fibrinogen).

Conclusions: The primary outcome of these studies is a catalog of physical properties that determine fluid and solute transport in thrombi as a function of their composition. These data provide bounds on how far zymogens and fibrinolytic agents can be expected to penetrate into clots with different composition. For example, at pressures typical of large human arteries one would expect plasmin travel no further than approximately 100 μm over 1 h into the interior platelet rich clot. In addition, the hindrance of diffusion of coagulation proteins and platelet agonists out of thrombi is a potential mechanism for the arrest of thrombi growth. Finally, these data will aid in the development of the growing number of computational models of thrombi formation, which, to date, have relied on semi-empirical correlations that are not valid for the wide range of solid fractions found in real thrombi.

Effect of coagulation factors and heparin on FXa inhibition by TFPI

Heinzmann CA[1], Thomassen LGD[1], Peraramelli S[1], Hackeng TM[1], Hartmann R[2], Scheiflinger F[2], Rosing J[1] and Dockal M[2]

[1]*Maastricht University, Maastricht, The Netherlands;* [2]*Baxter Innovations GmbH, Vienna, Austria*

Background: TFPI is protease inhibitor which contains three Kunitz domains (KD1, KD2 and KD3) and which down-regulates the extrinsic coagulation pathway by inhibiting FXa and FVIIa. All three Kunitz domains of TFPI contribute to the inhibition of FXa, indicating that inhibition is the result of multiple interactions between FXa and TFPI. FXa as well as TFPI have been reported to interact with several coagulation factors (e.g. protein S, FV, FVa, prothrombin), and with phospholipids and heparin.

Aim: To investigate the effect of proteins and other ligands that bind to FXa and TFPI on the efficacy of FXa inhibition by TFPI.

Methods: Recombinant full length TFPI ($TFPI_{fl}$) and TFPI constructs (KD2, $TFPI_{1–150}$) were purified from bacterial expression systems. Inhibition of FXa by TFPI and TFPI constructs was quantified by measuring progress curves of conversion of the FXa-specific chromogenic substrate CS11-(65) by FXa. The effects of prothrombin, FV, FVa and protein S on FXa inhibition were determined in the presence of negatively charged phospholipid vesicles and Ca^{2+} ions. Heparin and FXa antibody effects were determined in the presence of Ca^{2+} ions.

Results: A monoclonal FXa antibody (aBFX-2b), which is an exosite-directed inhibitor of prothrombinase that does not inhibit the active site of FXa and that has no effect on its amidolytic activity, impairs FXa inhibition by both $TFPI_{fl}$ and KD2. Unfractionated heparin, which binds both FXa and $TFPI_{fl}$, stimulated FXa inhibition by $TFPI_{fl}$ approximately 10-fold at low heparin concentrations (0.2–1 U/mL), but impaired inhibition at higher concentrations (> 1 U/mL). Unfractionated heparin had virtually no effect on FXa inhibition by $TFPI_{1–150}$ and fondaparinux, a synthetic pentasaccharide related to heparin that specifically enhances antithrombin-mediated inhibition of FXa, had also no effect on FXa inhibition by $TFPI_{fl}$ at concentrations up to 800 mg/mL. Protein S, which binds to KD3 of TFPI, and thrombin-cleaved protein S enhanced FXa inhibition by TFPI ($t_{1/2}$ approximately 3 min), but not by $TFPI_{1–150}$. Physiological concentrations FV (20 nM), which like protein S binds $TFPI_{fl}$, enhanced FXa inhibition by $TFPI_{fl}$ approximately 2–3 fold and had virtually no effect on FXa inhibition by $TFPI_{1–150}$. Thrombin-activated FV (FVa) did not enhance the anticoagulant activity of $TFPI_{fl}$, but in contrast impaired the ability of $TFPI_{fl}$ to inhibit FXa, particularly at low TFPI concentrations. $TFPI_{fl}$ appeared to be a potent inhibitor of FXa-catalyzed prothrombin activation in the absence of FVa, but hardly inhibited prothrombin activation by FXa in the presence of FVa.

Summary and Conclusions: $TFPI_{fl}$ is a potent inhibitor of FXa which at physiological concentrations (0.25–0.5 nM TFPI) inhibits FXa with a $t_{1/2}$ = 3–15 min. Direct inhibition of FXa by $TFPI_{fl}$ is modulated by other coagulation factors (prothrombin, FV and FVa), protein S and heparin. These modulating effects indicate that interactions of the various Kunitz domains of TFPI with epitopes on FXa distinct from the active site contribute to FXa inhibition. Modulation of TFPI activity was observed at physiological concentrations indicating that they are important for the *in vivo* expression of anticoagulant activity of TFPI.

PA 1.15-2

Implication of the protein S/Growth arrest-specific gene 6 pathway in the pathophysiology of purpura fulminans

Angelillo-Scherrer A[1], Prince R[2], Calzavarini S[2], Saller F[3], Racine M[2] and Azevedo M[2]

[1]*University Hospital of Lausanne (CHUV);* [2]*Lausanne University Hospital, Lausanne, Switzerland;* [3]*Université Paris-Sud-XI, Châtenay-Malabry, France*

Background: Purpura fulminans (PF) is an acute skin disorder that involves a complete blood flow blockade in dermal and subcutaneous vasculature. Common causes of PF are severe infection and deficiency of the natural anticoagulants in the blood. Current knowledge on its pathologic mechanisms is still limited.

ProS is an anticoagulant protein, its deficiency is associated to the development of PF as documented by newborns homozygous for ProS

mutations. Beside its role in blood coagulation, ProS exerts cellular functions by binding to and activating cell surface Tyro3, Axl, and Mer tyrosine kinase receptors (TAM). Recently, the characterization of murine model of partial and complete ProS deficiency has shown defects in vessel development and function for those mice.
The product of Growth arrest-specific gene 6 (Gas6) is a protein showing an high degree of similarity compared to ProS both in module organization and at the amino acid level. Gas6 has been shown to be a ligand for the TAM receptors as ProS. Unlike ProS, Gas6 displays a procoagulant effect by amplifying platelet activation and upregulating the expression of vascular tissue factor. Interestingly, both Gas6 and ProS belongs to the family of vitamin K-dependent proteins.
Aims: To investigate the role of ProS, Gas6 and TAM receptors in PF pathophysiology.
Methods: We generated a model mimicking PF by exposing mice to warfarin, a vitamin K antagonist. 0.8 mg warfarin was administered *per os* for 5 days to wild-type (WT), *ProS*, *Gas6*, *Tyro3*, *Axl* and *Mer* deficient mice.
Results: Adult mice with complete *Gas6* or partial *ProS* deficiency did not develop spontaneous PF. To investigate the pathologic mechanisms leading to PF, we administer warfarin. We observed a difference in mortality for *Gas6*−/− (100%, $n = 20$) and *ProS*+/−/*Gas6*−/− (88%, $n = 8$) mice compared to the WT (6%, $n = 17$) mice ($P < 0.05$). In addition, mice deficient in TAM receptors where significantly affected by warfarin challenge (mortality rate: 43% in *Tyro3*−/− ($n = 7$), 38% in *Axl*−/− ($n = 8$) and 14% in *Mer*−/− compared to 6% in WT mice, $P < 0.05$). Notably, most of the mice with ProS/Gas6 pathway deficiency developed skin lesions involving ears, extremities and genital areas, compatible with PF. Such lesions were never observed in WT. Early lesions were erythematous with highly visible ear skin vessels, necrosis appearing in advanced lesions. Ear skin histology of mice with PF showed vascular engorgement, intradermal edema and only rare thrombosis in early lesions, whereas massive red blood cell extravasation, intra-epidermal hemorrhagic blisters and necrosis were found in advanced lesions.
Summary/Conclusions: These data suggest a prominent vascular involvement in PF lesions when the ProS/Gas6 pathway is deficient. Lack of Gas6 or TAM receptors being antithrombotic, the thrombotic process might be less central in PF pathophysiology than currently admitted. Thus, the vasculature might constitute the main target during PF development and the ProS/Gas6 pathway through the TAM receptors in the endothelium appeared to be involved in the process.
Interestingly, our warfarin-induced PF in $Pros^{+/-}/Gas6^{-/-}$could also be used as a mouse model of PF, which to our knowledge is still lacking.

PA 1.15-3
In vivo characterization of double deficiency in protein S and growth arrest-specific gene 6

Angelillo-Scherrer A[1], Prince R[2], Calzavarini S[2], Saller F[3], Azevedo M[2] and Racine M[2]
[1]*University Hospital of Lausanne (CHUV);* [2]*Lausanne University Hospital, Lausanne, Switzerland;* [3]*Université Paris-Sud-XI, Châtenay-Malabry, France*

Background: Protein S (ProS) and growth arrest-specific gene 6 (Gas6) are vitamin K-dependent proteins. ProS is a natural anticoagulant whose physiological importance is exemplified by life-threatening thrombotic disorders (e.g. purpura fulminans) occurring in newborns with homozygous ProS deficiency. Unlike ProS, Gas6 displays a procoagulant effect by amplifying platelet activation and upregulating the expression of vascular tissue factor. In tissues, ProS and Gas6 exert cellular functions by binding to and activating the same cell-surface tyrosine kinase receptors of the Tyro3 family (TAM).
Aims: To investigate the synergic role of ProS and Gas6 *in vivo* by using murine models.
Methods: We first crossed $ProS^{+/-}/Gas6^{+/+}$ with $ProS^{+/+}/Gas6^{-/-}$ mice. $ProS^{+/-}/Gas6^{-/-}$ strain was then used to obtain mice with a complete double deficiency in ProS and Gas6. In addition, $ProS^{+/-}/Gas6^{+/+}$ were mated in order to generate mice with single ProS deficiency. Genotypic and phenotypic analysis on embryos between E14 and E19, newborns and adults were performed to characterize the double deficiency of ProS and Gas6 in mice.
Results ProS+/−/*Gas6*−/− mice were viable and showed an apparently normal phenotype and development. During adult life, they were crossed to generate $ProS^{-/-}/Gas6^{-/-}$ mice, however among the newborns analyzed ($n = 30$), no double newborn deficient for ProS and Gas6 was observed. Similar results were obtained for the $ProS^{-/-}/Gas6^{+/+}$ genotype.
Macroscopic and histological analysis of $ProS^{-/-}/Gas6^{-/-}$ embryos at different developmental stages (E14–E19) was performed. Interestingly, 24% (5/21) embryos were found dead, showed brownish skin coloration, reduced size and presented developmental defects. Furthermore, 24% (5/21) of them showed relevant pallor with no macroscopically visible vascularization throughout the body, but normal size and development. These abnormalities were never observed in $ProS^{-/-}/Gas6^{+/+}$ embryos. The remaining 52% (11/21) of $ProS^{-/-}/Gas6^{-/-}$ embryos presented massive thrombosis associated with hemorrhages throughout the body, and the absence of the macroscopically visible principal blood vessels; a similar phenotype was previously observed in $Pros^{-/-}/Gas6^{+/+}$embryos. Moreover, we noticed the presence of red blood cells in the extra-vascular compartments, particularly in the head and back, pointing to a severe vascular defect in all $Pros^{-/-}/Gas6^{-/-}$ embryos. We analyzed the vascular network of whole-mounted dorsal skin E15 embryos, by using anti-Ter119 (specific for red blood cells) and anti-VE-cadherin (expressed by endothelial cells) antibodies. The dorsal skin of $Pros^{-/-}/Gas6^{-/-}$ embryos displayed areas with incomplete or collapsed vessels, and widespread red blood cells extravasation. A similar pattern was observed in $Gas6^{+/+}Pros^{-/-}$ embryos (preliminary data).
Summary/Conclusions: Double deficiency in ProS and Gas6 is lethal before birth. The phenotype of $Pros^{-/-}/Gas6^{-/-}$ embryos, characterized by a high percentage of pale embryos and about one fourth of necrotic embryos, appears more severe as compared to the phenotype of $Pros^{-/-}/Gas6^{+/+}$ embryos. Abnormalities in the vascular network were present in both genotypes. Further studies are ongoing to better understand the mechanisms responsible for the observed vascular defects.

PA 1.15-4
Autodegradation of murine activated protein C due to cleavage at Lys43

Burnier L, Fernandez JA and Griffin JH
The Scripps Research Institute, La Jolla, CA, USA

Background: Multiple protective effects of pharmacologic activated protein C (APC) are reported in several pathologies, mostly using mouse models. Murine APC mutants are valuable for mechanistic studies and proof-of-concept *in vivo* studies. Murine APC production requires multiple challenging steps due to autodegradation of APC. This is especially important when comparing *in vitro* and *in vivo* potencies of different APC variants.
Aims: To develop a new methodology that will decrease degradation of murine APC during activation and that will enable active site titration of APC.
Methods: Recombinant murine protein C (PC) was produced using conventional methods. Before activation, PC was dialyzed into different saline buffers (citrate pH 6.0, 2-(N-morpholino)ethanesulfonic acid (MES) pH 6.0 or Tris pH 8.0) containing EDTA or various different metal ions (calcium, zinc, manganese, magnesium). PC activation was performed using human thrombin (100 U/mL) at 37 °C for 4 h. SDS-PAGE was used and proteins visualized by Coomassie staining. Amidolytic activity assays were performed at pH 8.0 and 0.4 mM Pefac-

hrome PCa colorimetric substrate. Active site was titrated by incubating mouse APC with biotinylated FPR-chloromethylketone and quantified by Western blotting using infrared dye-conjugated-streptavidin. Human APC was used as a standard. For N-terminal amino acid sequence analysis, APC was run on SDS-PAGE and Western blotted on PVDF membrane. Protein bands were revealed by Coomassie and cleaved APC product bands removed for amino acid sequence analysis.

Results: A major problem during activation involved APC autodegradation of the light chain due the cleavage at the Lys43-Tyr44 peptide bond, as revealed by Western blotting using specific antibodies for the light chain and N-terminal amino acid sequencing. We compared the amount of this cleavage after PC activation in different buffers. Citrate or MES buffers (pH 6.0) showed reduced APC autodegradation in comparison to Tris buffer (pH 8.0). Activation of PC in presence of zinc (0.25–1 mM) at pH 6.0 showed a significant reduction of APC autodegradation. We did not observe differences in the activation rates in the presence of EDTA or zinc. After thrombin inhibition with hirudin, APC was purified by FPLC. We compared amidolytic activity of APC that was activated in EDTA or zinc buffer in a buffer containing 5 mM EDTA or 1 mM Zn2+, since zinc ions inhibit amidolytic activity of human APC. Direct comparison showed that APC generated in presence of Zn^{2+} had a higher activity than APC made in the presence of EDTA.

Conclusions: Murine APC autodegradation involves cleavage at Lys43 that can be avoided by simple buffer modifications. Mutation of Lys43 in murine PC should simplify the production of mouse quality murine APC for mechanistic and *in vivo* studies.

The search for functionally important residues in protein S required for its enhancement of TFPI

Reglinska NB[1], Andersson HMH[1], Rezende SM[2], Dahlbäck B[3], Crawley JTB[1], Lane DA[1] and Ahnström J[1]

[1]Imperial College London, London, UK; [2]Universidade Federal de Minas Gerais, Minas Gerais, Brazil; [3]Lund University, Malmö, Sweden

Background: Tissue factor pathway inhibitor (TFPI) is a natural anticoagulant protein that specifically inhibits the initiation of coagulation through direct binding and inhibition of FXa and the TF/FVIIa complex. Protein S acts as a cofactor for TFPI that critically reduces the inhibition constant for FXa to below the plasma concentration of TFPI – thus enabling efficient down-regulation of thrombin generation at physiological concentrations of TFPI. We recently showed that TFPI Kunitz domain three residue Glu226 constitute an essential residue for the interaction of TFPI with protein S during its inhibition of FXa. However, it is not known which domains or residues in protein S are required for its TFPI cofactor activity.

Aims: To fully understand the mechanism underlying the TFPI cofactor function of protein S, the present study aimed to determine the importance of solvent-exposed amino acid residues of protein S in its direct interaction and enhancement of TFPI.

Methods: A panel of 46 protein S variants, spanning the full length of the protein S molecule, were constructed, expressed and quantified in concentrated culture media. Residues were substituted either in composite or single point variants for the protein S Gla-TSR-EGF1-EGF2-EGF3-EGF4 domains. To study the importance of the SHBG-domain we used a previously described protein S chimera in which the SHBG domain was replaced by the corresponding domain of the homologous Gas6. The TFPI cofactor function of the protein S variants was examined using thrombin generation assays and the TFPI-protein S interaction by co-immunoprecipitation.

Results: In thrombin generation assays using protein S deficient plasma, TFPI was efficiently enhanced by recombinant wild-type (WT) protein S in a dose-dependent manner. When protein S variants were screened using this assay, a large proportion exhibited appreciable enhancement of TFPI. However, none of the protein S variants completely lacked TFPI cofactor function. To investigate the interaction between TFPI and the protein S variants a co-immunoprecipitation assay was developed. TFPI was immunoprecipitated using a monoclonal antibody, binding to the TFPI Kunitz domain 1. Co-immunoprecipitation of protein S was investigated by Western blotting. WT protein S co-immunoprecipitated with WT TFPI, whereas no WT protein S was detected after immunoprecipitation of TFPI E226A, suggesting that this method was suitable for screening our protein S variants for variants unable to interact with TFPI. However, similarly to the results from the thrombin generation assay, the protein S variants were co-immunoprecipitated with TFPI in either similar or only moderately decreased levels compared to WT protein S.

Summary: TFPI Glu226 has previously been shown to be essential for the interaction with protein S. The large number of protein S variants showing only modestly decreased enhancement of TFPI in the functional assays suggests that several protein S residues are cooperatively important for its enhancement of TFPI. Further functional assays and direct binding studies using purified components are required to identify these residues.

PA 1.15-6

Stabilization of N-glycosylation in Asn135 of antithrombin by an aromatic sequon

Aguila S[1], Martínez-Martínez I[1], Navarro-Fernández J[1], Gutiérrez-Gallego R[2], Pérez-Sánchez H[3], De La Morena-Barrio ME[1], Vicente V[1] and Corral J[1]

[1]Centro Regional de Hemodonación, Hospital Morales Meseguer, UMU, IMIB, Murcia; [2]IMIM-Hospital del Mar, Universidad Pompeu Fabra, PRBB, Barcelona; [3]Facultad de Ciencias Informáticas, UMU, Murcia, Spain

Background: *N*-glycosylation is a crucial post-translational modification. Two recent studies have demonstrated that an aromatic sequon (Phe-Y-Asn-X-Thr) in reverse β-turns increases the *N*-glycosylation efficiency and the global stability of three different proteins. However, the potential efficiency of this sequon in other contexts has not been evaluated. Antithrombin is a key anticoagulant serpin. Two main glycoforms of antithrombin are present in plasma: a and b, with four and three *N*-glycans, respectively. Although b-antithrombin is the less abundant glycoform in plasma (10%) the rate of secretion of both glycoforms is similar. The reduced efficiency of glycosylation of antithrombin at position Asn135 is not fully understood but has been suggested to be caused by an inefficient consensus sequence, Asn-X-Ser, while in the rest of glycosylation sites (Asn92, 155, 196) the consensus sequence is Asn-X-Thr. Interestingly, Asn135 lays in a loop between helix D and strand 2B.

Aim: To evaluate the effect of an aromatic sequon at Asn135 on the efficiency of glycosylation and the stability of the native conformation of antithrombin.

Methods: Single and multiple mutants affecting the Asn135 sequon (Lys133Phe, Ser137Thr, Ser137Ala and Lys133Phe/Ser137Thr) were produced in HEK-EBNA cells and purified by heparin affinity and anion-exchange chromatography. Biochemical and functional studies included mass spectrometry, differential scanning calorimetry, intrinsic fluorescence, stopped flow and functional chromogenic assays.

Results: The wild type sequence generated similar amounts of both glycoforms (α and β), while the incorporation of a Phe two residues before Asn135 (Lys133Phe), the generation of the common N-glycosylation sequence on antithrombin (Ser137Thr) or both mutations together (Lys133Phe/Ser137Thr) full improved glycosylation efficiency, leading to the secretion of only a-antithrombin glycoform (4 *N*-glycans) according to mass spectrometry and electrophoretic analysis. Differential scanning calorimetry revealed that the presence of the aromatic sequon did neither increase nor reduce the stability of

this conformationally sensitive serpin. However, stopped flow data suggested that the presence of a Phe two residues before Asn135 hindered the conformacional change induced by heparin. Accordingly, the Lys133Phe and the double (Lys133Phe/Ser137Thr) mutations impaired 2- and 4-fold, the heparin affinity, respectively. As expected, the anticoagulant activity of these variants in presence of heparin was paralleled affected in these mutants (80% and 50% of wild type activity, respectively).

Conclusion: Our data support that an aromatic sequon improves the efficiency of *N*-glycosylation in other contexts than in a reverse turn. These results open new possibilities for glycoengineery in other proteins. In antithrombin, this aromatic sequon allows a full glycosylation of Asn135, located in a loop between the helix D and the strand 2B. However, this sequon did not increase the global stability of this serpin, although it preserves the native conformation of the heparin binding domain, impairing the conformational change induced by the binding of heparin.

PA 1.16-1

Predictors of factor Xa generation in breast cancer

Lakoski SG[1], Bravo MC[1], Wolfe P[2], Cushman M[1], Thompson H[3] and Brummel-Ziedins K[1]

[1]University of Vermont, Colchester, VT; [2]University of Colorado, Denver, CO; [3]Colorado State University, Fort Collins, CO, USA

Background: Venous thromboembolism (VTE) is a serious complication commonly associated with hormone therapy for breast cancer. VTE can have a devastating effect on quality of life (e.g. post-thrombotic syndrome; chronic anticoagulation; bleeding complications) as well as result in premature death. Patients with breast cancer may be exposed to multiple VTE risk factors in addition to hormonal therapy over the course of their disease; however, an understanding of prior and concurrent VTE risks among breast cancer patients is not fully elucidated.

Aims: We determined associations with factor (f) Xa generation, a key predictor of thrombosis and therapeutic target for VTE among breast cancer patients.

Methods: In this cross-sectional study, we studied 181 overweight and obese non-smoking breast cancer patients who had completed primary adjuvant therapy. We measured coagulation factors II, V, VII, VIII, IX, X, antithrombin, and tissue factor pathway inhibitor to assess tissue factor-initiated fXa generation. We estimated Kendall's Tau-b and Pearson's correlation coefficients as well as ANOVA to identify predictors of fXa generation. Variables considered included age, anthropometric variables (BMI, waist-hip ratio, fat weight, percent body fat), adipocytokines (adiponectin, leptin), cardio-metabolic risk markers (LDL cholesterol, triglycerides, C-reactive protein, insulin, homeostasis model of assessment- insulin resistance [HOMA-IR]), tumor characteristics (tumor size, stage, lymph node status), prior adjuvant therapies (chemotherapy, radiation), hormonal therapy (tamoxifen, anastrozole) and statin use.

Results: The mean $\pm$ SD time from adjuvant therapy was 5 ± 5 years. Women were on average 55 ± 9 years old with BMI ranging from 25 to 35 kg/m². Of all variables considered, only leptin, LDL cholesterol, and tamoxifen were associated with peak fXa generation; leptin ($r = 0.19$, $P = 0.01$) and tamoxifen ($r = 0.29$, $P < 0.001$) were positively correlated while LDL cholesterol was negatively correlated (-0.21, $P = 0.003$). Tamoxifen users had significantly higher peak fXa generation (5.4 ± 1.7 nM) compared to breast cancer patients on aromatase inhibitor, anastrazole (4.1 ± 1.3 nM), or patients on neither therapy (3.9 ± 1.3 nM; $P < 0.001$).

Conclusion: Among a group of overweight and obese breast cancer patients, tamoxifen use was the strongest driver of peak fXa generation. In contrast, anastrazole therapy was not correlated with fXa. Measures of adiposity were not related to fXa generation, except leptin, a metabolically active adipokine important in the regulation of body weight. To our knowledge, these are the first data elucidating exposures and risk factors in breast cancer patients impacting peak fXa generation.

PA 1.16-2

Clinical course of cerebral venous thrombosis in adults with acute lymphoblastic leukemia

Lauw MN[1], Zuurbier SM[1], Coutinho JM[1], Majoie CBLM[1], Van Der Holt B[2], Cornelissen J[2], Middeldorp S[1], Biemond BJ[1] and Stam J[1]

[1]Academic Medical Center, Amsterdam; [2]Erasmus MC – Daniel den Hoed, Rotterdam, The Netherlands

Background: Venous thromboembolism (VTE) occurs frequently in patients with acute lymphoblastic leukemia (ALL). Reported incidence varies between 2% and 36%. Remarkably, cerebral venous thromboses (CVT) form a relatively large proportion of VTE and represent up to 50% of events.

Aims: To explore the clinical course of a large number of CVT episodes that occurred in a well-defined cohort of adult patients treated for ALL. We analyzed clinical characteristics, prodromal symptoms, radiological characteristics, temporal relationships with treatment components of ALL, clinical outcome of CVT and impact of CVT on ALL treatment.

Methods: CVT incidence was assessed in 240 adults (16–59 years) treated for newly diagnosed ALL in the Dutch-Belgian HOVON-37 multicenter study (1999–2005; NTR228 on www.trialregister.nl). Patients generally received three cycles of combined chemotherapy before stem cell transplantation assessment. CVT was defined as an intraluminal filling defect or presence of a thrombus in one of the cerebral veins or sinuses, detected with magnetic resonance venography or computed tomographic venography. For patients with CVT, we systematically extracted clinical data from patient records and re-evaluated imaging results. We conducted a nested case-control study to explore relevant prodromal symptoms. Associations were expressed as odds ratios (OR) with corresponding 95% confidence intervals (CI).

Results: Nine of 240 patients experienced CVT (4%; median age 33 years (range 17–49), 56% female, five with B-ALL and four with T-ALL). CVT was preceded by headache in eight of nine patients, while only five of 18 matched controls without CVT reported headache (OR 20.8; 95% CI 2–212). Seizures occurred in eight of nine patients with CVT and in none of 18 controls (OR 138.7 (10–6422); six patients with CVT presented with focal neurological deficits vs. two of 18 controls (OR 13.8; 95% CI 2–142). Median time between symptom onset and CVT diagnosis was 1 day (range 0–6). CVT was located in the superior sagittal sinus in eight of nine patients. Seven of nine patients had brain parenchymal lesions (five hemorrhagic infarcts, two non-hemorrhagic infarctions). All CVT events occurred during Cycle I of remission induction treatment; in eight of nine patients during or shortly after L-asparaginase therapy (E.coli) and in all patients after at least one dosage of intrathecal methotrexate. CVT formed 38% of all VTE during Cycle I. Eight of nine patients were treated with therapeutic dose (low-molecular-weight) heparin. Two patients also underwent endovascular thrombolysis; both died in the acute phase due to transtentorial herniation. Two of nine patients with CVT had recurrent VTE, none a recurrent CVT. CVT occurrence was adversely associated with obtainment of complete remission on protocol (adjusted OR 0.12; 95% CI 0.03–0.51).

Conclusions: Although CVT is a rare manifestation of VTE, our study indicates it is much more common among adult ALL patients. CVT often occurred during L-asparaginase and methotrexate therapy in Cycle I and had an adverse impact on ALL treatment outcomes. Presence of headache and seizures were strongly associated with CVT. Close monitoring of headache during ALL treatment may contribute to earlier detection of CVT and could improve its outcome.

PA 1.16-3

Plasma fibrin clot abnormalities in patients with multiple myeloma: association with thromboembolic events during induction therapy

Undas A[1], Usnarska-Zubkiewicz L[2], Helbig G[3], Woszczyk D[4], Kozinska J[5], Dmoszynska A[5], Podolak-Dawidziak M[2] and Kuliczkowski K[2]

[1]Jagiellonian University Medical College, Krakow; [2]Wroclaw Medical University, Wroclaw; [3]Silesian Medical University, Katowice; [4]Department of Hematology, Opole; [5]Medical University of Lublin, Lublin, Poland

Introduction: Multiple myeloma (MM) is associated with increased risk of venous and arterial thromboembolism. Formation of denser and poorly lysable fibrin clots is observed in patients with arterial and venous thromboembolism.

Aims: We investigated fibrin clot properties and their treatment-induced alterations in MM patients.

Patients and Methods: *Ex vivo* plasma fibrin clot permeability, turbidity and susceptibility to lysis induced by recombinant tissue-type plasminogen activator (tPA) were evaluated in 106 MM patients (55 men and 51 women aged 34–85 years), vs. 100 age- and sex-matched controls. Patients on thromboprophylaxis with aspirin or heparins were eligible. The patients were evaluated prior to and following 3 months of induction therapy, mainly using thalidomide-based regimens.

Results: MM patients had lower clot permeability (−34%), compaction (+34%), indicating denser fibrin clots, impaired fibrin polymerization with longer lag phase (+20%) and lower final turbidity (−25%), combined with hypofibrinolysis reflected by longer clot lysis time ($t_{50\%}$, −24%) and slower rate of D-dimer release from fibrin clots (D−D_{rate},-10%) compared with controls (all $P < 0.001$). Maximum D-dimer levels released from clots (D−D_{max}) were elevated by 24.3% in the patients compared to controls ($P < 0.001$). Patients with IgG MM had lower clot permeability compared with IgA MM (5.9 [5.1–6.4] vs. 6.3 [5.9–7.2] 10^{-9} cm^2; $P = 0.007$). The MM patients had higher peak thrombin concentration (+63.5%), thrombin-activatable fibrinolysis inhibitor (TAFI) activity (+32.9%), plasminogen activator inhibitor-1 (PAI-1) activity (+56.6%) and FVIII (+72.3%, all $P < 0.01$). Clot permeability in MM patients was associated with peak thrombin generation ($r = -0.63$, $P < 0.001$), PAI-1 activity ($r = -0.57$, $P < 0.001$) and TAFI activity ($r = -0.58$, $P < 0.001$), but not with fibrinogen. Similar but positive associations were observed for clot lysis time. Scanning electron microscopy confirmed abnormal clot morphology. A 3-month therapy resulted in improved clot properties observed in 48 MM (45.3%) patients in whom blood samples were available (all $P < 0.01$). Clot permeability and compaction increased (+10% and +16.7%, respectively). Fibrinolysis was accelerated ($t_{50\%}$ by 7.8% and D−D_{rate} by 7.5%). Posttreatment absorbancy of a fibrin gel increased (+19.7%) and lag phase became shorter (−5.9%). Posttreatment clot permeability and lysis time remained significantly associated with peak thrombin generation, PAI-1 activity and TAFI activity (all $P < 0.01$). Thromboembolism ($n = 12$, venous thromboembolism, $n = 10$) observed in 12 patients during induction treatment despite thromboprophylaxis (nine patients received low-dose ASA, three were on prophylactic heparin) were associated with reduced clot permeability (−8.4%), higher D−D_{max} (+13.3%), lower D−D_{rate} (−9%) and 20% longer lag phase at baseline (all $P < 0.05$). Thromboembolism in MM patients was associated with higher baseline peak thrombin concentration (+18.9%), TAFI activity (+20.8%) and PAI-1 activity (+37.5%) together with slightly lower plasminogen (−7.8%; all $P < 0.05$).

Conclusion: Substantial prothrombotic alterations of fibrin clot properties occur in patients with MM. More compact fibrin clots with reduced lysability characterize subjects who experienced thrombotic complications during induction treatment. Our findings show a new prothrombotic mechanism in MM and its determinants.

PA 1.16-4

Incidental venous thromboembolism in kidney cancer patients: a case–control study

Yokom DW[1], Ihaddadene R[1], Le Gal G[2], Moretto P[3] and Carrier M[2]

[1]University of Ottawa; [2]Ottawa Hospital Research Institute and University of Ottawa; [3]The Ottawa Hospital Cancer Centre, Ottawa, ON, Canada

Background: The incidence of venous thromboembolism (VTE) in kidney cancer patients has been previously reported to be between 1.6% and 3.4%. VTE seems to be associated with an increased mortality among kidney cancer patients (hazard ratio [HR] = 1.3–3.2). However, these studies did not report the localization (e.g. lower vs. upper limb) or extent (e.g. distal vs. proximal) of the included VTE. Furthermore, it is unclear if all events were suspected or incidental.

Computed Tomography (CT) is routinely used for staging of the underlying malignancy. As the resolution of CTs increases, more incidental VTEs are being detected. Previous reports showed that incidental VTE might be associated with lower overall survival in cancer patients. However, a wide variety of tumor sites were included and a standardized definition of thrombotic events was not used. The clinical significance of symptomatic and incidental VTE in kidney cancer patients is unknown.

Aims: To determine the effect of suspected and incidental VTE on overall survival in kidney cancer patients.

Methods: A case-control study of all kidney cancer patients treated at our institution between January 1, 2005 and July 1, 2012 was conducted. Cases with VTE (suspected and incidental) were matched in a ratio of 1:2 to controls by gender, age (± 3 years) and stage at cancer diagnosis (TNM stage 1–4). Imaging studies were reviewed to identify the location of the VTE and whether it was symptomatic or incidental. VTE was defined as: (i) proximal DVT of the lower and upper extremities; (ii) pulmonary embolism (PE; segmental or more proximal); and (iii) any intra-abdominal VTE. The primary outcome was overall survival 2 years following the diagnosis of cancer for all symptomatic and asymptomatic VTE.

Results: A total of 1140 primary kidney cancer patients were reviewed for inclusion into the study. Sixty-eight patients (6.0%) had a VTE event. Men represented 69% of cases, mean age 62 years old (range 35–79 years), 53% were early stage (stage 1–3). Twenty-four (35%) cases of VTE were incidentally detected.

Compared to matched controls, all patients with VTE did not have worsened overall survival (HR = 0.97; 95% CI: 0.60–1.56). Treated symptomatic or incidentally discovered VTE were not associated with an increased risk of death compared to controls (HR = 0.82; 95% CI: 0.46–1.46 and HR = 1.31; 95% CI: 0.68–2.52 respectively). Similarly, symptomatic or incidentally discovered PE were not associated with lower overall survival (HR = 1.48; 95% CI: 0.70–3.13 and HR = 0.92; 95% CI: 0.37–2.30 respectively).

Conclusions: Kidney cancer patients are at high risk of VTE (6.0%), of which 35% were found incidentally on staging CT. Treated symptomatic and incidental VTE are not associated with worse overall survival among kidney cancer patients. Future studies assessing the clinical impact of VTE (incidental or symptomatic) among cancer patients need to adjust for tumor type, stage and other important confounders.

PA 1.16-5

Association of interleukins with venous thromboembolism and mortality in cancer patients

Reitter E-M, Ay C, Kaider A, Pirker R, Zielinski C, Zlabinger G and Pabinger I

Medical University of Vienna, Vienna, Austria

Background: Elevated rates of interleukins (ILs) were reported to be related to the risk of cancer development and cancer progression. The

survival of cancer patients seems to correlate with various IL-levels and IL-levels differ depending upon the tumor type. Studies showed an association between elevated IL-levels and venous thromboembolism (VTE) in non-cancer patients. There is also some evidence that such an association is present in cancer patients.

Aims: The present study aims to evaluate an association between different ILs and the occurrence of VTE as well as the patients' overall survival.

Methods: Patients with solid tumors, either newly diagnosed or progressing after partial or complete remission, were included. Recruitment took place within the framework of the Vienna Cancer and Thrombosis Study (CATS), which is an on-going prospective and observational study. At inclusion, the patients are questioned regarding their medical history and a blood sample is drawn. All participants have been observed for a maximum period of 2 years. Study endpoints are the occurrence of objectively confirmed VTE, death or completion of the study period. IL-levels (ie. IL-3, -4, -6, -8, -10, -11 and -1ß) were determined by using the xMAP technology of Luminex.

Results: We included 726 patients with solid tumors (344 female/382 male, mean age 60 years). Thereof, 337 patients died within the observation period. During the median follow-up time of 705 (quartiles: 262–731) days, 52 patients developed a VTE. The investigated ILs did not show a statistically significant association with the occurrence of VTE. In univariate analyses, levels of IL-1β, IL-3, IL-4 and IL-10 were not associated with survival of patients, whereas an increase of IL-6 [hazard ratio (HR) comparing values > 0–0 of levels: 1.60, 95% confidence interval (CI) 1.29–1.99, $P < 0.001$] and IL-8-levels [HR 1.57, 95% CI 1.04–2.39, $P = 0.032$], respectively, correlated with an increased risk of death. We have also noticed a higher mortality in patients with IL-11-levels above 0 (HR 1.373 [95% CI, 1.103–1.709], $P = 0.005$); however, this difference was not affected by the extent of increase (HR 0.971 [95% CI, 0.908–1.037], $P = 0.376$). In multivariate analyses after adjustment for age and gender, the associations between IL-6-, IL-8- and IL-11-levels and survival were statistically significant. Regarding different tumor entities, higher IL-6-levels correlated with worse prognosis in patients with colon carcinoma (HR 2.405, [95% CI 1.252–4.618], $P = 0.008$) and elevated IL-10-levels with an increased risk of death in patients with lung cancer (HR 1.824, [95% CI 1.098–3.031], $P = 0.020$).

Summary/Conclusions: We did not find an association between the investigated IL-levels and the risk of developing VTE in cancer patients. However, there was a significant higher risk of mortality in patients with elevated IL-6- and IL-8-levels. Furthermore, worse prognosis was observed for patients with lung cancer and increased IL-10-levels, and for patients with colorectal cancer and increased IL-6-levels.

PA 1.16-6

Prolonged thromboprophylaxis with low molecular weight heparin to prevent venous thromboembolism after abdominal cancer surgery: a systematic review

Rasmussen MS[1], Jorgensen LN[1], Prandoni P[2] and Kakkar VV[3]

[1]Bispebjerg Hospital, Copenhagen, Denmark; [2]University of Padua, Padua, Italy; [3]Thrombosis Research Institute, London, UK

Background: Patients undergoing major abdominal surgery are at high risk of postoperative venous thromboembolism (VTE). The efficacy and safety of thromboprophylaxis (TP) with low molecular weight heparin (LMWH) administered during the in-hospital period has been proven in several clinical studies. Accordingly, LMWHs are recommended during the in-hospital period. However, clinical studies have shown that patients remain at risk of VTE complications even after hospital discharge.

Aims: In order to clarify the role of prolonged TP with LMWH in patients undergoing abdominal surgery for malignant diseases, we performed a systematic review of all randomized clinical trials, assessing the efficacy and safety of prolonged TP with LMWH after abdominal surgery.

Methods: Electronic searches were performed in the Medline, Embase, Lilacs and the Cochrane Library databases. The most recent search was performed in November 2012. We assessed both randomized and non-randomized controlled clinical trials comparing prolonged LMWH prophylaxis with TP during the in-hospital period only. The patient population in the trials included patients undergoing major abdominal or pelvic surgery for malignant diseases. The outcome measures included symptomatic and asymptomatic cases of VTE, as assessed by objective tests. Safety outcomes were defined as bleeding complications and mortality within 3 months after surgery.

Results: Our search revealed five studies which met the inclusion criteria and were included in the meta-analysis. The total number of patients undergoing curative or palliative surgery for malignant disease was 1210. All studies used bilateral ascending venography to evaluate the VTE end-point. All patients received LMWH during the in-hospital period usually for 1 week, and were then randomized to receive an additional 3-week treatment with LMWH or placebo/control. The venography was performed 30 ± 5 days after surgery. The administration of prolonged TP significantly reduced the incidence of overall VTE compared to in-hospital administration of TP by 50% (14.0% vs. 7.0%), leading to an OR of 0.46 (95% CI, 0.31–0.68; $P < 0.0001$). Also the incidence of proximal DVT was significantly reduced from 4.4% to 0.8% (OR 0.20; 95% CI 0.08–0.50; $P = 0.0006$). There was no significant difference in the incidence of major bleeding complications (OR 1.3; 95% CI, 0.69–2.50). The number needed to treat in order to prevent one episode of the end points was 14 patients for all VTE and 28 for proximal DVT. The overall mortality was comparable in the two groups (4.7% in the treatment group and 4.1% in the control group), with OR 1.21 (95% CI, 0.73–1.99; $P = 0.46$).

Summary/Conclusions: This meta-analysis provides further compelling evidence in support of extending the administration of LMWH for up to 4 weeks after operation in patients undergoing major abdominal or pelvic surgery for malignant diseases. The strong reduction in both asymptomatic and clinically relevant major VTE events, which can be achieved by prolonging LMWH in low doses for a few additional weeks beyond the hospital stay, is not offset by bleeding complications.

Role of alpha6 integrin subunit in tumor growth and tumor angiogenesis

Helley D[1], Bouvard C[1], De Arcangelis A[2], Nizard M[3], Fischer AM[1] and Georges-Labouesse E[2]

[1]UMR-S765, Université Paris Descartes Sorbonne Paris Cité, Paris; [2]Inserm U964, Illkirch; [3]Inserm U970, Université Paris Descartes Sorbonne Paris Cité, Paris, France

Background: We have previously shown that alpha6 integrin subunit (α6) plays a major role in post-ischemic angiogenesis. α6 has been implicated in cancer cell migration and in the progression of several malignancies, but its role in tumor angiogenesis is still a matter of debate.

Aims: The aim of our study was to assess the role of α6 in tumor angiogenesis and thus in tumor growth.

Methods: Since α6 KO mice die at birth, we used the cre-lox system to generate a mouse line, α6 fl/fl-Tie2Cre+, with α6 gene deletion specifically in Tie2-expressing cells. Tie2 is a receptor of angiopoietin-2, expressed by endothelial cells, a subset of hematopoietic stem cells, and Tie2-expressing monocytes/macrophages (TEMs), known for their proangiogenic properties. To study the effect of this endothelial deletion of α6 on tumor growth and angiogenesis, one million B16F10 melanoma cells were injected subcutaneously in the right flank of

α6 fl/fl Tie2Cre+ and α6 fl/fl Tie2Cre- (control) male mice and the tumor growth was quantified. Twelve days later the mice were sacrified and tumors were harvested to study the vascular density and the macrophages infiltration in α6 fl/fl'-Tie2Cre+ compared to α6 fl/fl'-Tie2Cre- mice.

Results: Tie-2 dependent deletion of α6 gene reduced tumor growth in a murine B16F10 melanoma model by 56% ($P < 0.001$). Immunohistological analysis of the tumors showed that Tie2-dependent α6 gene deletion was associated with a decrease by 34% of tumor vascularization ($P < 0.05$). We also observed a decrease of 55% of tumor infiltration by proangiogenic Tie2-expressing macrophages ($P < 0.05$), whereas the total number of macrophages in tumors was not statistically significant between α6 fl/fl-Tie2Cre+ and α6 fl/fl-Tie2Cre- mice.

Conclusion: These findings demonstrate that α6 integrin subunit plays a major role in tumor angiogenesis and TEM infiltration. Targeting α6 could be used as a strategy to reduce tumor growth.

PA 1.17-2

Intramyocardial release of engineered chemokines from biodegradable hydrogels prevents injury extension after myocardial infarction

Projahn D[1], Simsekyilmaz S[2], Singh S[3], Groll J[4], Burlacu A[5], Bernhagen J[6], Weber C[1], Liehn EAM[2] and Koenen RR[1]

[1]Institut für Prophylaxe und Epidemiologie der Kreislaufkrankheiten (IPEK), München; [2]Institut für Molekulare Herz-Kreislaufforschung (IMCAR); [3]Institute for Technical and Macromolecular Chemistry, Aachen; [4]Department and Chair of Functional Materials in Medicine and Dentistry, Würzburg, Germany; [5]Institute of Cellular Biology and Pathology "Nicolae Simionescu", Bucharest, Romania; [6]Institute of Biochemistry and Molecular Cell Biology, Aachen, Germany

Background: Myocardial infarction (MI) induces an inflammatory immune response, which causes a progressive expansion of the infarcted area and dilation of the ventricles with replacement of the adjacent myocardium by connective tissue, the so-called 'remodeling' of the heart muscle. The regeneration of the blood vessel network system by recruitment of hematopoietic stem cells for recovering the supply of the infarcted area with oxygen, nutrients, and the prevention of apoptosis of myocytes can be beneficial for heart function.

Methods and Results: We designed a novel therapeutic strategy with Met-CCL5, a chemokine receptor antagonist to suppress initial neutrophil infiltration, and a proteaseresistant CXCL12 (S4V) variant, which is inert to matrix metalloproteinase-2 and exopeptidase cleavage, but retains its chemotactic bioactivity for recruitment of circulating hematopoietic stem cells, promoting neovascularization after MI. To control the proper timing and local release of Met-CCL5 and CXCL12 (S4V), two different biodegradable hydrogels were implemented, a fast degradable hydrogel (FDH) for delivering Met-CCL5 over 24 h and a slow degradable hydrogel (SDH) for a gradual release of CXCL12 (S4V) over 4 weeks.

Summary/Conclusions: We demonstrate that time-controlled release using Met-CCL5-FDH and CXCL12 (S4V)-SDH blocks neutrophil recruitment to the inflamed myocardium, recruits stem cells from circulating blood, and improves cardiac function after MI. Therefore, this study describes a novel and promising therapeutic strategy to sustain the endogenous reparatory mechanisms, and may represent a viable alternative to cell-based therapies, with notable clinical significance.

PA 1.17-3

Characterization of a reduced form of plasma plasminogen as the precursor for angiostatin formation

Butera D and Hogg PJ

University of New South Wales, Randwick, NSW, Australia

Plasma plasminogen is the precursor of the tumor angiogenesis inhibitor, angiostatin. Generation of angiostatin in blood involves activation of plasminogen to the serine protease plasmin and facilitated cleavage of two disulfide bonds and up to three peptide bonds in the kringle five domain of the protein. The mechanism of reduction of the two allosteric disulfides has been explored in this study. Using thiol alkylating agents, mass spectrometry and an assay for angiostatin formation, we show that the Cys462–Cys541 disulfide bond is already cleaved in a fraction of plasma plasminogen and that this reduced plasminogen is the precursor for angiostatin formation. From the crystal structure of plasminogen, we propose that plasmin ligands such as phosphoglycerate kinase induce a conformational change in reduced kringle 5 that leads to attack by the Cys541 thiolate anion on the Cys536 sulfur atom of the Cys512–Cys536 disulfide bond, resulting in reduction of the bond by thiol/disulfide exchange. Cleavage of the Cys512–Cys536 allosteric disulfide allows further conformational change and exposure of the peptide backbone to proteolysis and angiostatin release. The Cys462–Cys541 and Cys512–Cys536 disulfides have ‴/+RHHook and ‴LHHook configurations, respectively, which are measures of the geometry of the disulfide bond. Analysis of the structures of all known allosteric disulfide bonds identified six other bonds that have these configurations. This suggests that the ‴/+RHHook and ‴LHHook disulfides, along with the ‴RHStaple bond, are potential allosteric configurations.

PA 1.17-4

Targeting VEGFR1 on endothelial progenitors modulates their differentiation potential

D'Audigier C[1], Gautier B[2], Yon A[1], Alili J-M[1], Evrard S[1], Inguimbert N[2], Vidal M[2], Gaussem P[1] and Smadja D[1]

[1]Inserm UMR-S 765; [2]CNRS UMR 8638, Paris, France

We studied whether plasma levels of angiogenic factors and endothelial markers in coronary artery disease patients or undergoing cardiac surgery are modified, and whether those factors modulate endothelial progenitor's angiogenic potential.

One hundred and forty-three patients' plasmas from two different studies were analyzed (30 coronary artery disease patients, 30 patients with stable angina, coupled with 30 age and sex-matched controls; 53 patients underwent cardiac surgery). Among factors screened, only placental growth factor (PlGF) was found significantly increased in these populations. PlGF has been described acting in pathological angiogenesis through binding to VEGF receptor-1 (VEGFR1)/Flt-1, which also links VEGF-A and -B isoforms. PlGF-1 and -2 were then tested on human endothelial colony forming cells (ECFC). We found that PlGF-1 and -2 induce VEGFR1 phosphorylation and potentiate ECFC tubulogenesis *in vitro*. ECFC VEGFR1 gene expression was further inhibited using a specific small interfering RNA (siRNA, sc-29319, Santa Cruz Biotechnology, Santa Cruz, CA, USA) and the chemical compound 4321 (firstly described in Gautier et al, Chem Biol. 2011). We then observed that the VEGFR1-siRNA and the compound 4321 decrease ECFC tubulogenesis potential *in vitro*. Finally we tested the compound 4321 in the preclinical Matrigel®-plug model with C57Bl/6J mice as well as in the hindlimb ischemia model with Swiss Nude mice. We found that 4321 inhibited the plug vascularization, attested by the haemoglobin content and the VE-Cadherin expression level, and that 4321 inhibited the post-ischemic revascularization in the hind limb ischemia model.

PlGF plasma levels were found increased in cardiovascular patients. Disrupting PlGF/VEGFR1 pathway could modulate ECFC induced tubulogenesis, the cell type responsible for newly formed vessels *in vivo*.

PA 1.17-5

Imbalances in angiopoietin 1 and 2 levels in steady state sickle cell disease

Colella MP, Traina F, Fiusa ML, Souza GR, Faiotto VB, Costa F, Annichino-Bizzacchi JM, Saad STO and De Paula EV
University of Campinas, Campinas, Brazil

Background: Angiopoetins (Ang) 1 and 2 are two important factors in the regulation of embryonic and post-natal angiogenesis. Ang-1 is important in vessel maturation, whereas Ang-2 is involved in vascular disruption and destabilization. Hence, imbalances in the relative concentrations of these antagonistic modulators of angiogenesis have been associated with the pathogenesis of several conditions associated with hypoxia and inflammation such as sepsis and tumour growth. In sickle cell disease (SCD), tissue hypoxia may also serve as a potent stimulus for this angiogenic switch, which could be related to the pathogenesis of complications such as proliferative retinopathy.
Aims: We herein aimed to evaluate serum levels of Ang-1 and Ang-2 in steady state SCD, and correlate our findings with clinical and laboratory parameters.
Methods: This was a cross-sectional study conducted on a cohort of adult SCD patients, with no history of painful crisis or transfusions in the previous 3 months. Biomarkers were measured by commercially available ELISA kits. Comparisons between patients and controls were performed by Mann-Whitney test. Correlations were evaluated by Spearman Rank correlation coefficient.
Results: A total of 79 adult SCD patients were included in the study, 28 HbSS and 51 HbSC, and 20 healthy age-matched controls. Ang-2 levels were significantly elevated in SCD patients in comparison to controls (3081 vs. 1944 pg/mL; $P = 0.003$), whereas an inverse finding was observed with Ang-1, which was lower in SCD patients than in controls (47.835 vs. 56.292 pg/mL; $P = 0.03$). Since the imbalances between Ang-2 and Ang-1 ratio have been considered more informative than the isolated values of these biomarkers, the Ang-2/Ang-1 ratio was analyzed. As expected, the Ang-2/Ang-1 ratio was much higher in SCD patients than in controls (0.07 vs. 0.03; $P < 0.0001$). When HbSS and HbSC patients were compared, significantly higher Ang-2 levels were observed in HbSS patients compared to HbSC (4877 vs. 2338 pg/mL; $P < 0.0001$). Although no difference was observed in Ang-1 levels between these two patient groups (43.799 vs. 48.566 pg/mL; $P = 0.80$), the Ang-2/Ang-1 ratio was significantly higher in HbSS than in HbSC patients (0.12 vs. 0.05; $P < 0.0001$). When analyzing the whole SCD cohort, Ang-2 levels presented significant correlations with hemolysis markers (hemoglobin, hematocrit, reticulocyte count, lactate dehydrogenase levels, total and indirect bilirrubin) and leukocyte and platelet counts (all P values < 0.001). Ang-1 was significantly correlated with lactate dehydrogenase, total bilirrubin, leukocyte and platelet counts (all P values < 0.05). No significant associations were found between the presence of retinopathy and Ang-2, Ang-1 levels or Ang-2/Ang-1 ratio.
Conclusions: SCD patients present higher serum levels of Ang-2 and a high Ang-2/Ang-1 ratio, both suggestive of the activation of pro-angiogenic programs in these conditions. These findings are present in both HbSS and HbSC patients, but are much more intense in HbSS patients. In other conditions associated with hypoxia and inflammation, a high Ang-2/Ang-1 ratio represents a poor prognosis marker and an important factor in the pathogenesis of these conditions. Further studies are warranted to elucidate the relevance of these findings in the pathogenesis of SCD complications.

PA 1.17-6

Thrombin induces pro- angiogenic signals and disruption of the retinal blood barrier- an *in vitro* model

Livnat T[1], Dardik R[1], Nisgav Y[2], Weinberger D[3] and Kenet G[1]
[1]Institute of Thrombosis and Hemostasis and the National Hemophilia Center, Tel Hashomer; [2]Laboratory of Eye Research, Felsenstein Medical Research Center (FMRC)?; [3]Department of Ophthalmology, Rabin Medical Center, PetachTikva, Israel

Purpose: Thrombin is a multifunctional protease. Apart from its central role in coagulation, thrombin was found to exert some cellular effects and to be involved in inflammatory processes. The retinal pigment epithelium (RPE) forms the outer blood retina barrier (BRB) and its integrity is essential for normal function of the retina. Retinal pathologies such as pathological choroidal neovascularization (CNV), age related macular degeneration, inflammation and vascular occlusions may be accompanied by local thrombin elevation. Moreover, fibrin matrixis found in the areas of pathological newly CNV and acts as a scaffold upon which new blood vessels are grown.
Aims: In the present work, we aimed to explore the impact of thrombin on the integrity and function of the RPE blood barrier. We induced a short-term exposure of RPE to pathological levels of thrombin *in-vitro* and studied the immediate and long lasting changes in the RPE permeability and angiogenic balance.
Methods: ARPE-19 cells were grown for a month to achieve definite polarity properties. Following a short (10 min) exposure to thrombin (1–10 units/mL), the cells were washed and covered with new medium until measurements were performed. Permeability was evaluated based on spectrophotometric monitoring of the leakage of labeled dextran molecules. The expression of pro- and anti- angiogenic genes was evaluated using real time PCR. Protein levels were measured by ELISA or by FlowCytomix[TRADEMARK]. Matrix metalloproteinases (MMPs) activity was examined by zymography.
Results: Short-term exposure to thrombin induced an increase in RPE permeability to 10, 40 and 70 kD dextran that persisted for several hours. Sixty percent decrease in pigment derived growth factor (PEDF) mRNA and twofold increase in vascular endothelial growth factor (VEGF) mRNA expression and protein levels were detected even 24 h after the 10 min exposure to thrombin. MMPs 2 and 9 activities were also increased for several hours after the short-term exposure to thrombin.
Conclusions: Short-term exposure to thrombin induced proangiogenic signals in RPE and caused disruption of barrier properties. The data indicate that short-term exposure to thrombin induces changes in permeability, gene expression, protein levels and activity that persisted for hours following the exposure to thrombin. Based on our *in vitro* findings, we suggest that accumulation of short-term thrombin exposures over years may contribute to the pathological processes of retinal barrier breakage and CNV development in the elderly.

PA 1.18-2

A systematic review and meta-analysis of pathogenic mechanisms of the antiphospholipid syndrome

Du V[1], Kelchtermans H[2], Al Dieri R[2], De Groot PG[1] and De Laat B[3]
[1]University Medical Center Utrecht, Utrecht; [2]Synapse BV, Cardivascular Research Institute Maastricht, Maastricht University; [3]Maastricht University Medical Center, Maastricht, The Netherlands

Background: The antiphospholipid syndrome (APS) is diagnosed by the combination of vascular thrombosis and/or pregnancy morbidity and the detection of antiphospholipid antibodies (aPLs) in plasma. A

vast amount of mechanisms have been proposed to explain why aPLs can cause thrombosis and/or pregnancy morbidity. The focus of the mechanism studies seems to be largely diffused, given the heterogeneity in the proposed mechanisms. This heterogeneity hinders the effectiveness in pursuing the ultimate goal of benefiting the patient care. Attention and efforts are required to find the underlying reasons and solutions for this problem.

Aims: (i) to provide a systematic review of the studies investigating the pathogenic mechanisms of aPLs, (ii) to identify differences in methodology in these studies that may contribute to the heterogeneity of the proposed mechanisms.

Methods: One hundred and twenty-four studies focusing on the mechanistical actions of aPLs, published between February 2006 and March 2012, were analyzed. Besides the proposed mechanisms, we investigated the following aspects in the selected studies: (i) origin of the aPLs used (mouse/human), (ii) character of the antibodies (monoclonal or polyclonal), (ii) the criteria used to diagnose the APS patients from whom the antibodies were derived, and (iv), confirmation of the involvement of β_2GPI.

Results: The main focus of studies from the last 6 years have been the effects of aPLs on monocytes, platelets, and endothelial cells (37%). aPLs have been demonstrated to cause dysfunctions of these cells via various receptors, signaling pathways and mediators. Other studies focused on the effect of aPLs on the coagulation system (13%), fetal loss (15%), immunopathology (9%), arthrosclerosis (4%) and central nervous system (6%), resulting in five subcategories. Our analysis revealed a great heterogeneity in the methodology part in these studies: (i) heterogeneity in types of aPLs used (patient-derived total IgG antibodies 54%, human/mouse monoclonal antibodies 36%, and others 19%); (ii) heterogeneity in application of APS classification criteria (criteria not mentioned 54.4%, old Sapporo criteria 22.3%, new Sydney criteria 23.3%); and (iii) heterogeneity in the involvement of β_2GPI (anti-β_2GPI together with β_2GPI in the *in vitro* experiments 10%; β_2GPI as the primary reagent 10%, purified human aPLs alone without β_2GPI 55%). Interestingly, the subcategories of aPLs-mediated mechanisms demonstrated different profiles regarding the type of antibody that was used, the applied selection criteria and the involvement of β_2GPI, illustrating that the methodology can influence the eventual demonstrated mechanism.

Conclusions: The great diversity in methodology studying the pathogenicity of aPLs renders the mechanism studies less effective in making noticeable progress in either true knowledge seeking or patient care. This diversity may be minimized by finding a consensus on the optimal approach, more specifically regarding the type of antibody to use, the application of selection criteria if patient-related materials are used, and the eventual necessity to include β_2GPI as a control. By following such consensus methodology, the main target of these aPLs can hopefully be identified, ultimately leading to a strategy tackling the actual cause instead of the peripheral mechanisms.

PA 1.18-3

Increased levels of thrombin activatable fibrinolysis inhibitor – TAFI in patients with the antiphospholipid syndrome

Antovic A[1], Vikerfors A[2], Antovic JP[1], Woodhams B[3], Adam M[4] and Svenungsson E[2]

[1]Karolinska Institutet; [2]Karolinska University Hospital and Karolinska Institute, Stockholm, Sweden; [3]HaemaCon Ltd, Bromley, Kent, UK; [4]Diagnostica Stago SAS, Gennevilliers, France

The Antiphospholipid syndrome (APS) is diagnosed when arterial/venous/small vessel thrombosis or obstetric morbidity occur together with positive laboratory tests for antiphospholipid antibodies (aPL, including anticardiolipin (aCL) and/or anti-$\beta_2$glycoprotein-I (a β_2GPI) and/or the functional lupus anticoagulant (LA) test). The pathophysiology behind aPL associated thrombosis is still unclear. Thrombin activatable fibrinolysis inhibitor (TAFI) represents a link between coagulation and fibrinolysis. Active form of the enzyme removes carboxyl-terminal lysine residues from partially degraded fibrin, thus maintaining fibrin clots and having a prothrombotic function. TAFI has been considered a potential acute phase protein while it may mediate anti-inflammatory effects by regulating complement anaphylatoxins.

Objective: To investigate underlying mechanisms behind the development of thrombotic complications in patients with APS with the focus on TAFI levels, the tightness of the fibrin network and fibrinolytic function.

Methods: Twenty-four patients with APS and 14 controls were included. The levels of pro-TAFI (proenzyme) and TAFI/TAFIi (complex of active and inactive form which corresponds to the concentration of the active form that cannot be measured because of instability) were analysed with a chromogenic assay for TAFI and a specific ELISA for TAFIa/ai (both from Diagnostica Stago, Asnieres, France). Permeability of the fibrin network was assessed by flow measurement technique and clot density together with fibrinolytic function, analysed by a turbidimetric clotting and lysis assay.

Results: The levels of proenzyme – Pro-TAFI (%) as well as the levels of active enzyme TAFIa/TAFIai (ng/mL) were significantly increased in patients with APS compared to controls (117 ± 4.9 vs. 88.7 ± 16.5; $P < 0.001$ and 18.7 ± 2.3 vs. 12.2 ± 0.7; $P < 0.001$, respectively). Fibrin network permeability expressed as permeability coefficient Ks ($cm^2 \times 10^{-9}$) was lower in samples from APS-patients compared to controls (6.4 ± 0.6 vs. 9.8 ± 0.8; $P < 0.001$) indicating a tighter fibrin structure. This finding was corroborated by the turbidimetric clotting assay which demonstrated higher maximum absorbance and longer clot lysis time – CLT ($P < 0.01$) in APS-samples compared to controls. TAFI levels did not correlate with CLT, neither with fibrin clot permeability in the investigated samples.

Conclusions: Increased levels both of TAFI-proenzyme and active form of TAFI were found in patients with APS. This is to the best of our knowledge a novel observation. Thus, TAFI activation may contribute to the thrombotic tendency in the APS by a mechanism which is independent of the antifibrinolytic action of this enzyme. However further studies are required to elucidate TAFIs role in the pathophysiology of APS.

A novel method for the diluted Russell's viper venom time (dRVVT) test that abrogates the effects of vitamin K antagonist (VKA) treatment

Misasa K[1], Morikawa C[1], Suzuki A[1] and Fryer H[2]

[1]Sekisui Medical Co., Ltd., Ibaraki, Japan; [2]Sekisui Diagnostics, LLC, Stamford, CT, USA

Background: Lupus anticoagulants (LA) are immunoglobulins that affect phospholipid-dependent coagulation reactions *in vitro*. Patients with LA have increased risk of thrombus formation and are treated with anticoagulants such as vitamin K antagonists (VKA). The diluted Russell's viper venom time (dRVVT) test and activated partial thromboplastin time (aPTT) test are clinical assays used for LA detection. Detecting LA in patients on VKA is difficult because basal clotting time is prolonged. To avoid false positives and negatives, ISTH guidelines recommend discontinuation of VKA or 1:1 mixing with pooled normal plasma. However, mixing studies are not always effective, because LA titer is diluted 2-fold and pooled normal plasma quality varies between laboratories.

Aims: In this study, we developed and assessed a new diluent for dRVVT that abrogates the effect of VKA treatment.

Methods: This study was performed comparing plasma samples obtained from healthy volunteers, LA-positive patients without VKA treatment, non-LA patients with VKA treatment and LA-positive patients with VKA treatment. The assays were performed using an in-

house dRVVT reagent, of low (screening) and high (confirming) phospholipids concentrations, with samples: (A) diluted with a new diluent including coagulation factors, (B) diluted 1:1 with normal plasma, and (C) undiluted. The assays were performed on the COAPRESTA [TRADEMARK] 2000 (Sekisui Medical), which has an automatic dilution system. We compared the performance of the assay to the Gradipore (GRA) dRVVT test performed on the Diagnostica Stago STA-R analyzer. Normalized lupus ratio (NLR) was determined, which is calculated according to the following formula:
NLR = (screening test – patient result/confirming test – patient result)/(screening test – mean normal time/confirming test – mean normal time).
Results: Based upon the analyses of samples of patients treated with VKA, we developed a diluent which include a high concentration of coagulation factors the lack of which affects clotting time. A cutoff based on the 99th percentile was determined by evaluating the diluent on samples from 52 healthy volunteers. Subsequently, commercially available samples from 50 LA patients not undergoing VKA treatment were assessed. Two of the patient samples were classified as normal when diluted 1:1 with normal plasma (B), whereas the sensitivity using the new diluent (A) was the same as undiluted (C) samples. We also assayed samples from 56 VKA-treated patients with LA or other diseases. Four of these patients, positive by method (A), (B), and GRA, were classified as negative using undiluted method (C). Twenty-one of these samples, negative by other methods, were classified as positive by GRA. The rate of agreement between the new method (A) and the mixing method (B) was 96%, with the former being more sensitive than the latter.
Summary/Conclusion: We developed a diluent for dRVVT that abrogates the effect of VKA treatment. This diluent can be used on Coapresta[TRADEMARK] 2000 which has an automatic dilution system. Using the new diluent enables sensitive detection of LA, regardless of the presence of VKA.

PA 1.18-5

Antibodies against domain I of beta2-glycoprotein I are a better predictor for the antiphospholipid syndrome than antibodies to the total protein

Hollestelle MJ[1], Van Schagen M[1], Kariman A[2] and Pequeriaux N[2]
[1]Sanquin Diagnostic Services, Amsterdam; [2]Jeroen Bosch Hospital, 's-Hertogenbosch, The Netherlands

Background: Antiphospholipid syndrome (APS) is difficult to diagnose, because currently used laboratory tests have limited specificity. One important assay is the detection of anti-beta2-glycoprotein I (anti-beta2GPI) antibodies. Recently, domain I of beta2-glycoprotein I (beta2GPI-DI) has been suggested to be an important target for antibodies in patients suffering from APS.
Aim: To evaluate whether beta2GPI-DI antibodies are more specifically associated with APS compared to antibodies to total beta2GPI using the same detection technique.
Methods: From May 2010 until November 2012 blood samples were collected from patients referred to our hospital for suspicion of APS. Final diagnosis of APS was based on results of local routinely used tests (lupus anticoagulant and anti-cardiolipin antibodies) in combination with clinical criteria following the International Consensus Statement classification criteria. Antibodies (IgG) against beta2GPI-DI and the complete protein were determined in all samples using the chemiluminescence immunoassay technique based on the BIO-FLASH system (INOVA Diagnostics). Results were correlated with diagnosis of APS. Ethical approval was obtained for conducting the study.
Results: Seventy-nine patients were included and screened, containing 24 (30%) patients with APS and 55 (70%) patients without APS. Domain I antibodies were demonstrated in 12 patients where of 67% were diagnosed with APS. On the other hand, 22 patients were found positive for IgG antibodies against the complete beta2GPI protein of which 41% were APS patients. This resulted in an odds ratio for anti-domain I of 6.4 (1.7–24.0), 95% confidence interval) for APS. In contrast to antibodies to total beta2GPI which were not significantly correlated with APS in our study (odds ratio: 1.9, 0.7–5.5, 95% confidence interval).
Conclusion: In this patient population, the detection of IgG antibodies directed against domain I of betaGPI proved to be more strongly associated with APS than the detection of antibodies against the total beta2GPI protein. These preliminary results must be confirmed in larger clinical studies.

PA 1.18-6

Investigation of resistance to exogenous activated protein C and activation of endogenous protein C in thrombotic patients with or without antiphospholipid syndrome

Jayakody Arachchillage D[1], Efthymiou M[1], Mackie IJ[1], Lawrie AS[1], Machin SJ[1] and Cohen H[2]
[1]University College London; [2]University College London Hospitals NHS Foundation Trust, London, UK

Background: It has been suggested that activated protein C resistance (APCr), in the absence of the factor V Leiden genotype, may indicate an increased risk of thrombosis in patients with antiphospholipid syndrome (APS).
Aim: The aim of this study was to investigate APCr with either exogenous recombinant human APC (rhAPC) or by activation of endogenous protein C, in thrombotic patients with and without APS receiving warfarin anticoagulation.
Methods: Plasma from 70 individuals was analysed: 60 patients with a history of venous thromboembolism on warfarin (30 with APS diagnosed in accordance with the international [revised Sapporo] consensus APS criteria, 29 of whom had lupus anticoagulant (LA); 30 non-APS patients; and 10 [not anticoagulated] normal controls). Patients with protein C/S deficiency, factor V Leiden, on hormone replacement therapy or oral contraceptive preparations, were not included in the study.
APCr was expressed as the percentage inhibition of the endogenous thrombin potential (ETP) using the calibrated automated thrombography CAT system in the presence and/or absence of either rhAPC (Eli Lilly) or Protac® (Pentapharm), to activate endogenous protein C. All results were normalised using pooled normal plasma (PNP) as a reference and all patient samples were mixed 1:1 with PNP to correct the reduced coagulation factor activity due to warfarin. rhAPC and Protac concentrations producing approximately 50% inhibition of ETP in the reference plasma were selected. APCr was expressed as normalised ETP, and as normalised percent inhibition of ETP by dividing the percent inhibition of ETP in test plasma, caused by either rhAPC or Protac, by the percent inhibition of ETP determined in PNP alone where decreased values indicate APCr.
Results: Using rhAPC, no significant differences were observed in APCr with exogenous rhAPC between APS patients, non-APS patients and normal controls, median values (observed ranges) for APCr: 123.9 (21.9–221.5), 120.0 (59.2–241.6) and 145.5 (68.2–319.2) respectively. However using protac to activate endogenous protein C, significant differences were observed between the three groups ($P = 0.0015$), with APS patients showing more resistance to activation endogenous protein C than non-APS patients ($P = 0.023$), median values (observed ranges): 77.0 (5.6–96.3), 91.4 (41.6–347.2) and 168.9 (60.2–213.5) in APS patients, non-APS patients and normal controls, respectively. There was a significantly greater degree of resistance to activation of endogenous protein C than to exogenous rhAPC in both APS ($P < 0.0001$) and non-APS thrombotic patients ($P = 0.0021$). Five patients in the APS group demonstrated marked APCr with both method and these patients have experienced clinically more severe disease, i.e. both arterial and venous thrombosis and/or multiple events whilst on therapeutic anticoagulation.

Conclusion: These results suggest that irrespective of the presence of APS/LA, thrombotic patients have a greater degree of resistance to activation of endogenous protein C. Whether this is due to the presence of autoantibodies that interfere with protein C activation, and/or changes in the activity of other haemostasis modulators, remains to be elucidated. APCr appears to be a marker of thrombosis risk not just in APS populations and may indicate a more severe clinical phenotype.

Plasma endothelial protein C receptor influences innate immune response in ovarian cancer by decreasing the population of natural killer and TH17 helper cells

Besbes S[1], Mirshahi M[1], Azzazene D[2], Thawadi H[1], Al Farsi H[1], Mirshahi S[3], Pardo J[1], Faussat AM[1], Therwath A[1], Pujade-Lauraine E[3] and Soria J[1]

[1]Inserm, UMRS 872, CRC, Université Pierre et Marie Curie-Paris 6, Université Pari; [2]National Institut for Medical Research (Inserm), Cordeliers Research Center; [3]2 Hôtel Dieu Hospital, Paris, France

Background: In spite of the growing importance of endothelial protein C receptor/active protein C (EPCR/aPC) in tumor biology, their impact on immunological homeostasis remains largely unexplored.
Objective: To assess whether soluble plasma EPCR (s-EPCR), which is a regulator of circulating aPC, can be involved in innate immune response in cancer patients.
Patients/Methods: (i) In Ovcar-3 ovarian cancer line, the role of aPC in secretion of cytokines was analyzed by proteinarray using a set of 174 membrane coupled anti-cytokines. (ii) In 33 patients, with a diagnosis of ovarian epithelial cancer (asymptomatic disease in progression detected by increase in CA 125 level), s-EPCR was measured using Asserachrom s-EPCR immunoassay, blood immune cell phenotypes were determined by flow cytometry, using a set of 30 antibodies against factors of the immune system and plasma cytokines were evaluated using an array of 100 cytokine antibodies. Spearman's rank correlation coefficients (r) and Coefficient significance was determined by a statistical hypothesis test ($\alpha = 0.05$).
Results: (i) aPC induced the secretion of several cytokines in Ovcar-3 cells. (ii) 61% of patients exhibited a concentration of plasma s-EPCR well above the base-line (normal plasma level, 100 ± 28 ng/mL). Comparing immune cell phenotypes in patients having a normal level of s-EPCR with those having a high level of s-EPCR, it was found that s-EPCR level was correlated with high intensity of cells expressing CD45ra, CD3, CD8, CD25 and low intensity of cells expressing CD56 (NK cells), IL2, IL10, IL17a (TH17 cells), IL21 (TH 21 cells) and CD29 markers ($r \geq 0.60$). In addition, when level of s-EPCR was high, a decrease in IL17a-expressing cells was associated with decrease of cells expressing CD161 and ROR-γ involved in the secretion of IL17. (iii) High level of s-EPCR correlate with high levels of plasma bio active proteins such as insulin-like growth factor-2 (IGFII), IL13rα, macrophage inflammatory protein (MIP1α) and matrix metalloproteinase-7 (MMP7) that have already been proposed as biomarkers for ovarian cancer and particularly those with poor prognosis.
Conclusions: s-EPCR produced by ovarian cancer cells, by modulating circulating aPC, influences secretary behavior of tumor cells (cytokines and interleukins). Consequently, s-EPCR in turn acts on the innate immune response by decreasing the effectors cells such as Natural killer and T helper cells. (TH2, TH17, TH21).

Acute hypoxia induced adhesion of leukocyte are mediated through toll-like receptor3-interferon? Signal transducers and activators of transcription1 pathway

Biswas I[1], Singh B[1], Sharma M[1], Agrawala P[2] and Khan GA[1]

[1]Defence Institute of Physiology and Allied Sciences; [2]Institute of Nuclear Medicine and Allied Sciences, Delhi, India

Background: Leukocyte adhesion associated with local or systemic hypoxia can lead to prothrombotic diatheses. Cell adhesion molecules (CAMs) like Intra Cellular Adhesion Molecule-1 (ICAM) and Platelet Endothelial Cell Adhesion Molecule (PECAM) are critical for the recruitment, and transendothelial migration of leukocyte at the site of vascular injury. Inflammatory cytokines play an important role in leukocyte adhesion and trans-endothelial migration. But the molecular mechanism of acute hypoxia (AH) induced vascular inflammation and leucocytes adhesion remains unknown. Ligands released from dying cells activate pattern recognition receptors including toll-like receptor3 (TLR3). The TLRs are innate immune receptors which play a key role in immune activation and inflammation. Therefore, we hypothesized that AH might up-regulate TLR3 which subsequently facilitates leukocyte adhesion to endothelium through interferon (IFN α/γ)-STAT1 pathway.
Aim: Aim of the present study is to delineate the role of TLR3 in AH induced adhesion of leukocyte and underlying signalling mechanism.
Methods: Mice (Swiss albino, 25–30 g, male, each group contains 4–6 mice) were subjected to AH (in an environmental chamber) equivalent to the prevailing atmospheric conditions at an altitude of 7628 m (282 mm Hg barometric pressure) having O_2 content approximately 8.5% for 0–24 h. The temperature and humidity were constantly maintained to 25 ± 2 °C and 55 ± 5% respectively throughout the whole experiment. Age and sex matched control mice (normoxia, not exposed to AH) were maintained in 21% O_2 with same environmental conditions. Leukocyte was isolated from freshly drawn blood though density gradient centrifugation. Lung immunohistochemistry were performed as described. The expressions of TLR3, IFNs and CAMs were analyzed by immunoblotting, flowcytometry, enzyme-linked immunosorbant assay (ELISA) and Immunohistochemistry. The interaction between human umbilical vein endothelial cells (HUVEC) and leukocyte were evaluated by *in-vitro* adhesion assay. *In vivo* inhibition of TLR3 and IFNs were performed by tail vein injection of anti-TLR3 and anti-IFN neutralizing antibody 2 h before AH exposure respectively. A similar injection of poly I:C for indicated time was made to observe the TLR3 activation. Selective inhibition of STAT-1 phosphorylation was performed through tail vein injection of AG 490 (10 mg/kg) 2 h before AH or poly I:C treatment.
Results: The expression of TLR3, IFNs and CAMs were increased significantly following AH exposure. Pretreatment of TLR3 immunoneutralising antibody significantly decreased AH induced IFNs and CAMs expression as well as adhesion of leukocyte to HUVEC. We also showed that pretreatment of IFNγ neutralizing antibody significantly inhibited CAMs expression and leukocyte adhesion to HUVEC, but pre-treatment of IFNα neutralizing antibody fails to do so. We also found increased STAT-1 phosphorylation both in AH and poly I:C treatment. But the pre-treatment of TLR3 neutralizing antibody or STAT-1 inhibitor (AG490) 2 h prior to AH exposure or poly I:C treatment completely abrogated STAT-1 phosphorylation, CAMs expression and leukocyte adhesion to endothelium.
Conclusions: Collectively, these data show that AH induced adhesion is mediated through TLR3-Interferon γ- STAT1 axis.

Protease-activated receptor (PAR) 1 impairs host defense during severe Gram-negative sepsis (melioidosis)

Kager LM, Wiersinga WJ, Meijers JC, Van't Veer C and Van der Poll T

Academic Medical Center, Amsterdam, The Netherlands

Background: Melioidosis, an endemic disease in Southeast Asia caused by the gram-negative bacterium *Burkholderia* (*B.*) *pseudomallei*, is associated with pneumonia often leading to severe sepsis. Protease-activated receptor-1 (PAR-1) is a G-coupled transmembrane receptor expressed by multiple cell types present in the lungs that can be activated by various proteases generated during acute inflammation.
Aims: In this study we aimed to investigate the role of PAR1 during melioidosis.
Methods: Wildtype (WT) and PAR1 knockout (KO) mice were infected intranasally with *B. pseudomallei* to induce melioidosis. Mice were sacrificed after 24, 48 or 72 h and survival studies were done. Lungs, liver and blood were harvested to measure bacterial loads, cytokines, clinical chemistry, pathology scores and coagulation parameters. Additionally, bronchoalveolar lavages (BAL) were done and the BAL-fluid (BALF) and cells were analyzed.
Results: PAR1 KO mice showed decreased bacterial loads in lungs, BALF and liver (all $P < 0.01$ vs. WT). In addition, 72 h after infection, PAR1 mice displayed a decreased cell influx in the lungs ($P < 0.05$), which was due to a lower number of neutrophils. No differences in levels of pro-inflammatory cytokines (TNF-α, IL-6, IL-10, IFN-γ and MCP-1) and lung histopathology were seen between WT and PAR1 KO mice. Mortality was similar in WT (65%) and PAR1 KO mice (82%) ($P = 0.2$).
Conclusion: PAR1 impairs host defense during severe Gram-negative sepsis caused by *B. pseudomallei* by facilitating bacterial growth.

PA 1.19-4

Thrombin receptor activation impairs TLR mediated whole blood TNF production by thrombin induced MKP-1 expression and p38 deactivation

Van't Veer C, Yang J, Versloot M, Van Den Boogaard F, Kruijswijk D, Van Der Poll T, Van Der Meer J and Keizer V

AMC, Amsterdam, The Netherlands

Blood coagulation may play a decisive role during infections and the sepsis syndrome. However how coagulation influences host defense and cytokine responses in whole blood and infection models is poorly understood. In a new *in vitro* human recalcified whole blood coagulation model we found that the early TNF response to viable *E. coli* is specifically down regulated by thrombin generation. Prevention of whole blood clotting by either APC, heparin, LMWH, TFPI or the specific thrombin inhibitor Lepirudin all increased TNF production by *E. coli*. Prevention of blood clot formation by fibrin polymerization inhibitor did not influence TNF production, and it could be concluded that thrombin itself downregulates TNF production. Accordingly, thrombin receptor activation by the PAR-1 activation peptide TRAP decreased TNF production induced by TLR4 or TLR2 stimulation in heparin blood. This indicates that PAR-1 stimulation actively inhibits TLR mediated TNF production. Phospho-P38 is pivotal for TNF expression and we found that MKP-1, the most important p-P38 inhibitor, is upregulated at the mRNA and protein level through PAR-1 activation by TRAP in combination with LPS. In line we found in our whole blood coagulation model that thrombin generation synergizes with *E. coli* in the induction of MKP-1. Accordingly, phospho-P38 was consistently increased in leukocytes from *E. coli* stimulated whole blood when thrombin generation was inhibited compared to clotted controls or control with fibrin polymerization inhibitor. Moreover, thrombin inhibited TNF production by LPS stimulated isolated PBMC's. During sepsis, mice with impaired thrombin generation (lowTF) displayed decreased MKP-1 expression and increased TNF production compared to TF+ mice in affected organs. This indicates that thrombin may suppress local host defense during sepsis when TNF is limited and crucial for resistance to microbes. Indeed during *E. coli* peritonitis lower bacterial burden is observed in FVIII-deficient and TF-deficient mice in line with increased host defense to virulent *E. coli* when thrombin is inhibited. Our data indicates that thrombin receptor activation hampers TNF production during infection and sepsis.

PA 1.19-5

Thrombelastographic studies reveal a new mechanism in MASP-1-induced fibrin clotting

Jenny L[1], Dobo J[2], Gal P[2] and Schroeder V[1]

[1]University of Bern, Bern, Switzerland; [2]Hungarian Academy of Sciences, Budapest, Hungary

Background: The complement system is an integral part of the innate immune system and consists of plasma proteins which monitor the blood for foreign particles and participate in their clearance. It is not only phylogenetically related to the coagulation system, in addition a number of interactions between the two systems have been described. Mannan-binding lectin-associated serine protease-1 (MASP-1) is a protein of the complement lectin pathway. Due to structural features closely resembling thrombin, MASP-1 was assumed to interact with the coagulation cascade; recent findings have supported this hypothesis.
Aim: The aim of this study was to examine the effects of MASP-1 on kinetics of clot formation and clot structure along with comparing its effects on coagulation between whole blood (WB), platelet-poor plasma (PPP) and a purified system.
Methods: Thrombelastography using a ROTEM® device was the method of choice for this study because it allows to test coagulation in a global environment and study clot formation kinetics and viscoelastic properties of the clot. Freshly drawn citrated WB and directly derived PPP were incubated with three different concentrations of either MASP-1, thrombin or a combination of both flanking their physiological concentrations (10 μg/mL and 20 nM respectively, whereby the chosen thrombin concentration corresponds to the observed concentration during the initiation phase of plasmatic coagulation). The experiment was repeated in prothrombin-depleted plasma. In a second approach the same concentrations of thrombin and MASP-1 were tested in a purified system containing fibrinogen only or fibrinogen supplemented with $CaCl_2$ and factor XIII.
Results: In PPP, addition of the physiological concentration of MASP-1 reduced the clotting time (CT; the time until onset of clotting) by up to 15%, while thrombin decreased the CT by up to 89%. When PPP was supplied with both enzymes, the CT was not further reduced as it was with thrombin only. Similar results were obtained in WB.
The clot formation time (CFT; representing the duration from onset of clotting until reaching a clot of a certain firmness), was also shortened by MASP-1 in PPP and WB (29% and 41% respectively). The same was observed with thrombin, where a CFT-reduction of 38% (PPP) and 47% (WB) was reached. When both enzymes were added in their physiological concentration their effects on CFT added up to a 44% (PPP) and 67% (WB) reduction.
In the purified system as well as in prothrombin-depleted plasma, thrombin was able to generate a clot in both environments, while MASP-1 failed to induce clotting.
Conclusions: For the first time we used thrombelastography to investigate the influence of MASP-1 on whole blood and plasma clotting. MASP-1 showed strong and synergistic effects with thrombin on clot formation. The observed effects were more distinct in WB than in PPP suggesting that MASP-1 may interact with platelets. In the isolated system and in prothrombin-depleted plasma MASP-1 failed to induce clotting, indicating that it triggers the coagulation in an indirect way

via prothrombin activation. Further work is ongoing to unveil the underlying mechanisms and potential physiological relevance.

PA 1.19-6

The role of autoantibodies to heat shock proteins (HSP-70) in immune reactions in old-aged patients with chronic generalized periodontitis and coronary heart disease

Malezhik L, Pinelis Y, Tsybikov N and Malezhik M

Chita State Medical Academy, Chita, Russian Federation

Introduction: Autoimunne process is accompanied by any chronic inflammation and chronic generalized periodontitis is no exception. However, the role of autoimmune reactions in chronic periodontal inflammation in modern dentistry have not been evaluated.

We believe that one of the reasons supporting the chronic inflammation of the periodontium are autoimmune processes associated with the expression of HSP in the destruction.

Aim: To investigate the intensity of formation of autoantibodies to heat shock proteins (HSP-70), and some immunological parameters in peripheral blood and saliva of the elderly before and after treatment of chronic generalized periodontitis and coronary heart disease.

Materials and Methods: Ninety-six patients with chronic generalized periodontitis of moderate severity (age 64–75 years) and 25 controls aged 64–75 years with no signs of periodontal inflammation. Patients with chronic generalized periodontitis and controls enrolled in Veterans Hospital of war with clinical manifestations of coronary heart disease, and received on this occasion cardiovascular therapy. Patients with inflammatory periodontal received additional local anti-inflammatory therapy. The control and experimental groups did not include patients with lesions of the gastrointestinal tract, respiratory tract, allergic manifestations and with oncopathology.

Blood samples and saliva was performed before and after treatment. In the blood and saliva studied concentration of autoantibodies to HSP-70 content of interleukin and immunoglobulins (s IgA, IgA, IgM, IgG) by ELISA.

Results and Discussion: Our studies have shown that autoantibodies to HSP-70 in older people not suffering from chronic periodontitis, in saliva exist, but not at high concentrations (66.6 $\pm$ 7.1 ng/mL) in human blood of the control group required significantly more autoantibodies (164 $\pm$ 13.6 ng/mL).

When inflammation of the periodontal maintenance of autoantibodies to HSP-70 increased (212.2 $\pm$ 16.3 ng/mL) in saliva and blood. HSP act on antigen-presenting cells, that cause release of proinflammatory cytokines and chemokines. Our studies have shown that in chronic periodontitis concentration of Il-8, Il-a, IgG, IgA, Ig M, s/IgA were increased. In the blood of patients noted a significant increase in the level of Il-1a, Il-8 and IL-4. At the same time there is polyclonal activation of adaptive immunity to the increase in blood concentrations of IgG, IgM, IgA, and autoantibodies to HSP-70.

Following the local anti-inflammatory therapy and concomitant coronary artery disease symptoms, correction of immune parameters occurs in part. The level of IgG in saliva and blood is not changed, indicating a preserved because of their synthesis. The concentration of autoantibodies to HSP is somewhat reduced in the saliva and blood, but does not reach the reference values.

Conclusions: High levels of autoantibodies to HSP-70 in saliva and blood suggests about pathogenetic role of protein-chaperones in the development of periodontal inflammation and chronicity of the process.

Aspirin for the prevention of recurrent venous thromboembolism (VTE): the INSPIRE collaboration

Becattini C[1], Simes J[2], Agnelli G[1], Eikelboom JW[3], Kirby A[2], Mister R[2], Prandoni P[4], Brighton TA[5] and The INSPIRE Collaborators[2]

[1]University of Perugia, Perugia, Italy; [2]NHMRC Clinical Trials Centre, Sydney, NSW, Australia; [3]McMaster University, Hamilton, ON, Canada; [4]University of Padua, Padua, Italy; [5]Prince of Wales Hospital, Sydney, NSW, Australia

Background: In patients with a first unprovoked venous thromboembolism (VTE) who have completed initial and long-term oral anticoagulation, the risk of recurrent VTE is substantial after anticoagulant treatment is discontinued. The WARFASA and ASPIRE studies have recently shown that aspirin reduces the risk for recurrent VTE in these patients (NEJM 2012). An individual patient data meta-analysis of these two trials was planned in the INSPIRE project (ACTRN12611000684921) before the results of either study were known.

Aims: To assess effect of aspirin vs. placebo on recurrent VTE, major vascular events and bleeding.

Methods: WARFASA (n = 402) and ASPIRE (n = 822) were both randomized, double-blind, placebo-controlled studies with harmonized study protocols designed to evaluate the effect of aspirin on VTE recurrence, major vascular events and bleeding. Primary analysis of treatment was intention-to-treat using individual time to event data stratified by study and within 4 years of randomization on the primary outcome of VTE.

Results: Baseline characteristics were well balanced between the two treatment groups pooled over the two studies (1224 patients, 30.4 months median follow-up). WARFASA patients were older than ASPIRE (61 $\pm$ 15 vs. 54 $\pm$ 16 years, $P < 0.001$), had higher smoking rates (16% vs. 9%, $P < 0.001$) and were more often males (64% vs. 54%, $P < 0.01$). Aspirin reduced the risk of recurrent VTE (7.5% per annum (pa) vs. 5.1% pa; Hazard Ratio (HR) 0.68, 95% CI 0.51–0.90, $P = 0.008$) with a similar relative reduction of deep vein thrombosis (HR 0.66, 95% CI 0.47–0.92, $P = 0.01$) and pulmonary embolism (HR 0.66, 95% CI 0.41–1.06, $P = 0.08$). A similar reduction was also observed on the rate of major vascular events (recurrent VTE, MI, stroke and CVD death): 8.7% pa vs. 5.7% pa; HR 0.66, 95% CI 0.50–0.86, $P = 0.002$. The rate of major bleeding was low and similar in the two study groups (0.4% and 0.5% pa for placebo and aspirin, respectively). Similar relative reductions in risk were seen in pre-specified subgroups (each interaction $P > 0.1$), but larger absolute benefits were seen in men and those of older age. Larger treatment benefits were seen in the first year of treatment (11.0% pa vs. 5.4% pa; HR 0.49, 95% CI 0.32–0.76, $P = 0.001$) than in years 2–4: (3.6% v 3.2% pa HR 0.89, 95% CI 0.60–1.31, $P = 0.56$).

Conclusions: Aspirin given after anticoagulant treatment reduces the overall risk for recurrence by about one third in patients with a first unprovoked VTE without significantly increasing the risk of bleeding. Higher rates of VTE recurrence and larger absolute treatment benefits are seen during the first year.

PA 1.20-2

Low level of residual thrombotic obstruction following 6 months of anticoagulant treatment for acute pulmonary embolism

Den Exter PL[1], Van Es J[2], Kroft LJM[1], Erkens PGM[3], Douma RA[2], Jonkers G[4], Ten Cate H[3], Beenen L[2], Kamphuisen PW[5] and Huisman MV[1]

[1]Leiden University Medical Center, Leiden; [2]Academic Medical Center, Amsterdam; [3]Maastricht University Medical Center, Maastricht; [4]Rijnland Hospital, Leiderdorp; [5]University Medical Center Groningen, Groningen, The Netherlands

Background: In patients with acute pulmonary embolism (PE), systematic assessment of residual thrombotic obstruction after long-term anticoagulation has been understudied. This information may be of clinical importance for diagnostic baseline imaging, in case of clinically suspected recurrent PE or as a tool for risk stratification for recurrent venous thromboembolism (VTE). On the basis of retrospective, selective studies, nowadays physicians often order repeat CT scans after 6 months of anticoagulant treatment without solid evidence for clinical relevance.
Methods: In this prospective, multi-center cohort study, consecutive patients with acute PE underwent baseline CT pulmonary angiography (CTPA) following 6 months of anticoagulant treatment. Two independent, expert thoracic radiologists systematically and independently assessed all CTPAs for the presence of residual thrombosis. The degree of pulmonary obstruction was calculated using the obstruction index of Qanadli. A two-year follow-up was performed to assess the correlation between residual thrombotic obstruction and recurrent VTE. Ethical approval and informed consent was obtained.
Results: A total of 141 patients were included. At time of diagnosis, the mean obstruction index was 30% (standard deviation (SD) 20). After 6 months of treatment, 85% of the patients had complete clot resolution. Residual thrombotic obstruction was identified in 21 patients (15%; 95% confidence interval [CI]: 10–22%). Of these, seven (5%; 95% CI: 2–10%) had residual thrombosis in at least a segmental pulmonary artery, accounting for a mean obstruction index of 8% (SD: 5). In the other 14 patients (10%; 95% CI: 6–16%), non-occlusive post-thrombotic webs or strictures were found. During follow-up, 11 (7.8%) patients experienced recurrent VTE. Residual thrombosis did not correlate with recurrent VTE; hazard ratio: 0.6 (95% CI 0.08–4.7).
Conclusion: This study reveals that the incidence of residual thrombotic obstruction following treatment for acute PE is considerably lower than currently assumed. These findings, combined with the absence of a correlation between residual thrombotic obstruction and the occurrence of recurrent VTE, do not support the use of baseline CTPA imaging in patients treated for acute PE.

The prognostic significance of residual vein obstruction in patients with treated deep vein thrombosis: a patient-level meta-analysis

Donadini MB[1], Ageno W[1], Cosmi B[2], Poli D[3], Prandoni P[4], Rodger M[5], Siragusa S[6], Young L[7], Bonzini M[1] and Douketis JD[8]

[1]University of Insubria, Varese; [2]University Hospital S.Orsola-Malpighi, Bologna; [3]University Hospital Careggi, Florence; [4]University of Padua, Padua; [5]University of Ottawa, Ottawa, ON, Canada; [6]University of Palermo, Palermo, Italy; [7]University of Auckland, Auckland, New Zealand; [8]McMaster University, Hamilton, ON, Canada

Background: Risk stratification for recurrence after unprovoked deep vein thrombosis (DVT) could improve clinical decisions on the optimal duration of anticoagulant therapy. Residual venous obstruction (RVO) may be pivotal in clinicians' decision-making but results from clinical studies and study-level meta-analyses are conflicting
Aims: We aimed to determine if RVO is a valid predictor of recurrent venous thromboembolism (VTE) in patients with a first symptomatic unprovoked proximal DVT who had received at least 3 months of anticoagulant therapy.
Methods: Systematic search of electronic databases (Medline, Embase, Cochrane Library) until September 2012, supplemented by manual reviewing of the reference lists and contacting content experts. Prospective studies that investigated the association between RVO and recurrent VTE in patients with a first unprovoked proximal DVT were selected. Individual patient-level data were obtained from the datasets of selected studies and merged into a single database. A multivariate, shared-frailty Cox model was used to calculate hazard ratios (HRs) for recurrent VTE which included the following covariates: RVO; age; sex; anticoagulation duration before RVO assessment; and anticoagulation continuation after RVO assessment.
Results: There were 2527 patients studied from 10 prospective studies. RVO was found in 1380 patients (55.1%) after a median of 6 months (inter-quartile range [IQR]: 3–7.6) from a first unprovoked DVT. Recurrent VTE occurred in 399 patients (15.8%) during a median follow-up of 23.3 months (IQR: 12.8–30) from RVO assessment. After multivariate Cox analysis, RVO was independently associated with recurrent VTE (HR = 1.32, 95% CI: 1.06–1.65). RVO was a stronger predictor of recurrent VTE if detected early, i.e. at 3 months (HR = 2.17; 95% CI: 1.11–4.25), but no longer predictive if detected later, i.e. > 6 months (HR = 1.19; 95% CI: 0.87–1.61) after DVT is diagnosed.
Conclusion: In patients with unprovoked DVT who have received at least 3 months of anticoagulant therapy, RVO is a weak overall predictor of recurrent VTE and has predictive utility if detected at an earlier time (3 months) but not later time (> 6 months) after a diagnosis of DVT.

PA 1.20-4

Complication rates among patients treated for upper extremity thrombosis: a meta-analysis and systematic review

Tan M[1], Carrier M[2], Huisman MV[1] and Rodger M[2]

[1]Leiden University Medical Center, Leiden, The Netherlands; [2]Ottawa Hospital, Ottawa, ON, Canada

Background: Upper extremity deep vein thrombosis (UEDVT) accounts for 4–11% of all thromboses in the deep veins. Current guidelines advise to treat patients with an UEDVT similarly to patients with a lower extremity thrombosis, i.e. a minimum duration of treatment of 3 months. The risk of recurrent venous thromboembolism (VTE), recurrent pulmonary embolism (PE) and recurrent fatal VTE after a first lower extremity thrombosis in the first 3 months of anticoagulation have been reported to be 3.2% (95% CI, 2.4–4.1%), 1.3% (95% CI, 1.0–1.7%) and 0.3% (95% CI, 0.2–0.5%) respectively. The rate of major and fatal bleeding episodes have also been reported to be 1.6% (95% CI, 1.2–2.1%) and 0.2% (95% CI, 0.1–0.3%) respectively. However, the rates of recurrent VTE and major (fatal) bleeding episodes in patients with UEDVT receiving anticoagulant therapy are unknown. These point estimates are important to assess the risks and benefits of anticoagulation and to help counsel patients with UEDVT.
Aim: To summarize the risk of recurrent VTE (UEDVT, PE and fatal VTE), major, fatal bleeding rates and overall mortality in patients with UEDVT undergoing the first 3 months of anticoagulation therapy.
Methods: A systematic literature search was conducted to identify potential studies on MEDLINE, Embase, and Cochrane Central Register of Controlled Trials using an OVID interface to 20 December 2011. We included randomized controlled trials and prospective cohort studies. We calculated the pooled proportions for the different outcomes at 3 months of follow-up. Ninety five percent confidence intervals (95% CI) were calculated for each rate.

Results: Eleven studies met all inclusion criteria for our meta-analysis and 1162 patients with confirmed UEDVT were included in the analysis (all prospective cohort studies). The majority of patients were treated with unfractionated or low-molecular-weight heparin in combination with vitamin K antagonists. During the initial 3 months of anticoagulation, the rates of recurrent UEDVT was 1.7% (95% CI, 0.9–2.6%; I^2 = 7.6%), 1.6% (95% CI, 1.0–2.4%; I^2 = 0%) for PE, and 2.3% (95% CI, 1.2–3.8%; I^2 = 27.9%) for major bleeding. The rate of fatal PE and fatal bleeding was 0.5% (95% CI, 0.2–1.0%; I^2 = 0%) and 0.87% (95% CI, 0.39–1.54% I^2 = 0%) respectively. The overall mortality was 13.1% (8.3–19.0%; I^2 = 76.2%). All studies had adequate representativeness, assessment of outcome measures and follow-up.
Conclusion: The rate of recurrent VTE on anticoagulant therapy for patients with UEDVT is similar to patients with a lower extremity proximal deep vein thrombosis, however the rates of major and fatal bleeding episodes appear higher for patients with UEDVT. These results might suggest that a less aggressive treatment strategy for patients with UEDVT is warranted. There is an urgent need for randomized therapeutic management studies in UEDVT patients.

PA 1.20-5

The risk of venous thromboembolism in renal cell carcinoma patients with residual and non-resected tumor thrombus

Ihaddadene R[1], Yokom D[2], Le Gal G[1], Moretto P[3] and Carrier M[1]
[1]Ottawa Hospital Research Institute and University of Ottawa; [2]University of Ottawa; [3]The Ottawa Hospital Cancer Centre, Ottawa, ON, Canada

Background: Renal cell carcinoma (RCC) has a unique ability to invade the venous system in 4–10% of the cases. Radical nephrectomy with thrombectomy is the most effective treatment in patients with kidney cancer and tumor thrombus (TT), but the surgical approach depends on the tumor thrombus level, presence of metastases, comorbidities and patient performance status. Complete tumor thrombus extraction is not always possible and residual tumor fragments may remain within the venous system post-surgical thrombectomy. The long-term risk of venous thromboembolism (VTE) in RCC patients with TT and residual thrombus post extraction or not surgically removed is unknown.
Aims: Our objective was to determine the long-term risk of VTE in patients with persistent (residual and non-resected) tumor thrombus.
Methods: A cohort study of patients with stage 3–4 RCC was undertaken. All diagnostic imaging studies were reviewed to identify patients with tumor thrombus. TT was defined as the presence of an intra-luminal filling defect in the renal veins, hepatic veins, or inferior vena cava (below and above the diaphragm) directly extending from a renal mass detected on computed tomography (CT) or magnetic resonance imaging (MRI). Residual tumor thrombus was defined as the presence of TT fragments post thrombectomy seen on imaging. Patients with tumor thrombus in whom VTE occurred prior to surgical removal of the TT were excluded. The primary endpoint was the rate of VTE during a 2 year follow-up period. VTE was defined as proximal lower limb (popliteal vein or more proximal) deep vein thrombosis or pulmonary embolism. Rates between groups were compared using Pearson's Chi-square statistic.
Results: A total of 304 RCC patients with stage 3–4 kidney cancer were included in this study, of them 126 (41.4%) had tumor thrombus. 65.8% were males, median age was 65.0 years (range 22–91) and 63.9% were stage 4. Post-operatively, 61 (20.1%) patients had persistent tumor thrombus (37 residual tumor thrombus detected on CT or MRI post thrombectomy and 24 not surgically removed) whereas 243 did not (65 complete thrombectomy and 178 no tumor thrombus). The rate of VTE within 2 years of cancer diagnosis was 23.0% (95% CI: 14.2–34.9%) for patients with persistent TT compared to 6.2% (95% CI: 3.5–10.7%) for patients without TT ($P < 0.0001$), with a relative risk of 3.7 (95% CI: 1.8–7.7). The 2-year rate of VTE in patients with residual TT and in patients who could not have TT resection was 24.3% (95% CI: 13.4–40.1%) and 20.8% (95% CI: 9.2–40.5%), respectively. RCC patients who had complete resection of their TT had a 2-year VTE rate of 4.6% (95 CI: 1.6–12.7%). The 2-year relative risk of VTE in patients with residual TT compared to those with completely resected TT was 2.9 (95% CI: 1.2–7.4%).
Conclusions: The presence of persistent tumor thrombus is an important risk factor for VTE among RCC patients. Future trials assessing the clinical impact of thromboprophylaxis among RCC patients with residual tumor thrombus are needed.

PA 1.20-6

Predictors of recurrent venous thromboembolism in cancer patients: findings from the worldwide RIETE registry

Gussoni G[1], Frasson S[1], Di Micco P[2], La Regina M[3], Lorente MA[4], González E[5], Gonçalves F[6], Mahe I[7], Monreal M[8] and For the[9]
[1]FADOI Foundation, Milan; [2]Hospital Fatebenefratelli, Naples; [3]Hospital Spezzino, La Spezia, Italy; [4]Hospital de la Agencia Valenciana de Salud Vega Baja, Alicante; [5]Hospital Son Llatzer, Palma de Mallorca, Baleares, Spain; [6]Hospital General de Santo Antonio Porto, Porto, Portugal; [7]Hôpital Louis Mourier, Colombes, France; [8]Germans Trias I Pujol Hospital, Badalona; [9]RIETE Investigators, Madrid, Spain

Background: Patients with malignancy have a significant increased risk for venous thromboembolism (VTE), compared with non-cancer patients. A better understanding of the characteristics that may influence the risk of VTE recurrence in cancer patients is needed, with the aim to offer a better tailored treatment approach for cancer-associated VTE.
Aims: Aim of the present analysis was to evaluate potential predictors of recurrent VTE within 3 months from an index event, in patients with cancer.
Methods: RIETE is an ongoing, international, prospective cohort of consecutive patients presenting with symptomatic VTE confirmed by objective tests, and followed-up for at least 3 months. Each episode of recurrent deep vein thrombosis (DVT) or pulmonary embolism (PE) has to be documented by objective tests as well. Death is considered VTE-related if occurred within the first 10 days after a PE episode, or in case of sudden, unexpected death in the absence of alternative diagnosis. The association between occurrence of recurrent VTE (fatal or non-fatal) and potential predictors was evaluated by means of a multivariable logistic regression analysis. Odds ratios (OR) and corresponding 95% confidence intervals were calculated and a P-value < 0.05 was considered statistically significant.
Results: The overall population of cancer patients included in RIETE at January 2013 (n = 9280) was considered. Three-month recurrent VTE occurred in 3.8% of patients (fatal PE: 2.3%). Advanced disease was the strongest predictor of recurrent VTE (OR 2.09, 95% confidence interval 1.73–2.52). Lung and pancreatic cancer were significantly associated with the risk of recurrent VTE (OR 1.49, 1.18–1.88, and 1.52, 1.04–2.22, respectively), while no significant increase was shown in case of stomach and ovarian cancer, and patients with breast or colorectal cancer had lower risk of recurrent VTE (OR 0.50, 0.35–0.72, and 0.68, 0.50–0.91, respectively). Patients with reduced mobility had more frequent VTE recurrence (OR 1.50, 1.22–1.85), as it was in case of PE as VTE presentation (vs. isolated DVT, OR 1.72, 1.45–2.08), increased creatinine levels (OR 1.48, 1.20–1.83) and previous recent major bleeding (OR 1.75, 1.16–2.85). No significant correlation with risk of recurrent VTE was pertinent to other variables, namely

age, concomitant chronic pulmonary disease, history of VTE, presence of anemia, and body weight.

Summary/Conclusions: Recurrent VTE is a not negligible complication in cancer patients, and to evaluate characteristics of patients which lead to increased or decreased risk is of clinical interest. Some findings from our study may have been influenced by the observational approach of data collection. However, to our knowledge the present analysis is that with the highest statistical power ever conducted to examine predictors of recurrent VTE in cancer patients. In this perspective, some items we assessed as strongly related to increased risk (tumor stage, some types of cancer, PE at presentation, reduced mobility) could be considered for risk stratification for secondary prophylaxis in daily practice. The identification of patients at increased risk of recurrent VTE may be important for optimally adapting treatment and patients' management, a hypothesis to be addressed in future clinical trials.

PA2.01 – Antiplatelet Agents: Aspirin – I

PA 2.01-1

The response to enteric-coated aspirin is weight-dependent in multiple assays

Cox D[1], McCall M[1], Peace A[1], Conroy R[1] and Foley D[2]

[1]Royal College of Surgeons in Ireland; [2]Beaumont Hospital, Dublin, Ireland

Background: The response to aspirin as measured by serum thromboxane levels has been shown to be affected by weight and the use of enteric coating. However, it is not known if this applies to aspirin non-response as determined by other assays especially as they do not agree with non-response determined by serum thromboxane levels.

Aims: To determine if non-response to aspirin, as determined by VerifyNow® and platelet aggregation are affected by weight and enteric coating.

Methods: Patients (138) who had been prescribed aspirin for secondary prevention of cardiovascular disease were recruited after providing informed consent. They were designated as non-responsive if serum thromboxane levels were > 10 ng/mL, VerifyNow exceeded 550 aru or arachidonic acid-induced platelet aggregation was > 20%. This study was approved by Beaumont hospital, Dublin, REC.

Results: Thirty-five patients were considered to be non-responsive by at least one of the three assays. Only three of these patients were non-responsive by all three assays. After a reminder to take their medication the patients were re-tested and 14 patients were non-responsive. After being observed taking aspirin only seven were non-responsive. Weight was a key predictor of non-responsiveness (non-responders: 102.6 ± 20.6 kg, responders: 78.5 ± 14.0 (SD); $P = 0.0016$). After switching to plain aspirin only three were non-responders. After increasing their dose of aspirin to 150 mg all were subsequently responsive.

Conclusion: Approximately 25% of patients were identified as non-responsive to aspirin by at least one assay. However, 80% of these patients were found to be non-compliant. While there is little agreement between assays weight was an important factor in determining the response to aspirin in all three assays. Thus, it would be difficult to select one assay over the others, as all assays would miss some patients. However, a strategy of restricting 75 mg enteric-coated aspirin to patients under 90 kg and using plain aspirin in patients over 90 kg is a cheap and effective strategy to ensure full response to aspirin. One hundred and fifty milligram aspirin may be required in patients over 120 kg. However, as non-compliance was the biggest cause of non-response patient education is also important to ensure that patients achieve the full benefits of aspirin.

PA 2.01-2

Lack of aspirin resistance in patients with coronary artery disease

Muszbek L[1], Kovács EG[1], Homoródi N[1], Katona E[1], Bereczky Z[1], Balogh L[1], Péterfy H[2], Kiss RG[3], Édes I[1] and Muszbek L[1]

[1]University of Debrecen, Medical and Health Science Center, Debrecen; [2]Diagnosticum Co.; [3]State Health Center, Budapest, Hungary

Background: Due to its antiplatelet effect, aspirin (acetylsalicylic acid) is widely used in the prevention of atherothrombotic diseases. By acetylating Ser529 residue in platelet cyclooxygenase-1 (COX-1) it prevents the binding of arachidonic acid (AA) to the catalytic site and inhibits the production of thromboxane (TX) A_2. As aspirin prevents acute vascular events only in part of the patients, the controversial term aspirin resistance was introduced. We define aspirin resistance as the lack of sufficient acetylation of platelet COX-1 at Ser529 by aspirin, while insufficient protection against acute vascular events is considered as ineffectiveness. Most recently we developed two novel methods that directly and indirectly detects the acetylation of COX-1 by aspirin and demonstrated the lack of aspirin resistance in healthy volunteers taking aspirin for a week (Kovács et al. Thromb Res. 2013; accepted).

Aims: Using these new methods, we investigated the occurrence of aspirin resistance among patients with coronary artery disease (CAD) and evaluated several methods routinely used to detect the effect of aspirin.

Patients and Methods: One hundred and fifty-nine patients with CAD being on long-term aspirin monotherapy (100 mg aspirin/day) were enrolled in the study. Based on a priori exclusion criteria 11 subjects were excluded. The study was approved by the Regional Medical Ethics Committee; all patients gave informed consent.

Specific monoclonal antibodies, developed in our laboratory, were used to detect acetylated and non-acetylated COX-1 (acCOX-1, nacCOX-1) by Western blotting. Determination of AA-induced TXB_2 production in platelet rich plasma was used as an indirect measure of COX-1 inhibition. Both methods were sensitive enough to detect the presence of 2.5% of nacCOX-1 content of platelets from non-treated individuals. Methods used for the detection of aspirin effect in the clinical routine were also tested. Platelet COX-2 mRNA was determined by RT-PCR.

Results: With the exception of five patients only the band representing acCOX-1 appeared on the Western blot and TXB_2 production decreased into the very low reference interval (4–35 pg $TXB_2/10^6$ platelets) established for healthy volunteers on controlled aspirin intake. In a telephone interview the attention of the five patients demonstrating nacCOX-1 band and higher TXB_2 production was drawn to the danger of non-compliance and after 2 weeks they were recalled for repeated testing. Only in a single case of recalled patients was TXB_2 production slightly above the reference interval (42 pg TXB2/10^6 platelets) or appeared a faint nacCOX-1 band on the Western blot. In those platelets that expressed COX-2 mRNA the effect of aspirin was not diminished.

Results of AA-induced aggregation and ATP release were in complete accordance with those obtained by the above two methods, while three patients did not show definite aspirin effect by VerifyNow Aspirin assay. Platelet aggregation induced by ADP, epinephrine and collagen and PFA-100 assay with collagen/epinephrine cartridge revealed the effect of aspirin only in part of the patients.

Conclusions: If non-compliance was eliminated no aspirin resistance was observed, i.e. full acetylation of platelet COX-1 occurred in all patients with CAD. Only methods using AA as inducer detect the effect of aspirin on COX-1 reliably.

PA 2.01-3

The relationship between antiplatelet drug therapy and platelet microparticle formation and procoagulant activity in normals and patients with cardiovascular disease

Ly K, Aslam A, Low J, Jarvis S, Connor D and Joseph J
St Vincent's Hospital, Sydney, NSW, Australia

Background: Dual antiplatelet therapy with aspirin and clopidogrel is commonly used in order to prevent recurrent ischaemic events in patients with cardiovascular disease. It is unclear however whether antiplatelet drug therapy inhibits the formation of platelet-derived microparticles or their procoagulant activity. Platelet-derived microparticles are increasingly being recognised as pathogenic mediators in vascular disease.
Aims: The aim of this study was to investigate the relationship between antiplatelet therapy and its effect on platelet microparticle formation and procoagulant activity.
Methods: In *ex vivo* studies, blood samples from normal individuals ($n = 7$) who were not receiving antiplatelet therapy were incubated with buffer, aspirin or a P2Y12 inhibitor (MeSAMP). *In vitro* studies were performed on blood samples obtained from patients with known cardiovascular disease receiving long-term dual antiplatelet therapy ($n = 19$). Multiplate impedance aggregometry was used to assess the degree of platelet inhibition. Microparticle formation and procoagulant activity in response to adenosine diphosphate (ADP), arachidonic acid (AA) and thrombin receptor activating peptide (TRAP) stimulation was assessed by flow cytometric and Procoag-PL assays respectively. Multiplate reference ranges were established using 20 normal individuals not receiving antiplatelet therapy.
Results: In *ex vivo* studies, P2Y12 inhibition of normal platelets resulted in a significant inhibition of platelet aggregation to ADP and AA and a non-significant inhibition in response to TRAP. Aspirin significantly inhibited AA induced aggregation as expected. P2Y12 inhibition resulted in impaired microparticle formation in response to AA, ADP and TRAP, however increased procoagulant activity was detected in the presence of TRAP stimulation. Aspirin only inhibited microparticle formation and procoagulant activity following AA incubation.
In patients receiving dual antiplatelet therapy, there was a significant decrease in platelet aggregation in response to ADP, ADP-HS and AA. Very few patients remained in the reference range. Aggregation to TRAP was also significantly decreased, but the majority of patients still remained in the reference range. Microparticle-associated procoagulant activity in patients receiving dual anti-platelet therapy was inhibited in response to AA only and not to ADP or TRAP.
Summary/Conclusion: This study shows that the inhibition of P2Y12 is more effective at preventing platelet microparticle release and procoagulant activity when compared to aspirin. It also demonstrates that there are different effects of anti-platelet agents in *ex vivo* compared to *in vitro* studies. From these results, dual antiplatelet therapy appears to be effective at decreasing platelet aggregation, however it fails to completely inhibit microparticle release, particularly in response to ADP and TRAP. This could explain why some patients administered dual antiplatelet therapy experience ischaemic events.

PA 2.01-4

Safety and efficacy of dual antiplatelet therapy in transcatheter aortic valve implantation

Seidel H[1], Zeus T[2], Schleicher M[2], Polzin A[2], Kelm M[2], Hohlfeld T[3], Kirchhoff E[1] and Scharf RE[1]
[1]Department of Experimental and Clinical Hemostasis and Transfusion Medicine; [2]Division of Cardiology, Pulmonology, and Vascular Medicine; [3]Institute for Pharmacology and Clinical Pharmacology, Dusseldorf, Germany

Background: Dual antiplatelet therapy (DAPT) is widely used in patients undergoing transcatheter aortic valve implantation (TAVI). Clinicians and valve producing manufacturers recommend DAPT for 6 months after TAVI. However, this recommendation is not evidence-based and rather empirical.
Aims: The objective of our study was to examine the efficacy and safety in association to drug responsiveness in patients with DAPT after TAVI.
Methods: We investigated a retrospective cohort of 71 patients (age of 66–91, mean 81 years, 34 males, 37 females) undergoing TAVI procedure.
Prior to TAVI, 100 mg ASA and a loading dose of 300 mg clopidogrel were administered. DAPT was continued with 100 mg ASA and 75 mg clopidogrel daily for 6 months. Responsiveness to clopidogrel was measured postinterventionally by maximal intensity of ADP-induced platelet aggregation (5 μM) and phosphorylation of vasodilator-stimulated protein (VASP assay).
Results: Mean values ± SD for ADP-induced platelet aggregation were 50 ± 20% and 53 ± 26% for platelet reactivity index (PRI), respectively (correlation $r = 0.647$, $P < 0.01$). Low response to clopidogrel, defined as PRI > 61% and ADP-induced platelet aggregation > 46%, was seen in $n = 30$ patients (42%). No thrombotic adverse events were reported, but bleeds occurred in 20/71 (28%) patients. In 14 of 71 patients (19%) minor bleeds and in six of 71 (8%) patients major hemorrhagic complications were recorded according to the ISTH criteria. However, there were no significant differences for ADP-induced platelet aggregation and PRI comparing patients without documented bleeds (50 ± 21% and 53 ± 27%) to patients with minor (49 ± 20% and 56 ± 22%) and major bleeding (59 ± 20% and 42 ± 26).
Conclusion: Despite the high proportion of low clopidogrel responsiveness, the absence of thrombotic adverse events, i.e. valve thrombosis and embolization, indicate that DAPT appears to be effective in patients who underwent TAVI. However, the high incidence of reported bleeding events suggests re-evaluation of the need for DAPT after TAVI in future. The present results, obtained in a limited number of patients, do not support a critical influence of clopidogrel on post-procedural bleeding. Larger randomized prospective trials with more robust statistical power are required to determine optimal antiplatelet intensity and duration.

PA 2.01-5

Twice-daily administration of low-dose aspirin to patients with ischemic cerebrovascular disease

Santos MT[1], Lago A[2], Moscardo A[3], Latorre AM[3] and Valles J[3]
[1]University Hospital La Fe; [2]Department of Neurology, University Hospital La Fe; [3]Research Center, University Hospital La Fe, Valencia, Spain

Background: Aspirin is widely used for the secondary prevention of ischemic cerebrovascular disease (ICD). Patients may have increased platelet turnover due to atherosclerosis. We previously reported a reduction of platelet reactivity by the administration of twice-daily low-doses of aspirin to patients with vascular diseases [1] and that residual TXA_2 synthesis in patients was a determinant of aspirin resistance [2]. Down-regulation of platelet function by twice-daily administration of aspirin in patients with diabetes or coronary diseases and the kinetics of recovery of platelet cyclooxigenase-1 activity in patients with and without diabetes have been recently reported [3]. However, no data is presently available on the effect of twice-daily aspirin administration in patients chronically treated after ICD.
Aim: To compare the effect of a daily-dose of aspirin with a twice-daily regimen on platelet reactivity in patients with ICD.
Methods: Patients ($n = 59$) with a history of ICD treated with 200 mg/day aspirin for more than 3 months were consecutively included in the study after informed consent. The study was approved by the Institutional Review Board of the University Hospital la Fe. After an initial evaluation of platelet function, the aspirin regimen was changed in a

cross-over design to receive twice-daily 100 mg aspirin ($n = 35$ patients) or 50 mg twice-daily ($n = 24$ patients) for at least 2 months, and platelet function was evaluated again. Platelet function testing included collagen (1 μg/mL)-induced TXA_2 synthesis, dense granule release (^{14}C5HT), platelet recruitment (proaggregatory activity of cell-free releasates and light transmission aggregometry induced by arachidonic acid (AA, 1 mM), collagen (1 μg/mL) and ADP (3 μM) [2]. Compliance with the treatment was assessed by a personal interview and platelet TXA_2 inhibition > 80% [2].

Results: As compared with the administration of 200 mg/daily, the twice-daily 100 mg regimen significantly reduced the residual TXA_2 synthesis ($P = 0.002$), dense granule secretion ($P = 0.000$), recruitment ($P = 0.000$) and AA-induced aggregation ($P = 0.045$), while no differences were found when collagen or ADP were used as agonists for platelet aggregation. No significant differences in platelet reactivity were detected between the twice-daily 50 mg aspirin and 200 mg/day regimens.

Conclusions: A twice-daily dose of 100 mg aspirin administered to patients with ICD under chronic treatment improves the anti-platelet effect of the same dose of aspirin (200 mg) administered daily. Reducing the dose to 50 mg twice-daily is as effective as a double dose of aspirin administered daily. The most effective strategy for managing patients with high on-treatment platelet reactivity is not known, but the administration of a twice-daily low-dose aspirin may be a reasonable approach, particularly in patients at high risk of recurrence. However, more studies are needed.

Microfluidic assay of platelet deposition on collagen using perfusion of whole bllod from healthy subjects taking aspirin

Li R, Fries S, Li X, Grosser T and Diamond SL

University of Pennsylvania, Philadelphia, PA, USA

Background: Microfluidic devices can create hemodynamic conditions for platelet assays. An 8-channel device was validated in a study of inter-donor reponse to acetylsalicylic acid (ASA, aspirin) using whole blood from 28 healthy subjects)

Aims: To recreate the hemodynamic conditions for platelet assays while testing inter-donor whole blood response to aspirin and to domonstrate a novel and rapid assay for measing the effects of aspirin on platelet function under physiologically relevant conditions.

Methods: Platelet deposition was assessed prior to treament or 24-h after 325 mg ASA ingestion. Whole blood (plus 100 μM H-D-Phe-Pro-Arg-chloromethylketone to inhibit thrombin) was further treated *ex vivo* with ASA (0–500 μM) and perfused over fibrillar collagen for 300 s at a venous wall shear rate (200/s).

Results: *Ex vivo* ASA addition to blood drawn prior to aspirin ingestion caused a reduction in platelet deposition ($IC_{50} \approx 10$–20 μM), especially between 150 and 300 s of perfusion when secondary aggregation mediated by thromboxane was expected. Twenty-seven of 28 subjects displayed smaller deposits (45% average reduction; 10–90% range; $P < 0.001$) from blood obtained 24-h after ASA ingestion (no ASA added *ex vivo*). In replicate tests, an *R*-value to score secondary aggregation [deposition rate from 150 to 300 s normalized by rate from 60 to 150 s] showed $R < 1$ in only two of 28 subjects without ASA ingestion, with $R > 1$ in only three of 28 subjecst following 500 μM *ex vivo* ASA addtion. At 24-h after ASA ingestion, 21 of 28 subjects displayed poor secondary aggregation ($R < 1$) without *ex vivo* ASA addition, while the seven subjects with residual secondary aggregation ($R > 1$) displayed insensitivity to *ex vivo* ASA addition. Platelet deposition was uncorrelated with platelet count, *Ex vivo* ASA addition caused similar inhibition at venous and arterial wall shear rates.

Conclusions: Microfluidic devices quantified platelet depostion following ingestion or *ex vivo* addition of aspirin.

Mitochondrial permeability transition pore dependent intracellular pH elevation is associated with enhanced calpain activity and integrin aIIbβ3 inactivation

Liu F[1] and Jobe SM[2]

[1]Emory University; [2]Emory University and Children's Healthcare of Atlanta, Atlanta, GA, USA

Background: Thrombin (Thr) plus convulxin (Cvx) stimulation of platelets results in irreversible integrin $\alpha_{IIb}\beta_3$ inactivation, which is mediated by opening of the mitochondrial permeability transition pore (mPTP). Our lab previously showed that deletion of cyclophilin D (CypD), a regulator of mPTP formation, markedly blunts mPTP opening and abrogates integrin inactivation. However, the mechanism by which mPTP opening mediates integrin $\alpha_{IIb}\beta_3$ inactivation remains uncertain.

Aim: Investigate the mechanisms, subsequent to mPTP formation, that mediate integrin $\alpha_{IIb}\beta_3$ inactivation.

Methods: Platelets from wild type and $CypD^{-/-}$ mice were isolated. Cleavage of platelet integrin β_3 intracellular domain (C-terminus) and cytoskeleton protein talin were assessed simultaneously by Western blot analysis using their respective antibodies. Platelet function was evaluated in static conditions by platelet aggregation assay and in flow conditions by microfluidic assay. Intracellular pH was measured by flow cytometry assay using Snarf-1 AM as pH indicator.

Results: In strongly-stimulated (Thr/Cvx) platelets, 50% of both the integrin β_3 intracellular domain and talin was cleaved within 5 min. In platelets stimulated with either thrombin or convulxin alone, only minimal (10%) cleavage was observed. Cleavage of β_3 was temporally correlated with integrin $\alpha_{IIb}\beta_3$ inactivation. Calpain inhibition (MDL 28170) blocked the Thr/Cvx induced cleavage of β_3 and talin and integrin $\alpha_{IIb}\beta_3$ inactivation. Consistent with this inhibition of integrin inactivation, calpain inhibition resulted in increased platelet aggregation in static and flow conditions. Cleavage of integrin β_3 and talin and integrin inactivation were abrogated in Thr/Cvx treated-$CypD^{-/-}$ platelets. Calpain inhibition did not affect loss of mitochondrial membrane potential indicating that enhanced calpain activation occurred subsequent to mPTP formation.

A major regulator of calpain activity is an increased intracellular Ca^{2+} concentration. Surprisingly, an unaltered Ca^{2+} response was observed in $CypD^{-/-}$ platelets, despite the marked impairment of calpain-mediated integrin cleavage. This result indicates that sustained Ca^{2+} elevation alone is not sufficient for the enhanced calpain activity observed in strongly-stimulated platelets. Calpain activity can also be regulated by intracellular pH. Evaluation of intracellular pH by flow cytometry revealed that Thr/Cvx stimulation caused a marked increase in intracellular pH from a baseline pH of approximately 7.3–7.8–8.0. This increase in pH was primarily limited to the platelet subpopulation in which integrin inactivation had occurred. In contrast, in platelets treated with thrombin or convulxin alone and in CypD null platelets, only a slight increase of pH (approximately 0.1–0.2) was observed.

Conclusions: In strongly-stimulated platelets, mPTP formation results in enhanced calpain activation, enhanced integrin β_3 and talin cleavage, and irreversible integrin inactivation. An mPTP-mediated increase in intracellular pH may be the mechanism driving this enhancement of calpain activity in strongly-stimulated platelets.

PA 2.02-2

Redundant functions of TRPC6 and Orai1 in murine platelets

Chen W[1], Gupta S[2], Thielmann I[2], Gotru SK[2], Van Kruchten R[3], Dietrich A[4], Heemskerk JWM[3], Nieswandt B[2] and Braun A[2]
[1]Rudolf Virchow Center; [2]Rudolf Virchow Center, University of Wuerzburg, Wuerzburg, Germany; [3]Cardiovascular Research Institute Maastricht, University of Maastricht, Maastricht, The Netherlands; [4]Ludwig-Maximilians University, Munich, Germany

Background: Elevation of the intracellular Ca^{2+} concentration is an essential step during platelet activation. Store-operated Ca^{2+} entry (SOCE) through Orai1 is well described as the major route of Ca^{2+} influx in platelets. Recently, we found that diacylglycerol (DAG) activated Ca^{2+} influx was completely abolished in transient receptor potential cation channel 6 knockout (*Trpc6−/−*) platelets establishing TRPC6 as the only DAG induced receptor operated Ca^{2+} (ROC) channel in murine platelets. Surprisingly, this abolished ROCE did not affect agonist induced Ca^{2+} responses and SOCE. Furthermore, platelet activation and aggregation *in vitro* and thrombus formation *in vivo* were normal in *Trpc6−/−* mice. All together, these results indicated that TRPC6 mediated Ca^{2+} influx in platelet physiology may be dispensable or fully compensated by other Ca^{2+} channels.
Aims: In order to understand the functional redundancy between TRPC6 and Orai1 in Ca^{2+} homeostasis, platelets lacking both Ca^{2+} channels were analyzed.
Methods: Chimeric mice were generated by transplanting 13 days old fetal liver cells from *WT, Orai1−/− and Orai1−/−/Trpc6−/−* embryosinto lethally irradiated 6 weeks old C57Bl6 mice. Mutant platelets were analyzed using a wide range of *in vitro* and *in vivo* platelet functional assays.
Results: Decreased Ca^{2+} store content and severely altered agonist induced Ca^{2+} store release were observed in *Orai1−/−/Trpc6−/−* platelets whereas these responses were normal in *WT* and *s*ingle knockout platelets. Agonist and thapsigargin induced Ca^{2+} influx were further reduced in *Orai1−/−/Trpc6−/−* platelets in comparsion to *Orai1−/−* platelets. These insufficient Ca^{2+} responses inhibited GPVI mediated integrin activation, P-selectin and phosphatidyl-serine (PS) exposure in *Orai1−/−/Trpc6−/−* platelets, but did not affect G-protein coupled receptor (GPCR) – mediated platelet activation. Surprisingly and in sharp contrast to *Orai1−/−* platelets, *Orai1−/−/Trpc6−/−* platelets could form stable thrombi under flow resulting in comparable surface coverage and thrombus volume as *WT* platelets. Moreover, in the presence of high concentration of apyrase, aggregation response to platelet agonists were enhanced in *Orai1−/−/Trpc6−/−* platelets when compared to *Orai1−/−* platelets.
Conclusions: TRPC6 and Orai1 regulate Ca^{2+} store content in platelets. Orai1 induced SOCE dominates the process of platelet activation, aggregation and thrombus formation, whereas TRPC6 plays a minor role in these processes. Severe Ca^{2+} deficiency due to the blockade of SOCE and DAG mediated ROCE in platelets could enhance so far unknown signalling pathways which trigger platelet aggregation and thrombus growth.

PA 2.02-3

The chaperone protein, heat shock protein 47 (Hsp47): a novel platelet collagen receptor that contributes to thrombosis and haemostasis

Sasikumar P[1], Kaiser J[1], Vaiyapuri S[1], Sage T[1], Moraes LA[1], Farndale RW[2] and Gibbins JM[1]
[1]Institute of Cardiovascular and Metabolic Research/University of Reading, Reading; [2]University of Cambridge, Cambridge, UK

Background: Heat Shock Protein 47 (Hsp47) is a collagen binding protein that is normally localised within the secretory system of collagen producing cells, functioning as a chaperone for procollagen. However, some studies have shown they can be present on the surface of cells. We previously showed that HSP47 is present on the surface of platelets and that levels increased upon platelet activation. Since platelet function is dependent on their tethering to collagen exposed in the arterial wall upon injury, we investigated whether Hsp47 functions as a receptor for collagen.
Aim: To determine the role of Hsp47 in normal platelet function and thrombosis.
Methods: Immunofluorescence was performed on resting human and mouse platelets using specific Hsp47 antibodies. The role of Hsp47 on platelet function *in vitro* was established using platelet aggregation and thrombus formation assays in the presence and absence of Hsp47 inhibitors. The significance of platelet Hsp47 was studied *in vivo* using tail bleeding assay of haemostasis and intravital microscopy to measure thrombosis using laser injury model on mouse cremaster arterioles.
Results: The presence of Hsp47 on platelet surface and their progenitor cells, megakaryocytes was established by immunofluorescence. An inhibitory polyclonal antibody against Hsp47 (Rb anti-Hsp47) and a small molecule inhibitor of Hsp47(SMIH) were found to attenuate platelet aggregation induced with collagen fibrils (Horm, equine tendon) at 1 μg/mL, but not with CRP-XL (a GPVI selective agonist) and thrombin. Both SMIH and inhibitory antibodies reduced the size of thrombi formed when whole human blood was perfused over collagen *in vitro*. Further to findings from the *in vitro* assays, the role of Hsp47 in haemostasis and thrombosis was confirmed using the *in vivo* assays. Inhibition of Hsp47 using SMIH in mice increased tail bleeding times and the volumes of blood lost. Following the inhibition of Hsp47 a reduction of 66% in thrombus size was observed using a laser injury model of thrombosis on cremaster muscle arterioles.
Conclusions: Hsp47 on the platelet surface functions as a receptor for extracellular collagens that are exposed at sites of blood vessel injury. This facilitates the adhesion of platelets to the site of vessel damage, and thus inhibition of Hsp47 may be useful for the prevention of thrombosis.

PA 2.02-4

Inhibition of the Gas6/Mer pathway with novel compounds recapitulates the antithrombotic phenotype of Gas6−/− or Mer−/− mice in arterial and venous thrombosis models

Branchford BR[1], Law L[2], Sather S[2], Brodsky G[2], DeRyckere D[2], Earp SH[3], Wang X[3], Frye S[3], Graham DK[2] and Di Paola JA[2]
[1]University of Colorado-Denver and Children's Hospital Colorado; [2]University of Colorado Denver, Aurora, CO; [3]University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Background: Growth Arrest Specific gene 6 (Gas6) signals through platelet-surface Mer receptors, leading to platelet activation and thrombus stabilization. We previously used two novel compounds to inhibit this pathway, decreasing platelet activation in functional assays. iMer is an alternatively spliced form of the Mer receptor tyrosine kinase's extracellular domain that likely acts as a Gas6 trap. A selective UNC Mer small molecule inhibitor (UNC Mer TKI) inhibits Mer tyrosine phosphorylation.
Aims: We hypothesized that inhibiting the Gas6/Mer pathway with either compound would protect wild type (WT) mice against arterial and venous thrombosis to a similar degree as that seen in Gas6- or Mer-null mice.
Methods: We used a 6% ferric chloride ($FeCl_3$)-induced carotid artery injury model and a collagen/epinephrine-induced pulmonary embolism (PE) model to compare thrombosis protection between WT C57BL/6 mice treated with inhibitors or vehicle, and also Gas6- and Mer-null animals. Experiments ran for 30 min and reported values are

means ± standard error. Paired t-tests were used to compare times to initial and stable occlusions in the $FeCl_3$ model and survival time in the PE model. Bleeding time was assessed by tail-clip with stump insertion into 37° saline.

Results: In the $FeCl_3$ model, vehicle-treated control mice ($n = 6$) had faster times to initial (6.08 ± 0.12 min) and stable occlusion (7.36 ± 1.3 min) compared to 30 mg/kg iMer-treated mice ($n = 6$, 7.97 ± 0.64 min initial [$P = 0.03$] and 20.49 ± 4.61 min stable [$P = 0.02$]). Also, vehicle-treated control mice ($n = 10$) had faster time to initial (6.93 ± 0.25) and stable occlusion (15.59 compared to 3 mg/kg UNC Mer TKI-treated mice ($n = 9$, 7.97 ± 0.48 initial [$P = 0.06$] and 46.64 ± 7.72 min stable [$P = 0.002$]). Mer-null mice ($n = 3$) had prolonged time to both initial (5.9 ± 0.42 min, $P = 0.06$) and stable occlusion (15.87 ± 6.47 min, $P = 0.15$) compared to WTs ($n = 3$, 4.10 ± 0.59 min initial occlusion, all of which were stable). These experiments, including Gas6-null mice, are currently underway.

In the PE model, 30 mg/kg iMer-treated mice ($n = 9$) survived longer (15.7 ± 4 min) than controls ($n = 10$, 5.5 ± 2.7 min, $P = 0.05$), with three experimental mice (33%) and only one control (11%) surviving for 30 min. Similarly, 3 mg/kg UNC Mer TKI-treated mice ($n = 9$) survived longer (21.25 ± 4.7 min, $P < 0.01$, 6 [66%] surviving 30 min) than controls ($n = 7$, 3.09 ± 0.41 min, no survivors). Both Gas6-null mice ($n = 6$, 17.58 ± 5.11 min, $P = 0.04$, 3 [50%] survivors), and Mer-null mice ($n = 6$, 21.03 ± 5.26 min, $P = 0.02$, 4 [66%] survivors) survived longer than WT controls ($n = 5$, 2.70 ± 0.19 min, no survivors). Tail clip bleeding times did not vary significantly between WT controls ($n = 8$, 6.41 ± 0.89 min) and Gas6-null mice ($n = 5$, 6.5 ± 1.25 min, $P = 0.6$) or Mer-null mice ($n = 7$, 4.8 ± 0.8 min, $P = 0.2$).

Conclusions: Compared to genetic absence of Gas6 or Mer, pharmacological inhibition of the Gas6/Mer pathway protects mice from arterial and venous thrombosis with comparable effects. iMer and UNC Mer TKI may have translational applications as novel anti-platelet agents.

PA 2.02-5

VacA, the vacuolating cytotoxin of *Helicobacter pylori*, binds to multimerin 1 associated with platelet membranes

Satoh K[1], Toshiya H[2], Katsuhiro T[1], Tadashi S[1] and Yukio O[1]
[1]*University of Yamanashi, Chuo, Yamanashi;* [2]*Nagasaki University, Nagasaki, Japan*

Background: Immune thrombocytopenia is a frequent complication with *H. pylori* infection in Japan. While the mechanism by which *H. pylori* induces thrombocytopenia remains largely undetermined, there are several lines of evidence to suggest that its infection activates platelets. In this study, we investigated the role of vacuolating toxin A (VacA) in inducing platelet activation, and attempted to identify the target protein with which VacA interacts.

Results: The CD62P expression in platelets was 1.5 ± 3.9% in ITP patients free from *H. pylori* infection ($n = 18$). However, its expression was significantly increased to 9.5 ± 8.1% with *H. pylori* infection ($n = 17$, $P < 0.001$), and with those who underwent eradication successfully ($n = 5$), the CD62P expression was significantly lowered (1.9 ± 0.8%, $P < 0.02$).

Acid-activated VacA did not induce platelet aggregation, however, it increased the expression of CD62P upon interaction with platelets. Previously reported that VacA reacted with its receptors (EGFR, RPTPa, RPTPb, CD18) present on platelet membranes. However, we were not able to detect the binding between VacA and each of these receptors with the use of either anti-VacA antibody or the antibody against each of these receptors. We therefore analyzed VacA associated proteins obtained through VacA affinity chromatography, using MALDI-TOF-MS. As a result, a set of the peptides matched from the database suggested that multimerin 1 (MMRN1) was detected in two consecutive experiments, as the binding protein for VacA. A GST-fusion protein of MMRN1 corresponding to the 291–391 a.a peptide sequence reacted with VacA assessed by a Biacore system. We synthesized the 20-aa-length peptides, which partly overlap with one another, and checked the binding of VacA with the dot blot method. As a result, the peptide sequence corresponding to 321–340 a.a. showed the highest reactivity to VacA, suggesting that VacA binds to MMRN1 by interacting with this region.

Conclusion: We found that VacA binds MMRN1, and that its binding site for VacA appears to reside within the 321–340 aa sequence. However, how this translates into VacA-induced platelet activation remains an issue.

PA 2.02-6

Rational targeting of Rac-NOX2 pathway prevents ROS generation and platelet activation involving MLC, Akt and Ca++-PKC signaling induced by diverse agonists

Akbar H[1], Saleem S[1], Kuenzi A[2] and Zheng Y[2]
[1]*Ohio University, Athens, OH;* [2]*Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA*

Reactive oxygen species (ROS) play a critical role in platelet activation induced by diverse agonists. ROS generation by NOX2 depends on binding of activated Rac to $p67^{phox}$. We have shown that rationally designed small molecule inhibitors of Rac- $p67^{phox}$ interaction (Phox-I) inhibit ROS generation (Chem. Biol. 19, 228–242, 2012). In this study we investigated the role of Rac-NOX2 axis in platelet activation by determining the effects of a second generation $p67^{phox}$ inhibitor Phox-I3 on ROS generation and platelet activation induced by collagen, collagen related peptide (CRP) or thrombin. ROS generation in washed human platelets was quantified by flow cytometry using CM-H2-DCFDA. Thrombin, collagen or CRP stimulation dynamically increased ROS levels in platelets. Addition of NSC23766 (1–10 μM), a specific inhibitor of Rac GTPase activity, or Phox-I3 (1–10 μM), to platelets 2 min before stimulation with collagen, CRP or thrombin inhibited ROS generation in a concentration dependent manner. DPI, a non-selective inhibitor of NOX2, also inhibited ROS generation. Pre-incubation of washed human platelets with Phox-I3 inhibited: (i) thrombin or U46619, a TXA_2 analog, induced expression of P-selectin on platelet membranes; (ii) collagen or thrombin induced secretion of ATP from platelet dense granules; (iii) collagen, CRP or thrombin induced platelet aggregation. These data, taken together with our earlier findings that NSC23766 inhibits platelet secretion and aggregation by blocking activation of Rac GTPase (J Thromb Haemost 5, 1747–55, 2007), suggest that inhibition of the Rac-NOX2 pathway suppresses ROS generation and consequently platelet activation. Downstream from the Rac-NOX2-ROS axis, cytosolic calcium response, as well as phosphorylation of myosin light chain (MLC) and Akt, were inhibited in platelets treated with Phox-I3 prior to stimulation with collagen or thrombin, suggesting that the NOX2-ROS pathway regulates signaling through cytosolic calcium and phosphorylation of MLC and Akt. Further, Phox-I3 inhibited collagen, but not the phorbol dibutyrate (PDBu), induced phosphorylation of Pleckstrin, a critical substrate of Ca^{++}-Protein kinase C (PKC) signaling in platelets. All together, our data show that Rac-NOX2 pathway regulates ROS generation and subsequent MLC, Akt and Ca^{++}-PKC responses that are essential for platelet activation induced by diverse agonists.

Antiphospholipid antibodies-mediated platelet activation: a key role of PI3Ks beta and alpha

Terrisse AD[1], Garcia C[2], Séverin S[1], Laurent PA[1], Gratacap M-P[1], Van Haesebroeck B[3], Sié P[2] and Payrastre B[1]

[1]Inserm; [2]CHU Rangueil, Toulouse, France; [3]Queen Mary University, London, UK

Background: The antiphospholipid syndrome (SAPL) is a systemic autoimmune disorder characterized by the persistent presence of antiphospholipid antibodies (aPL) that cause the clinical features of vascular thrombosis. There is strong evidence that anti-β2GPI antibodies have thrombogenic properties. However, the mechanisms by which aPL induce platelet activation are still poorly characterized. Anti-β2GPI antibodies, through the formation of immune complexes with the plasmatic ß2-glycoprotein 1, induce a dimerization of the protein and the recruitment of platelet membrane receptors such as GPIbα, ApoER2 and possibly TLR4.
Aim of the Study: The goal of this study was to identify the cell surface receptors and the intracellular pathways involved in platelet activation by anti-β2GPI autoantibodies.
Methods: Antiphospholipid antibodies (aPL) were either commercial or isolated from plasma of thrombotic SAPL patients. Control IgG antibodies were isolates from plasma of healthy donnor in same conditions. Platelet activation was studied in presence of aPL (50 μg/mL) ± pharmacologic inhibitors. Anti-CD42b, anti-TLR2 and anti-TLR4 antibodies were used to block the signaling pathways initiated by these receptors. Platelet adhesion and aggregation was analyzed *ex-vivo* using either human or mice blood.
Results: We show that anti-β2GPI antibodies increase platelet adhesion to a collagen or von Willebrand matrix under flow at a physiological shear rate compared to control IgG with an implication of both GPIbα and TLR4. Using washed platelets, we found that aPL antibodies significantly sensitize platelet aggregation in the presence of suboptimal doses of thrombin (2.5 fold increase, $P > 0.001$ vs. control igG). This effect was totally prevented by blocking of GP1ba, TLR2 and TLR4 receptors. Moreover, inhibitors of PI3K totally blocked the aPL effect on human platelet aggregation as well as AKT activation. The implication of Class IA PI3K alpha and beta was confirmed using platelets from mouse deficient in these isoforms of PI3K selectively in megakaryocytes and platelets.
Conclusion: Overall our results suggest that inhibition of class IA platelet PI3K downstream of GP1ba and TLR could be an interesting therapeutic strategy in order to prevent thrombotic events in SAPL patients without increasing the hemorrhagic risk.

PA 2.03-2

Partial inhibition of serine/threonine phosphatase PP2A blocks clot retraction without reducing alphaIIbbeta3 receptor activation

Moscardó A[1], Vallés J[2], Latorre A[2], Madrid I[3], Dasí MA[4] and Santos MT[2]

[1]IIS La Fe; [2]Research Center, La Fe University Hospital; [3]Intensive Care Unit, University Hospital La Fe; [4]Pediatric Hospital, University Hospital La Fe, Valencia, Spain

Background: Platelet aggregation depends on changes in the integrin $\alpha_{IIb}\beta_3$ that allow fibrinogen binding. However, to retract the clot and stabilize the growing thrombus a new set of signal transduction mechanisms with origin at $\alpha_{IIb}\beta_3$ must take place. The $\alpha_{IIb}\beta_3$ receptor is known to be regulated by protein phosphorylation-dephosphorylation processes. Knowledge about the role of PP2A serine/threonine phosphatase in $\alpha_{IIb}\beta_3$ signalling is scarce, and no data is available on its participation in clot retraction.
Aim: To study the role of serine/threonine phosphatase PP2A in the mechanisms regulating clot retraction: (i) inside-out process that trigger $\alpha_{IIb}\beta_3$ activation and platelet aggregation, and (ii) in the subsequent outside-in signaling that reinforces aggregation and leads to clot retraction in thrombin activated platelets.
Methods: We used washed human platelets from healthy controls without medication. As inhibitor of PP2A we used okadaic acid (OA). Platelet agonist thrombin (1 U/mL) was employed. Platelet aggregation, cytoskeleton isolation, flow cytometry and inmunodetection of proteins were performed as previously described (1). Clot retraction was started by adding 1 U/mL thrombin to washed platelets in the presence of fibrinogen, and the evolution of the clot was photographed at intervals up to an hour.
Results: Inhibition of PP2A with OA strongly inhibited clot retraction of platelets at 100 or 500 nM. In contrast, OA 100 nM did not inhibit $\alpha_{IIb}\beta_3$ activation (PAC-1 binding) or platelet aggregation, while 500 nM strongly inhibited both processes. The down-regulation of the integrin activation with OA 500 nM could be related to the inhibition of tyrosine phosphorylation of proteins (1), since we observed that treatment with OA 500 nM but not with OA 100 nM strongly inhibited tyrosine phosphorylation of proteins in whole platelets lysates. OA 500 nM inhibited several signal transduction mechanisms associated with outside-in signaling such as cytoskeletal reorganization and incorporation of tyrosine phosphorylated proteins, β_3 and tyrosine kinases to the cytoskeleton; in addition, β_3 and FAK phosphorylation were also strongly reduced. In contrast, OA 100 nM only affected FAK incorporation to the cytoskeleton and FAK phosphorylation.
Conclusion: The level of inhibition of PP2A by low or high OA concentration differentially regulates platelet aggregation and integrin signalling, but have a common effect in blocking clot retraction. The latter may be associated with the presence of phosphorylated FAK in the cytoskeleton. This study reveals PP2A as a novel target for anti-platelet treatment to block clot retraction without affecting the platelet haemostatic function if a partial inhibition of PP2A could be achieved.

PA 2.03-3

Autocrine amplification of integrin aIIbβ3 activation and platelet adhesive responses by deoxyribose-1-phosphate

Pula G and Vara DS

University of Bath, Bath Spa, UK

Background: Platelet activation is a complex series of events originating from the stimulation of surface receptors by biochemical signals linked to vascular damage, such as the exposure of the subendothelial matrix and the generation of thrombin in the coagulation cascade. Besides responding to their microenvironment and to the biochemical messages released by other circulating or vascular cells, platelets also release their own rich array of extracellular signals. Amongst the small molecules released by platelets, thromboxane A_2 (TXA_2), adenosine diphosphate (ADP), epinephrine, and serotonin (5-HT) are key autocrine regulators of platelet responses. Recently, we utilised gas-chromatography mass spectrometry (GC-MS) to identify new molecules released by platelets. The pro-angiogenic metabolite deoxyribose-1-phosphate (dRP) was detected in micromolar concentrations in stimulated platelet supernatants.
Aims: In light of the ability of dRP to stimulate the generation of reactive oxygen species (ROS) in different cell types and the pro-aggregatory role of ROS in platelets, we investigated whether platelet-derived dRP plays any autocrine role in the regulation of the redox balance, the intracellular signalling, or the functional responses of platelets.

Methods: The experiments were performed on human platelets from healthy donors or mouse platelets, either wild type or transgenic characterised by genetic deletion of thymidine phosphorylase and uridine phosphorylase ($TP^{-/-}$ $UP^{-/-}$), which results in impaired dRP release upon platelet activation. The effects of deprivation of endogenous dRP (transgenic platelets) or addition of exogenous dRP were tested on washed platelet aggregation (by turbidimetry), integrin αIIbβ3 activation (by flow cytometry), washed platelet static adhesion (by phase contrast imaging), whole blood thrombus formation (by microfluidics and time-lapsed epifluorescence microscopy), ROS accumulation (by live platelet confocal imaging), and signal transduction pathway (by immunoblot).
Results: The addition of exogenous dRP to human platelets significantly increased platelet aggregation and integrin αIIbβ3 activation in response to thrombin. In parallel, genetically modified platelets with double genetic deletion of thymidine phosphorylase and uridine phosphorylase were characterised by reduced release of dRP, impaired aggregation and decreased integrin αIIbβ3 activation in response to thrombin. *In vitro* platelet adhesion onto fibrinogen and collagen under physiological flow conditions was potentiated by treatment of human platelets with exogenous dRP and impaired in transgenic platelets with reduced dRP release. Human and mouse platelets responded to dRP treatment with a sizeable increase in reactive oxygen species (ROS) generation and the pre-treament with the antioxidant apocynin abolished the effect of dRP on aggregation and integrin activation. Experiments directly assessing the activation of the small G protein Rap1b and protein kinase C suggested that dRP increases the basal levels of activity of these two pivotal platelet-activating pathways in a redox-dependent manner.
Summary/Conclusions: Taken together, we present evidence that dRP is a novel autocrine amplifier of platelet activation, which acts on platelet redox levels and modulates integrin αIIbβ3 inside-out signalling.

PA 2.03-4
Canonical and non-canonical cleavage patterns for protease-activated receptor (PAR) 1 and 3 by factor Xa reveal novel insights into the allosteric modulation of cytoprotective PAR1 signaling by PAR3

Stavenuiter F and Mosnier LO
The Scripps Research Institute, La Jolla, CA, USA

Endothelial barrier protective effects by APC require binding to the endothelial protein C receptor (EPCR) and protease activated receptor 1 (PAR1). In contrast, activation of PAR1 by thrombin results in endothelial barrier disruptive signaling, thus creating a paradox how PAR1 can mediate both of these opposite effects. Recently, we provided a partial explanation by demonstrating that APC cleaved PAR1 at Arg46 and that tethered-ligand peptides beginning at Asn47 mediated APC-like barrier protective effects *in vitro* and *in vivo*. Thus, PAR1 is a biased receptor that can initiate endothelial barrier protective or disruptive effects depending on the cleavage site of its tethered-ligand at either Arg46 or Arg41. We found another piece of the puzzle analyzing PAR3 cleavage by APC. Requiring EPCR, APC cleaved PAR3 at non-canonical Arg41, whereas thrombin cleaved at canonical Lys38. PAR3 non-canonical tethered-ligand peptides beginning at Gly42 mediated APC-like barrier protective effects *in vitro* and *in vivo* that required PAR1, whereas canonical PAR3 tethered-ligand peptides beginning at residue Thr39 had no effect. Similar to APC, factor Xa (FXa) blunts thrombin-induced barrier disruptive effects *in vitro*. To determine whether non-canonical PAR1 and PAR3 cleavages are generally applicable mechanisms for endothelial barrier protection, the PAR1 and PAR3 cleavage profiles for FXa were determined, using SEAP-PAR1 and PAR3 cleavage constructs in HEK293 cells. Cleavage of PAR1 by FXa was EPCR-dependent and required the FXa GLA-domain. Mutation of the canonical Arg41 to Gln abolished PAR1 cleavage, whereas FXa cleaved Arg46Gln PAR1 similar to wt-PAR1. Thus, FXa cleaved PAR1 at Arg41 like thrombin and not at Arg46 like APC. FXa cleaved PAR3 in the presence of EPCR but not in the absence of EPCR and required the GLA-domain. PAR3 cleavage by FXa was inhibited by blocking antibodies against FXa, PAR3, and the direct FXa inhibitor rivaroxaban. Interestingly, PAR3 could still cleave Lys38Gln-PAR3 but failed to cleave Arg41Gln-PAR3 or Lys38Gln/Arg41Gln-PAR3. Thus, FXa cleaved PAR3 at the non-canonical Arg41 similar to APC but not at the canonical Lys38 like thrombin. Since FXa cleaved PAR1 at Arg41 and PAR1 desensitization can give the false impressions of protection against thrombin-induced permeability, barrier protective effects of FXa were verified using histones to induce PAR1-independent barrier disruption. Both FXa and APC blunted histones-induced permeability, indicating that barrier protective effects were not due to PAR1 desensitization. The PAR3 non-canonical tethered-ligand peptide but not the canonical PAR3 tethered-ligand peptide also blunted histones-induced barrier disruption. In summary, the unique canonical/non-canonical PAR1/3 proteolysis profile of FXa, intermediate between thrombin and APC, provides unique opportunities for novel insights on the role of non-canonical PAR cleavages and of PAR3 in particular. Our data help conceptualize novel functions for non-canonical PAR3 activation at Arg41 as an allosteric modulator of canonical PAR1 activation.

Immobilized heparin enhances aIIbβ3-dependent outside-in signaling in human platelets

Gyenes M, Wildt K, Stoldt VR and Scharf RE
Heinrich Heine University Medical Center, Düsseldorf, Germany

Backround: Heparin is the most commonly used parenteral anticoagulant worldwide. Upon its administration, 10–30% of patients develop a mild, nonimmune thrombocytopenia. The nature of this heparin-induced thrombocytopenia (HIT, type I) is unknown (in contrast to the antibody-mediated HIT, type II). Recently, it has been suggested that heparin can promote platelet responsiveness by potentiating αIIbβ3-mediated outside-in signaling, thereby inducing HIT type I (Gao et al, Blood 2011; Yagi et al, Thromb Res 2012).
Aims: To analyze the role of αIIbβ3 in heparin-platelet interaction, we first studied platelet aggregation in the presence of unfractionated heparin (UFH). Moreover, we assessed platelet spreading and quantitatively investigated the activation of two tyrosine kinases, Src and focal adhesion kinase (FAK), in human platelets on immobilized UFH or its synthetic derivative fondaparinux. To examine the specificity of αIIbβ3 we used the αIIbβ3 antagonist abciximab and αIIbβ3-overexpressing HEK293 cells which lack other platelet receptors. As positive control, we applied immobilized fibrinogen.
Methods: We used human washed platelets or αIIbβ3-transfected HEK293 cells. Aggregation with platelets was performed in the presence of soluble UFH (0.2 or 1.0 U/mL). Adhesion was carried out under static conditions either on immobilized UFH (5, 10 and 50 U/mL) or fondaparinux (3 μg/mL) or fibrinogen (100 μg/m). BSA was used as negative control. Images of FITC-phalloidin-conjugated platelets and YFP-conjugated αIIbβ3-transfected HEK293 cells were taken with an Axiovert 100M microscope (Carl Zeiss). Specific phosphorylations of Src (pY418) and FAK (pY397) were determined by Western blot.
Results: UFH alone did not induce platelet aggregation, but it caused a 2-fold potentiating response upon platelet stimulation with ADP (300 nM). Platelets showed spreading on immobilized UFH to a similar extent as on a fibrinogen matrix. We detected the same effect with immobilized fondaparinux. In the presence of abciximab or on BSA, no platelet spreading was visible. We examined Src and FAK phosphorylation at various concentrations of immobilized UHF and detected maximal activation at 10 U/mL UFH matrix (twofold higher than at 5 U/mL; 1.5-fold higher than at 50 U/mL). Comparing Src and FAK signaling in platelets on immobilized UFH with that on immobilized fibrinogen, signaling to both kinases in platelets on

immobilized UFH were approximately 40% of that in platelets on a fibrinogen matrix. We observed comparable extents of activity in platelets on fondaparinux matrix as on UFH (5-fold increase in Src pY418 and 6-fold increase in FAK pY397 signaling compared to BSA control). Abciximab completely blocked the activation of both Src and FAK. αIIbβ3-transfected HEK293 cells also exhibited enhanced signaling on immobilized UFH. However, in contrast to platelets, we detected maximal kinase activities on UFH matrices with higher concentrations (Src at 100 U/mL and FAK at 50 U/mL UFH concentration, respectively).

Summary: We demonstrated enhanced Src and FAK activations both in platelets and αIIbβ3-transfected HEK293 cells on heparin and fondaparinux matrices. This activation is blocked by abciximab. Our results suggest a significant role of αIIbβ3 in the platelet-heparin interaction and are in accordance with earlier reports referring to enhanced platelet responsiveness by heparin.

Purinergic receptor modulation of platelet function *in vitro* and *ex vivo*

Momi S[1], Amison R[2], Momi S[1], Gresele P[1], Page CP[2] and Simon PC[2]

[1]University of Perugia, Perugia, Italy; [2]King's College London, London, UK

Background: Platelets express $P2Y_1$ and $P2Y_{12}$ receptors which are involved in ADP-induced activation under both aggregatory and inflammatory conditions. Whilst the relative role of $P2Y_1$ and $P2Y_{12}$ receptors has been extensively documented for platelet aggregation and thrombus formation, their role in inflammatory conditions is less understood.

Aims: Aim of the present study was to assess the role of P2Y receptors in platelet-induced leukocyte chemotaxis, platelet leukocyte conjugation and platelet aggregation in an established mouse model of allergic asthma.

Methods: Studies were carried out in an established model of allergic asthma in mice. Balb/c mice were immunised with ovalbumin (OVA, 30 μg/mouse) on day 1, 5 and 11. On days 15 mice were pre-treated with MRS2500, (3 mg/kg i.v.), AR-C66096 (3 mg/kg i.v.) or Clopidogrel (75 mg/kg) and challenged with 3% nebulised OVA for 30 min. Using flow cytometry and the platelet and leukocyte antibodies CD41 and CD45, platelet-leukocyte aggregation were quantified 6 h post allergen challenge. Platelet aggregation induced by 2–10 μM ADP was also measured at 6 h. For *in vitro* chemotaxis studies, platelets were isolated from OVA sensitised Balb/c mice and pre-treated with either MRS2500 or AR-C66096 (0, 1, 10, 100, 1000 nM). Platelets were then stimulated with 100 nM ADP and mixed with PMNs isolated from Balb/c mice. Using chemotaxis plates (3 μM pores), leukocyte migration towards 100 nM MDC was quantified after 90 min incubation.

Results: Circulating platelet-leukocyte aggregates, expressed as mean fluorescence intensity (MFI) of the platelet antigen CD41/CD61 on the leukocyte surface, were significantly elevated 6 h post allergen challenge compared to sham controls (1.8 ± 0.4% vs. 0.9 ± 0.15%, $P < 0.01$). Circulating platelet-leukocyte conjugates remained significantly elevated in animals pre-treated with AR-C66096 compared to sham controls (1.85 ± 0.3%, $P < 0.05$) but not in animals pre-treated with MRS2500 (1.3 ± 0.2%).

MDC enhanced platelet-induced PMN chemotaxis compared to vehicle (PMN + platelets: chemotaxis index (CI) = 1.00 ± 014; PMN + platelets + MDC: CI = 2.69 ± 0.13). Pre-incubation of platelets with the $P2Y_1$ antagonist MRS2500 inhibited MDC-induced PMN chemotaxis in a concentration dependent manner (1 nM: 2.99 ± 0.23, 10 nM: 2.54 ± 0.16, 100 nM: 2.03 ± 0.21 $P < 0.05$, 1000 nM: 1.68 ± 0.14 $P < 0.001$). In contrast, incubation with ARC60996 did not affect MDC-induced PMN chemotaxis (1000 nM [top dose]: 2.42 ± 0.14).

ADP (2–10 μM) induced platelet aggregation (52.50 ± 7.50%) was signficantly suppressed (by 75%, $P < 0.05$) in mice treated with Clopidogrel (75 mg/kg) and it was reduced by 40% in AR-C66096 (3 mg/kg) pretreated animals ($P < 0.05$). On the contrary, in mice administered MRS2500 (3 mg/kg) ADP-induced platelet aggregation was not inhibited (−12%, P = NS).

Conclusions: Our data show that the $P2Y-_1$ but not the $P2Y_{12}$ receptor plays an important role in the inflammatory function of platelets in allergic asthma in mice (platelet-leukocyte conjugation and platelet-leukocyte chemotaxis), whilst in contrast in $P2Y_{12}$ receptor plays a major role in ADP-induced platelet aggregation.

Microtubule plus-end tracking protein CLASP2 KO mice phenocopy CAMT: a role for CLASP2 in hematopoiesis and hematopoietic stem cell maintenance

Gutierrez L[1], Drabek D[2], Robin C[2], Galjart N[2], Vermeij M[2], Clapes T[2], Patel SR[2], Boisset J-C[3], Van Haren J[3], Pereira AL[2], Liu Z[2], Akinci U[2], Nikolic T[2], Van Ijcken W[3], Van Den Hout M[3], Meinders M[2], Melo C[2], Sambade C[2], Drabek K[3], Hendriks RW[2], Philipsen S[2], Mommaas M[2], Grosveld F[2], Maiato H[2], Italiano JE[4], Robin C[3] and Galjart N[3]

[1]Sanquin Research and Landsteiner Laboratory, Amsterdam, The Netherlands; [3]Erasmus MC, Rotterdam, The Netherlands; [4]Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA

Background: Haematopoietic cell lineage commitment is determined by signalling mechanisms that require ligands of various origins, as well as the appropriate expression and functioning of the cognate receptors. Receptor activation leads to intracellular signalling cues that trigger different processes, e.g. cell division, attachment, or migration. Mammalian CLASPs (CLASP1 and CLASP2) are microtubule plus-end tracking proteins whose essential function as regulators of microtubule behaviour has been studied mainly in cultured cells. However, the role of these proteins in haematopoiesis is not yet explored.

Aims and Methods: We generated Clasp2 KO mice to analyze its role in haematopoiesis. We used cell culture assays, flow cytometry, immunohistochemistry, confocal microscope imaging, RNAseq, transplant experiments.

Results: We show here that absence of murine CLASP2 *in vivo* results in thrombocytopenia, progressive anaemia, and pancytopenia, due to defects in megakaryopoiesis, in erythropoiesis, and in the maintenance of haematopoietic stem cell activity, similarly to what occurs in Congenital Amegakaryocytic Thrombocytopenia patients (CAMT). Interestingly, CLASP2-deficient haematopoietic cells show accumulation of intracellular cMpl and cKit receptors (personal observation). Furthermore, microtubule stability and organization are affected upon attachment of Clasp2 knockout haematopoietic stem-cell-enriched populations, and these cells do not home efficiently toward their bone marrow niche. Strikingly, CLASP2-deficient haematopoietic stem cells contain severely reduced mRNA levels of c-Mpl, which encodes the thrombopoietin receptor, an essential factor for megakaryopoiesis and haematopoietic stem cell maintenance.

Summary/Conclusion: CLASP2 is a microtubule-stabilizing protein and Clasp2 knockout mice display progressive pancytopenia which phenocopies the human syndrome congenital amegakaryocytic thrombocytopenia (CAMT). Our data suggest that thrombopoietin signal-

ling is impaired in Clasp2 knockout mice. We propose that the CLASP2-mediated stabilization of microtubules is required for proper attachment, homing, and maintenance of haematopoietic stem cells and that this is necessary to sustain c-Mpl transcription. Furthermore, we hypothesize that CLASP2-mediated microtubule stabilization is necessary for the trafficking of cMpl and cKit receptors in haematopoietic cells.

The epigenetic landscape of platelet and red blood cell traits

Paul D[1], Albers CA[2], Rendon A[2], Voss K[2], Stephens J[2], Van Der Harst P[3], Chambers JC[4], Soranzo N[1], Ouwehand WH[2] and Deloukas P[1]

[1]Wellcome Trust Sanger Institute; [2]University of Cambridge, Cambridge, UK; [3]University of Groningen, Groningen, The Netherlands; [4]Imperial College London, London, UK

Platelet count and volume are independent risk factors for heart attacks and ischaemic stroke. We used meta-analysis of genome-wide association (GWA) studies to identify genes encoding novel regulators of megakaryopoiesis and platelet formation. Over three-quarters of the 68 genetic signals associated with platelet count and volume are located at non-protein coding regions (Nature 2011; 480, 201). We postulated that the common variants at many of the discovered platelet quantitative trait loci (QTLs) exert their effects through cell type-dependent transcriptional regulation. To investigate this, we integrated GWA data of 75 genetic signals associated with red blood cell indices (Nature 2012; 492, 369).

We aimed to assess the role of candidate regulatory variants associated with platelet and red blood cell QTLs in the regulation of lineage-specific gene expression during blood stem cell differentiation.

We used formaldehyde-assisted isolation of regulatory elements followed by next-generation sequencing (FAIRE-seq) to map regions of open chromatin genome-wide in blood stem cell-derived megakaryocytes and erythroblasts, the precursors of platelets and red blood cells, respectively, as well as in peripheral blood monocytes. We applied these epigenomic data sets to define cell type-dependent enrichment patterns of GWA signals associated with platelet and red blood cell QTLs at regions of open chromatin.

In megakaryocytes and erythroblasts, we found that open chromatin patterns reflect the corresponding hematopoietic lineages of the studied cell types, and associate with the cell type-specific gene expression patterns. Open chromatin regions coinciding with platelet trait-associated SNPs were more likely to be restricted to megakaryocytes than expected by chance. We observed the same cell type-dependent effect for red blood cell trait-associated SNPs at erythroblast-restricted open chromatin sites. The majority (63.6%) of candidate regulatory variants at platelet QTLs overlapped with binding sites of transcription factors key to regulating megakaryopoiesis, namely FLI1, GATA1, GATA2, RUNX1 and TAL1 (also known as SCL). We experimentally tested 13 candidate regulatory variants at 10 platelet QTLs in gel shift assays (MLSTD1, PTGES3-BAZ2A, RAD51L1, DNM3, LRRC16, PDIA5, ABCC4, CTSZ-TUBB1, KALRN and SATB1). We found all but 3 candidate SNPs affected nuclear protein binding, suggesting this to be a frequent mechanism by which regulatory variants influence the formation of platelets from megakaryocytes.

GWA studies have placed a plethora of genetic markers at genes encoding novel regulators of platelet and red blood cell formation. Here, we show that epigenetic annotation of precursor cell genomes combined with GWA results aids the identification of candidate regulatory variants, which may exert their effect through disruption or introduction of nuclear protein binding sites. We have recently shown that differential binding of transcription factors at the PIK3CG (PLOS Genetics 2011; 7, e1002139) and DNM3 (Blood 2012; 120, 4859) platelet QTLs affects expression levels of genes critical in megakaryopoiesis and platelet formation.

PA 2.04-3

Biogenesis of the demarcation membrane system in megakaryocytes

Eckly A[1], Heijnen HF[1], Pertuy F[1], Proamer F[1], Rinckel J-Y[1], Lanza F[2] and Gachet C[1]

[1]UMR_S949 INSERM, Université de Strasbourg, Etablissement Français du Sang; [2]UMR_S949 INSERM, Université de Strasbourg, EFS-Alsac, Strasbourg, France

Background: The demarcation membrane system (DMS) in megakaryocytes (MKs) forms the plasma membrane of future platelets. One MK is supposed to produce an average of 4000 platelets and during its maturation the DMS increases its total surface about 26-time. The exact origin of this unique membrane system and the molecular mechanisms driving its explosive growth are unknown. A current view is that the DMS develops from the invagination of the MK plasma membrane (PM).

Aims: Considering the importance of the DMS as the major membrane supply for platelet production, the aim of this study was to investigate the biogenesis of the DMS.

Methods: Using confocal microscopy, dual axis electron tomography, and large volume FIB-SEM analysis, we have determined the sequential developmental steps of DMS formation, both *in situ* in mouse bone marrow MKs, and *in vitro* in cultured MKs generated from progenitors. Early DMS phenotypes have been identified using the platelet lineage specific markers glycoprotein GPIb, known to be expressed at the early stages of MK maturation.

Results: We have identified a pre-DMS precursor form which initiates at the cell periphery through invagination of GPIb-positive membranes, and which gradually develops towards a well-defined perinuclear oriented membrane complex. Confocal microscopy and electron tomography analysis revealed that at all developmental stages the DMS is continuous with the cell surface, suggesting that its origin is determined through invagination of the plasma membrane (PM). Remarkably, the precise location of the pre-DMS is between the nuclear lobes, and the number of PM invaginations coincides well with MK ploidy, suggesting a relation with cleavage furrow formation. Upon DMS expansion Golgi complexes assemble around the pre-DMS and fusion profiles of TGN-derived vesicles with the DMS are observed. Treatment with Brefeldin A, an inhibitor of anterograde membrane transport, reduced the expansion of the DMS, indicating that the exocytic pathway is an essential determinant for DMS biogenesis. In addition, close contacts (< 30 nm) between endoplasmic reticulum (ER) and DMS are frequently detected suggesting a physical interaction between the two membranes. These ER-DMS contact sites were free of ribosomes and contained filamentous electron-dense material reflecting cross-linking/anchoring molecules. FIB-SEM analysis of late stages reveals that the DMS forms a highly intertwined tubular membrane network with numerous connections with the cell surface, resembling the future open canalicular system of platelets.

Conclusion: We propose the following model for the biogenesis of the DMS: (i) DMS formation starts at focal locations at the cell surface, and (ii) is followed by an invagination process that resembles cleavage furrow formation; (iii) formation of the pre-DMS and further expansion require vesicular membrane delivery from multiple targeted Golgi complexes to the DMS, and possibly direct lipid transfer through ER to DMS tethering.

Platelet bioreactor-on-a-chip

Thon JN[1], Mazutis L[2], Weitz D[2] and Italiano JE[1]
[1]*Brigham and Women's Hospital, Boston, MA;* [2]*Harvard University, Cambridge, MA, USA*

Background: Morbidity and mortality from bleeding due to low platelet count is a major clinical problem encountered across a number of conditions. Despite serious clinical concerns owing to their immunogenicity and associated risk of sepsis, and inventory shortages owing to their high demand and 5-day shelf life, platelet transfusions total more than 14 million units per year worldwide.
Aims: By modeling human physiology and mimicking nature's design principles *in vitro* we will identify components of the vascular bone marrow microenvironment that promote thrombocytopoiesis, and yield novel approaches to accelerate platelet production *in vivo*"circumventing transfusion-related complications. An alternative source of infusible platelets will obviate risks associated with platelet procurement and storage, and help meet growing transfusions needs.
Methods: We have developed a microfluidic platelet bioreactor that recapitulates key aspects of bone marrow physiology, including bone marrow rigidity, extracellular matrix composition, microchannel size, hemodynamic vascular shear, and endothelial cell contacts. Bone marrow biochips are based on custom-built PDMS devices bonded to glass slides, and comprise of an upper and lower microfluidic channel separated by a series of columns spaced 3 μm apart. Primary megakaryocytes infused along the top channel sequentially become trapped between the columns, and extend proplatelets into the lower channel.
Results: Physiological shear rates (500–2500/s) can be tightly regulated and were shown to increase both the rate and extent of proplatelet production. Median proplatelet extension rates under physiological flow velocities were roughly one order of magnitude higher than has been calculated for proplatelet-producing megakaryocytes under static conditions (36 μm/min vs. 0.85 μm/min) and correspond to recent estimates from *in vivo* multiphoton intravital microscopy studies of mouse bone marrow (Zhang et al. J Exp Med. 2012). Interestingly, increasing shear rate from 500 to 2500/s did not further accelerate proplatelet extension, and suggests that elongating microtubule bundles comprising the proplatelet shaft actively resist vascular shear forces to regulate proplatelet telescoping. To more accurately reproduce the bone marrow stiffness (approximately 1000 Pa), the uppermost channel was selectively filled with a low melting point agarose solution comprising primary megakaryocytes, and polymerized inside this space to trap megakaryocytes in a physiologically relevant three-dimensional environment. Extracellular matrix proteins native to the bone marrow vascular niche were included in the low melting point agarose solution individually and in combination to recapitulate the bone marrow vascular niche. The lowermost channel was selectively coated with extracellular matrix proteins and seeded with human endothelial cells to generate a sinusoidal blood vessel adjacent the megakaryocyte microenvironment. Proplatelet production was visualized by high resolution live-cell microscopy. Platelets released into the lower channel by megakaryocytes enter the fluid stream. Bioreactor-derived platelets were collected from the effluent, and are structurally equivalent to human blood platelets.
Summary: Platelet bioreactor-on-a-chip devices recapitulate the bone marrow vascular microenvironment to increase/accelerate proplatelet production *ex vivo* and support physiological platelet release.

Sp1/Sp3 transcription factors are essential for megakaryopoiesis

Kulu I[1], Meinders M[2], Suske G[3], Gutierrez L[2] and Philipsen S[1]
[1]*Erasmus Medical Center, Rotterdam;* [2]*Sanquin Research, Amsterdam, The Netherlands;* [3]*Institute for Molecular Tumor Research, Marburg, Germany*

Specificity proteins (Sp) are closely related family of zinc finger transcription factors that are important components of the eukaryotic cellular transcription machinery. They have been implicated in the regulation of many physiological processes including cell cycle, growth control, apoptosis, hormonal activation and angiogenesis.
Sp1 and Sp3 are ubiquitously expressed and can either activate or repress the expression of a variety of genes by interacting with the GC- and GT-boxes of the DNA with similar specificity and affinity. They play a critical role during embryogenesis as *Sp1* knockout embryos die around embryonic day 10.5. Sp3 deficient embryos are postnatal lethal. *Sp1ko/wt::Sp3ko/wt* compound heterozygous embryos display a multitude of developmental abnormalities resulting in late prenatal mortality. Thus, functional redundancy exists between the Sp factors. To investigate their functions beyond embryogenesis we generated mice with conditional *Sp1* and *Sp3* knockout alleles. Using a pan-hematopoietic Cre line (Mx1-Cre), we conditionally deleted the *Sp1* and *Sp3* genes from the entire hematopoietic system. The results revealed the importance of these genes in hematopoiesis particularly in megakaryopoiesis.
Pf4-Cre mediated deletion of *Sp1* and *Sp3* (dKO) confirmed the importance of these genes in megakaryopoiesis. These mice exhibited a significant reduction in platelet counts but normal TPO levels in plasma and an increase in platelet volume. The dKO platelets responded normally when stimulated with PMA (fibrinogen receptor) but showed a decreased response to aggretin A (Clec-2), collagen (integrin β1 and GPVI) and did not respond to Botrocetin (vWF receptor or GPIb complex). These platelets were also functionally impeded as they displayed a decreased adhesion to collagen type1. Flow cytometry analysis of the four vWF receptors revealed very low expression levels of GP1bα in the dKO platelets.
Our results suggest that these mice are a phenocopy of patients with Bernard-Soulier syndrome (BSS), a coagulopathy caused by a defect of the vWF receptor due to mutation in either the GP1b or GPIX subunits leading to macrothrombocytopenia characterized by prolonged bleeding time and the absence of Botrocetin/Ristocetin induced platelet agglutination. Our data also suggested that GP1bα is a target for Sp1/Sp3 in megakaryoctes.
We are currently analyzing RNA sequencing data and will perform ChIP sequencing to unravel functional genomic targets of Sp1/Sp3 in megakoryocytes.

PA 2.04-6
Microtubule plus-end tracking APC negatively regulates proplatelet formation

Strassel C[1], Bull A[1], Leguay C[1], Eckly A[1], Freund M[1], Williams B[2], Gachet C[1] and Lanza F[1]
[1]*UMR_S949, Inserm, Université de Strasbourg, EFS-Alsace, Strasbourg, France;* [2]*Laboratory of Cell Signaling and Carcinogenesis, Van Andel Research Institute, Grand Rapids, MI, USA*

Background: Platelets are produced from mature megakaryocytes following profound cellular reorganization leading to proplatelet elongation, a highly dynamic process mainly driven by microtubules (MT). Despite some progress, the mechanisms regulating MT dynamics and reorganization remain poorly defined. Adenopolyposis Coli (APC) is a microtubule plus-end tracking protein (+TIPS) involved in the regulation of MT in a number of cell systems (Akhmanova and Steinmetz,

2010) and its inactivation has been reported to alter hematopoiesis (Qian et al., 2008).
Aim: The aim of our study was to investigate a role for APC in megakaryopoiesis.
Methods: We used a loss of function approach using shRNA and a knock-out murine model. Megakaryocytes (MKs) were obtained by culturing hematopoietic stem cells (Lin-) and APC was knocked down using two different APC shRNAs lentiviral constructs. Mice with APC-deficiency in the megakaryocytic lineage were obtained by crossing APCflx/flx (Qian et al., 2008) with Pf4-Cre mice.
Results: APC shRNA induced a 70% (shAPC1) and 54% (shAPC2) decrease in APC transcript levels, respectively, when compared to a control shRNA. Down-regulation of APC promoted endomitosis, as evidenced by a higher percentage of Mks > 8 N. In addition, an increased proportion of mature megakaryocytes was observed that were able to extend proplatelets (68.8% (shAPC1) and 52.5% (shAPC2) vs. 28.1% (control); $n = 3$). Loss of APC also exacerbated proplatelet branching. Similar results, in terms of ploidy and amplification of the proplatelet network were also observed when MKs were differentiated from Lin- cells from mice with megakaryocyte-restricted APC deficiency. In addition these mice exhibited increased platelet counts when compared to control mice (1200 ± 61 vs. 990 ± 36 platelets/μL; $n = 25$, $P = 0.0061$**) with a similar size, ultrastructure and number of microtubules coils. Platelet functions were also preserved. A ggregation in responses to several agonists and von Willebrand factor and fibrinogen-mediated platelet adhesions were normal.
Conclusion: Loss of APC leads to an amplification of proplatelet formation, indicating a negative role of this +TIP stabilizing factor in thrombopoieisis.

PA 2.05-1

The platelet response is inherited and dependent on the number of shared alleles

Korporaal SJA[1], Estourgie-van Burk F[2], Jones CI[3], Bartels M[2], Boomsma DI[2], Ouwehand WH[4], Goodall AH[3] and De Groot PG[1]
[1]University Medical Center Utrecht, Utrecht; [2]VU University, Amsterdam, The Netherlands; [3]University of Leicester, Leicester; [4]University of Cambridge, Cambridge, UK

Background: The platelet response to agonist stimulation shows a high degree of inter-individual variability. While this may be the result of external factors, the fact that the individual platelet response is reproducible over time, suggests that the platelet response must somehow also be genetically controlled.
Aim: Since a well-defined platelet phenotype is informative when assessing the risk of an individual to develop e.g. arterial thrombosis, the current study aimed to elucidate the relative contribution of inherited gene variation on platelet count and function.
Methods: Blood was collected from an unselected cohort of 18 year-old monozygotic ($n = 12$ pairs) and dizygotic twin pairs ($n = 19$ pairs). After measurement of the platelet count, the response of platelets to agonist stimulation was assessed in whole blood by flow cytometry by measuring fibrinogen binding and surface expression of P-selectin, each in response to two concentrations of adenosine 5'-diphosphate (ADP), or the glycoprotein (GP) VI-specific collagen peptide mimetic, cross-linked collagen-related peptide (CRP-XL). Major secondary signaling pathways were inhibited to guarantee ADP- and CRP-XL-pathway specificity. Data were recorded as percentage of cells positive for the activation markers. Agreement between the platelet counts or platelet responses of subjects of monozygotic or dizygotic twin pairs, or between non-related subjects (subject from one twin pair randomly paired with a subject from another twin pair) was quantified by the Pearson correlation coefficient with two-tailed P-value after logit transformation of the data to ensure Gaussian distribution of the data populations. The study was approved by the institutional review board of the VU University, Amsterdam. Written informed consent was obtained from all participants.
Results: Platelet counts were not significantly different between monozygotic and dizygotic twins compared to subjects from a singleton population. However, heritability of the platelet count was shown to correlate with the number of shared alleles: within monozygotic twins the correlation between twins was high ($r^2 = 0.73$, $P < 0.001$), whereas correlation was lower within dizygotic twins ($r^2 = 0.196$, $P = 0.066$) and completely absent in a random population of subjects ($r^2 = 0.01$, $P = 0.60$). Similarly, there was a high degree of correlation within the pairs of twins for both fibrinogen binding and surface expression of P-selectin after stimulation with ADP or CRP-XL. The level of correlation was highest within pairs of monozygotic twins and less profound in case of dizygotic twins. No correlation was found for the platelet response in the random population.
Summary/Conclusions: These observations suggest that the platelet response through $P2Y_1/P2Y_{12}$ or GPVI is under genetic control and dependent on the number of shared alleles.

PA 2.05-2

Genome-wide association study of aspirin and clopidogrel response in patients with percutaneous coronary intervention

Timur AA[1], Murugesan G[2], Barnard J[3], Gandhi S[4], Bhatt DL[4] and Kottke-Marchant K[2]
[1]Cleveland Clinic; [2]Robert J. Tomsich Pathology and Laboratory Medicine Institute, Cleveland Clinic; [3]Quantitative Health Sciences, Cleveland Clinic; [4]Heart and Vascular Center, MetroHealth Campus-Case Western Reserve University, Cleveland, OH, USA

Background: Inter-individual variability exists in response to antiplatelet therapy. A significant minority of patients show poor platelet inhibition, which has been associated with adverse clinical events.
Aims: To investigate possible genetic determinants of platelet reactivity in patients receiving antiplatelet therapy.
Methods: Patients who underwent percutaneous coronary intervention (PCI) and were on both aspirin and clopidogrel were enrolled in an Institutional Review Board approved Observational Study (ASCLOGEN). Platelet function was measured using light transmission aggregometry (LTA) with arachidonic acid (AA) and ADP, Verify*Now* with aspirin (ARU) and P2Y12 (PRU) cartridges, *ex vivo* TxB_2, urinary $11dhTxB_2$, and VASP (PRI) assays. A genome-wide association study (GWAS) was performed in 409 Caucasian patients using a cardiovascular gene-centric Illumina 50 K SNP array. TaqMan assay was also utilized for additional SNPs selected from P2RY1, P2RY12, and CD36 genes. SNPs were filtered for MAF, H-W equilibrium, and call rate. Subjects were filtered for excess heterozygosity, genetic relatedness, gender mismatch, call rate and genetic population outliers. Gene-based tests were conducted using a linear kernel machine approach. All Ensembl gene IDs containing at least three typed SNPs were tested (Ensembl 69; 2297 gene IDs) for the association with platelet function measures. Among the tested genes, we also selected a focused set based on literature review. Regression analyses were adjusted for gender, age at PCI procedure and genetic relatedness. For genome-wide associations, a P-value < 2.16E-6 and < 1E-4 was deemed significant for SNP- and gene-based tests, respectively, and P-value < 1E-2 for candidate gene test.
Results: Three SNPs from *CYP2C19* (rs2281891, rs1322179, and rs4244285) showed significant association with high PRI and a SNP from *NR5A2* (rs2821369) was associated with higher urinary $11dhTxB_2$ levels. Gene-based tests indicated a significant association between *P2RY12* and PRI, and also *NLRP1* and $11dhTxB_2$. Candidate-gene approach revealed association of *CYP2C19* with clopidogrel-related assay measures including PRU, LTA-ADP, and PRI. Other candidate genes that have shown association with platelet mea-

sures are: *PTGS2* (LTA-ADP), *HTR2B* (PRU), *ITPR1* (LTA-ADP), *PLAT* (LTA-AA) and *UGT1A6-A10* (11dhTxB_2).
Conclusion: This GWAS revealed an association between *CYP2C19* and clopidogrel response. Other genes identified in this study require further evaluation to establish their relationship with platelet reactivity.

PA 2.05-3
Systematic characterization of human platelets by quantitative proteomics

Burkhart JM[1], Vaudel M[1], Becker K[1], Gambaryan S[2], Walter U[3], Martens L[4], Geiger J[2], Sickmann A[1] and Zahedi R[1]
[1]Leibniz Institut für Analytische Wissenschaften – ISAS – e.V., Dortmund; [2]Universität Würzburg, Würzburg; [3]Center for Thrombosis and Haemostasis (CTH), Mainz, Germany; [4]Vlaams Instituut voor Biotechnologie (VIB), Ghent, Belgium

Anti-platelet treatment is of fundamental importance in combatting functions/dysfunction of platelets in the pathogenesis of cardiovascular and inflammatory diseases. Dysfunction of anucleate platelets is likely to be completely attributable to alterations in protein expression patterns and post-translational modifications. Combining elaborate protocols for platelet isolation from fresh blood donations in conjunction with quantitative mass spectrometry, we created the first comprehensive and quantitative proteome of highly pure human platelets, comprising almost 4000 unique proteins with copy number estimates for approximately 3700 of those and relatively quantified approximately 1900 proteins between four different healthy donors – with negligible contamination by leukocytes, erythrocytes and plasma, respectively. For the first time, our data allow for a systematic and weighted appraisal of protein networks and pathways in human platelets, and indicate the feasibility of differential and comprehensive proteome analysis from small blood donations. Since 85% of the platelet proteome show no variation between healthy donors, this study represents the starting point for disease-driven platelet proteomics. These findings allow for correlation to genome-wide association studies which identified in a retrospective manner a set of chromosomal regions affecting the risk of cardiovascular diseases. While respective gene products could be identified in platelets, a comprehensive and quantitative comparison of protein patterns between patients and relevant controls such as relatives and spouses to validate risk factors is still missing. In order to improve cardiovascular risk management, genomic and proteomic analyses of respective corresponding gene loci and proteins using next generation sequencing and targeted MS strategies are applied with the final goal to characterize valuable biomarkers for biomedical screenings.

PA 2.05-4
Association between the microarray-based CYP2C19 genotyping assay and the platelet function test in cardiovascular patients receiving clopidogrel

Choi JL, Kim BR, Kim JE, Woo KS, Kim KH, Kim JM, Kim MH and Han J-Y
Dong-A University College of Medicine, Busan, Korea

Background: Clopidogrel is a widely used antiplatelet agent that irreversibly inhibits platelet P2Y12 ADP receptors after transformation into an active metabolite by cytochrome P450 (CYP) in the liver. Especially, CYP2C19 polymorphism has been reported to be associated with altered antiplatelet activity of clopidogrel, and this polymorphism reveals considerable inter-ethnic variation.
Aims: In this study, we would perform the CYP2C19 genotyping in Korean cardiovascular patients receiving clopidogrel to assess the frequency of polymorphism and analyze the association with the efficacy of treatment. And we would investigate the applicability of CYP2C19 genotyping to decide the direction of treatment as well as the prediction of the efficacy of treatment.
Methods: Polymorphisms of CYP2C19*2, *3, *17 and the degree of inhibition of platelet function were determined in 155 patients who were being treated with clopidogrel following cardiovascular interventions. CYP2C19 genotyping was performed by the Verigene® system CLO+ test (Nanosphere, USA) for the first time in Korea, and the results were categorized as ultra-rapid metabolizer (UM, including *17/*17 and *1/*17), extensive metabolizer (EM, including *1/*1), intermediate metabolizer (IM, including *1/*2 and *1/*3), and poor metabolizer (PM, including *2/*2, *3/*3, and *2/*3). The degree of platelet inhibition was assessed by the VerifyNow P2Y12 system (Accumetrics, USA), and the pre-procedure/post-procedure PRU and percent inhibition were measured to check the association with genotype. This study was approved by the Institutional Review Board of Dong-A University Hospital. Informed consent was obtained.
Results: Four of 155 patients were UM (2.6%), 56 EM (36.1%), 69 IM (44.5%), and 26 PM (16.8%). The pre-procedure/post-procedure PRU values of EM patients (268.0 ± 81.0/222.2 ± 91.3) were lower than those of IM and PM patients (294.8 ± 90.5/246.8 ± 105.7 and 336.2 ± 79.9/259.5 ± 96.0, respectively; $P = 0.001/0.168$). The pre-procedure/post-procedure percent inhibition values of EM patients (20.5 ± 23.1/31.1 ± 27.1) were higher than those of IM and PM patients (10.5 ± 16.4/21.9 ± 23.6 and 7.7 ± 18.2/12.7 ± 16.2, respectively; $P \leq 0.001/0.004$).
Conclusion: About 60% of Korean patients with cardiovascular diseases receiving clopidogrel have CYP2C19 loss-of-function genotypes classified as IM or PM, and the frequency is similar with the reported data of Asian. And these genotypes are significantly associated with reduced antiplatelet activity of clopidogrel. There are no consented cutoff values of the platelet function test, the prediction of therapeutic efficacy and the decision of therapeutic direction based on the genotyping could be useful. And the Verigene® system used in this study is fast and simple, so genotyping with this instrument would improve the clinical usefulness of genotyping.

PA 2.05-5
Genes in arterial thrombus formation: a comparison of *in vivo* and *in vitro* studies

De Witt SM[1], Nergiz-Ünal R[1], Feijge MAH[1], Wiese A[1], Jupe S[2], Prins MH[1], Cosemans JMEM[1] and Heemskerk JWM[1]
[1]Maastricht University, Maastricht, The Netherlands; [2]University of Cambridge, Cambridge, UK

Background: Arterial thrombus formation relies on activation of blood platelets and the coagulation system. Although antiplatelet and anticoagulant agents are successful in the prevention of cardiovascular diseases, they are directed against one of only few molecular targets. On the other hand, *in vivo* studies of arterial thrombosis using genetically modified mice show that multiple platelet- and plasma-derived proteins contribute to thrombus formation. In many of these studies also flow chamber technology for screening of thrombus formation at arterial shear rates *in vitro* is included. Systematic comparisons of the *in vivo* and *in vitro* measurements have not been made up to now.
Aims: (i) Systematic comparative within-study analysis of effects of genetic modification on arterial thrombus formation *in vivo* and whole-blood thrombus formation in parallel-plate flow devices *in vitro*. (ii) Use bioinformatics technology to construct networks of genes of human signaling proteins implicated in arterial thrombus formation to identify novel candidate genes.
Methods: An extensive search in PUBMED was performed, including original studies where effects are reported of genetic modification on murine thrombus formation both *in vivo* and *in vitro* from 1993 to 2013. Reviews were excluded. Information was categorized with respect to the type of genetic modification, the vascular bed, the

thrombosis model, dose and duration of vascular injury and pulmonary thromboembolism *in vivo*; the thrombogenic surface, flow protocol and flow device *in vitro*. Three different scoring scales were employed to quantify antithrombotic or pro-thrombotic effects of mass-, time- or stability-dependent parameters of thrombus formation indicating thrombus size, thrombus build-up in time and degree of embolization respectively. Statistical analysis was performed using the program SPSS version 19. The Reactome database was used to construct extended networks of human proteins corresponding to the analyzed mouse genes.

Results: Information was obtained of > 200 mouse genes with a positive or negative role in arterial thrombus formation. These included genes encoding for platelet proteins (68%), for transcription factors expressed in megakaryocytes (3%), for plasma coagulation and other plasma factors (20%) and for endothelial-expressed proteins (5%). The majority of genes contributed positively to thrombus formation *in vivo* (75%) and *in vitro* (71%).

Time and mass-dependent parameters, reflecting thrombus build-up in time and thrombus size respectively, correlated for all thrombosis models and vascular beds ($P < 0.01$). Thrombus size also correlated with the degree of death of mice due to pulmonary thromboembolism ($P < 0.01$). Mass-dependent parameters *in vitro* correlated with mass-dependent parameters *in vivo* ($P < 0.01$). Over-representation analysis and construction of extended protein networks using Reactome indicated a potential role of multiple novel genes in less well studied intracellular signaling pathways.

Conclusions: This logistic analysis indicates that: (i) The overall set of measurements *in vivo* of thrombus buildup (in time) and thrombus size (mass) produces a coherent database, in spite of the differences in experimental models and conditions used in individual laboratories. (ii) Mass parameters of thrombus formation *in vitro* are predictive for those *in vivo*. (iii) Combined information on mouse genes involved in thrombus formation can be used to obtain logical networks of human proteins, potentially involved in cardiovascular diseases.

PA 2.05-6

A new aIIb platelet antigen p.M841 (HPA-27bw) involved in materno-fetal alloimmunization and HPA-27bw genotyping by PCR-HRM (high resolution melting) technique

Jallu V[1], Bertrand G[1], Le Toriellec E[1], Bianchi F[1], Chenet C[1], Poulain P[2] and Kaplan C[1]

[1]INTS; [2]Inserm U665 – INTS, Paris, France

Fetal/Neonatal Alloimmune Thrombocytopenia (FNAIT) diagnosis relies on materno-fetal incompatibility and alloantibody identification. In unsolved FNAIT, genotyping for rare platelet polymorphisms allowed the identification of three families with materno-fetal incompatibility for the αIIb-c.2614C>A mutation (Halle et al, Transfusion 2008). This mutation leads to the L841M substitution. In one case, the alloimmunization was confirmed by detecting an antibody to the M841 form of αIIb.

The mutation was originally detected in 2001 as it introduced an unexpected restriction profile by using the Fok-I enzyme in a PCR-Restriction Length Polymorphism genotyping technique. To quickly explore unsolved FNAIT, a PCR- sequence specific primer amplification (SSP) assay was designed to genotype the αIIb-c.2614C>A mutation. Seven hundred and fifty-two DNA samples collected over 10 years were genotyped and four parents presenting the αIIb-c.2614A allele were detected. Nonetheless the materno-fetal incompatibility was suspected or confirmed in only three cases. The classic Monoclonal Antibody Specific-Immobilization of Platelet antigen Assay (MAIPA) initially used in diagnosis failed to detected alloantibodies to the αIIb-M841 antigen in maternal sera. Thus HEK-293 cells expressing αIIb-leu841 or αIIb-Met841 αIIbβ3 forms were used to probe the reactivity of maternal sera. Tested by flow cytometry, one serum specifically reacted with αIIb-M841 but not with αIIb-L841 αIIbβ3. This specificity revealed the αIIb-L841 polymorphism as a new alloantigen named HPA-27bw in the international nomenclature. New blood samples from the concerned family obtained in the context of a new pregnancy, allowed detecting the alloantibody using heterozygous platelets in flow cytometry. The anti-HPA-27bw alloantibody remains undetectable using either transfected HEK-293 cells or platelets in MAIPA. As observed for HPA-3a (or -3b) and HPA"-9bw alloantibodies, anti-HPA-27bw alloantibodies appeared difficult to detect and required whole platelet assays when classical MAIPA failed. Co-localization of the HPA-27bw, HPA-3a (or -3b) and HPA"-9bw antigens on the same very flexible αIIb loop (amino acids 827–855) may explain the difficulty to detect antibodies upon platelet solubilization. Similarly to alloimmunizations in HPA-3 and -9 systems, the immune response to the HPA-27bw antigen might induce severe thrombocytopenias and life-threatening hemorrhages. The p.L841M substitution has limited effects, if any, on expression and functions of αIIbβ3 in transfected HEK-293 cells. MD simulations done with 3D structural models of the αIIb peptide 827–855 correlated these last results as the L841M substitution had any effect on the model structures.

The HPA-27bw variant, apparently rare in Caucasian, reaches an allelic frequency up to 8.2% in Sub-Saharan African populations, where homozygous people are observed (Halle et al, transfusion 2008).

This case of alloimmunization underlies the necessity to perform genotyping of rare variants in unsolved FNAIT. Furthermore, it also highlights that other serologic techniques must be used to complete FNAIT diagnosis when MAIPA failed. We have developed a PCR-High Resolution Melting (HRM) for quick simultaneous genotyping of the HPA-3, -9 and -27bw variants to provide a technique complementary to the PCR-SSP in population studies. Furthermore PCR-HRM may help to detect new variants. Future studies will concern the HPA-27a allele immunogenicity to further characterize this particular immune response.

Treatment for life for severe haemophilia A. A cost-utility model for prophylaxis vs. on-demand treatment

Farrugia A[1], Bansal M[1], Cassar J[2], Kimber MC[1], Auserswald G[3], Fischer K[4], O'Mahony B[5], Noone D[5] and Tolley K[6]

[1]Plasma Protein Therpeutics Association, Annapolis, MD, USA; [2]Almar Therapeutics, Canberra, ACT, Australia; [3]Prof.- Hess Kinderklink, Klinikum Bremen-Mitte, Bremen, Germany; [4]Van Creveldkliniek, University Medical Center Utrecht, Utrecht, The Netherlands; [5]Irish Haemophilia Society, Dublin, Ireland; [6]Tolley Health Economics, Derbyshire, UK

Introduction: Prophylaxis has been established as the treatment of choice in children with haemophilia and its continuation into the adult years has been shown to decrease morbidity throughout life. The cost of factor therapy has made the option questionable in cost-effectiveness studies.

Aim: The role of prophylaxis in pharmacokinetic dosage and tolerisation against inhibitor formation were used to model the cost-utility of prophylaxis vs. on-demand (OD) therapy over a lifetime horizon in severe haemophilia A.

Methods: Commercial software (TreeAge[TRADEMARK]) was used to construct a Markov model with 80 cycles of 1 year each. The model was populated with variables for costs and effectiveness for haemophilia outcomes including joint and soft tissue bleeds, inhibitors and dosage. Key inputs into the model which differed from previous exercises included the use of pharmacokinetic dosage and effect of prophylaxis on the probability of developing inhibitors. The model was applied to a single provider national health system exemplified by the

United Kingdom's National Health Service and a third party provider in the United States. The incremental cost effectiveness ratio was (ICER) was estimated and compared to threshold values used by payer agencies to guide reimbursement decisions. A cost per quality adjusted life year (QALY) was also estimated for Sweden.

Results: Applying a bidiurnal dosage regimen and using the early tolerisation protocol of Kurnik et al (Haemophilia. 2010;16(2):256–62), prophylaxis was shown to be more effective and less costly (dominant) relative to OD treatment in the UK. In the USA, the model resulted in an ICER – $68,000, which is within the range of treatments reimbursed by third party payers in that country. In Sweden, a cost/QALY of SEK 1.1 million was also within the range of reimbursed treatments in that country, and prophylaxis was dominant over OD treatment when daily dosage was applied. Sensitivity analysis showed that dosage and treatment-induced inhibitor incidence were the most important variables in the model.

Conclusion: Subject to continuing clinical evidence of the effectiveness of pharmacokinetic dosage and the role of prophylaxis in decreasing inhibitor incidence, treatment for life with prophylaxis is a cost-effective therapy, using current criteria for the reimbursement of health care technologies in a number of countries.

PA 2.06-2

Severe haemophilia a: different regimens for starting prophylaxis (in PedNet)

Nijdam A[1], Petrini P[2], Carcao M[3], Kurnik K[4], Auerswald G[5], Nolan B[6], Ljung R[7], Molinari A[8], Makipernaa A[9] and Fischer K[10]

[1]University Medical Center Utrecht, Utrecht, The Netherlands; [2]Karolinska University Hospital, Stockholm, Sweden; [3]Hospital for Sick Children, Toronto, ON, Canada; [4]University of Munich, Munich; [5]Klinikum Bremen-Mitte, Bremen, Germany; [6]Our Lady's Children's Hospital, Crumlin, Dublin, Ireland; [7]Lund University, Malmö, Sweden; [8]Giannina Gaslini Children's Hospital, Genoa, Italy; [9]Hospital for Children and Adolescents, University of Helsinki, Helsinki, Finland; [10]Van Creveldkliniek, University Medical Center, Utrecht, The Netherlands

Background: The practice of prophylaxis in children with severe haemophilia A (FVIII < 1%) is changing. Prophylaxis is started at a younger age and at lower frequencies and doses. Different step up regimens are used for patients starting at low frequencies. The general objective is to eventually progress to full prophylaxis (3–3.5×/week) for optimum protection against bleeding.

Aims: To describe regimens of starting prophylaxis and compare their effects on bleeding and use of central venous access devices (CVADs).

Methods: Data for this project were extracted from the 'European Paediatric Network for Haemophilia Management' (PedNet) registry. Patients with severe haemophilia A, born January 2000–January 2010, who started prophylaxis before inhibitor development were included. Detailed data on treatment and bleeding were collected until May 2012 or up to 7 years of age. Data were censored at inhibitor development or loss to follow up. Different regimens of starting prophylaxis were compared. Cumulative incidences and age at start of full prophylaxis (≥ 3× per week) were calculated using Kaplan Meier survival analysis.

Results: 319/425 patients with severe haemophilia A started prophylaxis before the age of 7 years. Median follow up was 2.6 years (range: 0.1–7.0). Three regimens for starting prophylaxis were identified: 138 (43%) patients started 1×/week, 97 (30%) 2×/week and 84 (26%) ≥ 3×/week. Patients started prophylaxis around a median age of 1.4 years and median one joint bleed (range 0–15) for all regimens. Significantly less CVADs were used when starting with lower frequencies: 18% for 1×/week, 36% for 2×/week and 41% for full prophylaxis (*P*-value < 0.01).

Almost all (90%) patients who started prophylaxis 1×/week first progressed to 2×/week before progressing to full prophylaxis. Patients in both regimens reached full prophylaxis around the same age: 5.4 and 5.1 years respectively. Median dose used was 500 IU/infusion for all regimens.

At the end of follow up, 4% of patients infused 1×/week and 24% 2×/week without having progressed to full prophylaxis. Compared to those who started with full prophylaxis (after a median of one joint bleed, 41% without joint bleeds), patients who started with less frequent infusions had suffered more bleeding at reaching full prophylaxis: for 1×/week this was after median four joint bleeds (16% no joint bleeding) and for 2×/week after median three joint bleeds (20% no bleeding, *P*-value < 0.01).

Summary/Conclusion: Overall, prophylaxis was started at a median of 1.4 years of age after one joint bleed. Starting prophylaxis with less frequent infusions but progressing to full prophylaxis in 3.9 years was associated with limited additional joint bleeding, and a lower use of CVADs. More research on the effects of step up regimens on life-threatening bleeds, and long term outcome is needed.

PA 2.06-3

Population pharmacokinetic analysis of long-lasting recombinant factor VIII Fc fusion protein (rFVIIIFc) in patients with severe haemophilia A

Neelakantan S[1], Li S[1], Powell J[2], Josephson N[3], Pasi J[4], Perry D[5], Shapiro AD[6], Ragni M[7], Kulkarni R[8], Fogarty P[9], Brennan A[1], Pierce G[1], Jiang H[1] and Nestorov I[1]

[1]Biogen Idec, Weston, MA; [2]University of California at Davis, Davis, CA; [3]Puget Sound Blood Center, Seattle, WA, USA; [4]Barts and the London School of Medicine and Dentistry, London; [5]Addenbrookes Hospital, Cambridge, UK; [6]Indiana Hemophilia and Thrombosis Center, Indianapolis, IN; [7]University of Pittsburgh and the Hemophilia Center of Western Pennsylvania, Pittsburgh, PA; [8]Breslin Cancer Center, East Lansing, MI; [9]Penn Hemophilia Program, Philadelphia, PA, USA

Introduction: In a recently completed Phase 3 clinical study (A-LONG), rFVIIIFc, a recombinant fusion protein composed of a single molecule of human B-domain-deleted recombinant coagulation factor VIII (BDD-rFVIII) attached to the Fc domain of human immunoglobulin G_1 (IgG_1), was well-tolerated and effective in the treatment of bleeding, routine prophylaxis, and perioperative management in patients with haemophilia A. The half-life of rFVIIIFc was prolonged, compared to a marketed recombinant FVIII product, octocog alfa (Advate).

Objectives: To characterize the activity-time profiles of rFVIIIFc in haemophilia A patients by population pharmacokinetic (PK) analysis and to identify intrinsic covariates that may affect the variability of rFVIIIFc PK parameters.

Methods: The modelling dataset included activity-time profiles of 180 subjects (15 from a Phase 1/2a study and 165 from a Phase 3 study [A-LONG], collected over ≤ 52 weeks of treatment). Subjects were 12–65 years old and weighed 41–132 kg. The analysis was done with NONMEM 7 software, and included model building, covariate search, and model qualification steps.

Results: A two-compartmental model adequately described the activity of rFVIIIFc. The population estimate for clearance (CL) was 1.65 dL/h; and for volume of distribution at steady state (Vss) was 44.4 dL. The inter-individual variability (IIV) of CL was moderate (24.3%) and central volume of distribution (V1) was low (13.4%). The inter-occasional variability (IOV) of both CL and V1 was low (20.6% and 12.0% respectively). The additive residual error was very low (0.208 IU/dL), as was the proportional residual error (13.6%), approximating the variability of the one-stage clotting assay for FVIII activity. Von Willebrand Factor (VWF) level was identified as the major covariate for CL; higher levels of VWF yielded lower clearance values, reflecting the protective role that VWF has on FVIII activity.

Body Weight (BW) and haematocrit (HCT) were identified as weak covariates on V1.

Conclusion: This is the first population PK analysis that systematically describes and characterizes the prolonged activity profile of long-lasting rFVIIIFc. The population PK model of rFVIII activity adequately describes the observed activity-time profiles. The clearance of rFVIIIFc activity is lower than the clearance observed for octocog alfa, resulting in longer duration of activity. The relatively low IIV underlines the consistency and homogeneity of the activity profiles. The low IOV indicates that rFVIIIFc maintains stable and predictable activity with long term administration over time. The set of covariates identified is physiologically relevant. Therefore, the population model developed can be used to simulate various dosing scenarios in support of dosing regimen selection and other decision making related to rFVIIIFc therapy. This approach represents an advance over the current approach, wherein the efficacy of a treatment regimen cannot be evaluated until after a patient has a bleeding episode.

PA 2.06-4

High-resolution peripheral quantitative computed tomography (HR-pQCT): a novel imaging technology detects microarchitectural skeletal pathology in hemophilia patients

Lee A, Boyd S, Kline G and Poon M-C

University of Calgary, Calgary, AB, Canada

Background: Osteoporosis is a pathologic bone disorder characterized by low bone mineral density (BMD) and microarchitectural bone disruption that can result in increased risk of fracture. Recent studies based on dual X-ray absorptiometry (DXA) showed a high prevalence of low BMD in persons with hemophilia (PWH). However BMD measured by DXA is limited by its inability to measure true volumetric BMD and to determining bone microarchitecture that is directly related to bone strength and resistance to fracture. HR-pQCT is a novel technology that provides 3D imaging of human bone microarchitecture by measuring BMD and characteristics of different bone compartments, and can predict resistance to fracture using finite element (FE) method.

Aim: To determine the microarchitectural differences in the bone of moderate and severe PWH compared to age and sex-matched controls using HR-pQCT. (Approved by University of Calgary Research Ethics Board)

Methods: Informed consent was obtained from severe and moderate adult hemophilia patients (males, ≥ 18 years-old, factor VIII or IX level ≤ 5%) recruited from the Southern Alberta Rare Blood and Bleeding Disorders Clinic, Calgary. BMD and bone measurements included DXA (reported as *T*-scores) and HR-pQCT imaging. HR-pQCT results were compared to age-and sex-matched normative data from a healthy patient cohort collected from a previous study (Canadian Multicentre Osteoporosis Study) conducted at our centre. Bone turnover markers (C-telopeptide CTX, N-telopeptide NTX) and bone formation markers (osteocalcin, P1NP) were measured.

Results: Sixteen hemophilia patients (A:B = 14:2, 87.5%(A); 12.5% (B), mean age: 34 years) were included in this pilot study. Vitamin D deficiency was present in 47% of patients. Bone turnover markers were elevated (mean: CTX 385.7 ng/L, NTX 83.3 nmol/mmol Cr) in 44%, and bone formation markers were decreased (mean: P1NP 66.2 μg/L, osteocalcin 4.2 μg/L) in 40%. Preliminary analysis of BMD measurements showed a mean *T*-score of −1.0 (hip) and −1.2 (L-spine) with 53% of patients meeting criteria for osteopenia. HR-pQCT measurements of patients in the hemophilia group (compared to control group) showed (i) lower total volumetric BMD (282 ± 75 vs. 331 ± 44 mg hydroxyapatite (HA)/cm3); (ii) lower trabecular BMD (expressed as Bone/Trabecular volume fraction) (0.142 ± 0.04 vs. 0.178 ± 0.02); but (iii) higher cortical BMD (872 ± 87 vs. 784 ± 52 mg HA/cm^3). At the microarchitectural level, the hemophilia group compared to the controls demonstrated (i) fewer trabecular number (TbN); (ii) thinner trabeculae (TbSp) but (iii) thinner cortex thickness (CtTH) compared to the controls (data not shown). Finite element (FE) analysis estimating bone strength (failure load) showed significantly lower mean failure load, in the hemophilia group compared to controls (6288 ± 1850 vs. 13,720 ± 1561 Newtons, $P < 0.05$).

Conclusion: This preliminary data demonstrates remarkably poor bone health in PWH with detectable skeletal pathology at the microarchitectural level in addition to low BMD. The resulting poor bone quality may result in increased fracture risk in PWH. This study provides some insight into how hemophilia affects bone metabolism and bone structure, and suggests HR-pQCT may serves as a tool for early detection of poor bone quality. However, further studies are need to confirm the significance of our findings and translation into clinical practice.

PA 2.06-5

Association between predicted FVIII levels and risk of bleeding episodes in clinical trials with turoctocog alfa, a new rFVIII product from Novo Nordisk

Ozelo MC[1], Veljkovic D[2], Klamroth R[3], Misgav M[4], Nielsen R[5] and Groth A[5]

[1]INCT do Sangue Hemocentro Unicamp (University of Campinas), Campinas, SP, Brazil; [2]Institute for Mother and Child Health Care of Serbia, Belgrade, Serbia; [3]Hämophiliezentrum/ Gerinnungssprechstunde, Berlin, Germany; [4]Chaim Sheba Medical Center affiliated to the Sackler School of Medicine, Tel Aviv, Israel; [5]Novo Nordisk A/S, Soeborg, Denmark

Background: Novo Nordisk has conducted phase III clinical trials (guardian[TRADEMARK]) with the new rFVIII product turoctocog alfa in adult (≥ 12 years) and paediatric (< 12 years) patients with severe haemophilia A. In these trials, patients received prophylactic turoctocog alfa doses in the range 20–50 IU/kg (adult patients) or 25–60 IU/kg (paediatric patients), the doses being adjusted according to bleeding patterns of the individual patient during the trial.

Aims: To demonstrate the association between predicted FVIII:C and estimated bleeding rates for spontaneous and traumatic bleeding episodes in adult and paediatric patients.

Methods: All patients ($N = 214$) reported detailed information about dosing and bleeding episodes (spontaneous and traumatic), including the time points of these events, in diaries. Initial results showed that the estimated annualised bleeding rates (ABRs) increased with time since the latest prophylactic dose. Furthermore, a subset of patients ($N = 50$) underwent pharmacokinetic assessments. Based on the observed PK properties and the patient-reported information, a profile of predicted FVIII:C at all time points during the trial was constructed for each patient and correlated to the time pattern of reported bleeding episodes. This amounts to a population pharmacodynamic analysis of the association between predicted FVIII:C and the risk of experiencing either a spontaneous or traumatic bleeding episode. FVIII:C profiles from patients ($N = 67$) who did not experience a bleeding episode during the trial also contributed to the analysis, whereas patients ($N = 3$) with insufficient reporting of dosing were excluded.

Results: In all, the 211 patients were exposed to turoctocog alfa in daytime hours (06.00–24.00) for a total of 76.1 patient years (58.1 patient years for adults and 18.0 patient years for children) and reported a total number of 550 bleeding episodes during these hours (326 spontaneous, 188 traumatic and 36 not categorised). Overall, the results of the analysis demonstrate that the risk of experiencing a bleeding episode decreases with increasing FVIII:C. The protection provided by FVIII:C in the range of 1–5%, corresponding to moderate haemophilia, appears to be better for paediatric than for adult patients, particularly for spontaneous bleeding episodes. Between-patient

variability of bleeding risk at any specified FVIII:C was substantial in both age groups.

Conclusion: The protective effect of increasing FVIII:C appears more pronounced for our paediatric vs. adult patients, and for spontaneous vs. traumatic bleeding episodes. The high variability between patients reflects the global character of the trials, spanning patients with highly different treatment histories reflecting different economic resources in the participating regions. The estimated relations between predicted FVIII:C and bleeding risk could serve as a model to predict mean ABRs not only in trials with multiple dosing regimens of standard FVIII products, but also in trials using next generation FVIII compounds with prolonged PK profiles.

PA 2.06-6

Parameters influencing factor VIII half-life and recovery in patients with haemophilia A

Kepa S[1], Reitter-Pfoertner SE[1], Horvath B[1], Heistinger M[2], Neumeister P[3], Rosenlechner S[4], Schuster G[5], Petz B[1], Mannhalter C[1] and Pabinger I[1]

[1]Medical University of Vienna, Vienna; [2]Clinical Centre of Klagenfurt am Woerthersee, Klagenfurt; [3]Medical University of Graz, Graz; [4]Medical University of Salzburg, Salzburg; [5]Blood Transfusion Service of the Austrian Red Cross, Linz, Austria

Background: Factor VIII (FVIII) half-life and recovery vary widely among patients with haemophilia A. Therefore, for tailored prophylactic treatment regimens the knowledge of FVIII half-life and recovery in individual patients is important.

Aim: The aim of the current study was the identification of factors influencing FVIII pharmacokinetics in patients with haemophilia A.

Methods: Peripheral venous blood samples were collected in adult patients (≥ 18 years) with severe and moderate haemophilia A pre- and post-infusion after a washout period of at least 72 h after the last factor VIII injection. Patients were on prophylactic or on-demand treatment and received their usual recombinant or plasma-derived FVIII concentrates. All patients had to give their written informed consent. Exclusion criteria were a current or past FVIII inhibitor, bacterial infection or inflammation at inclusion, active bleeding or other coagulation disorders. Blood samples for the pharmacokinetics were collected before and at ten time points after FVIII infusion (according to the recommendations of the ISTH). If desired by patient, sampling was reduced to at least five time points after FVIII infusion. All FVIII half-lives were evaluated by the Bayesian analysis (Bjoerkman, Blood, 2012, 119:612–618).

Results: Forty adult patients with haemophilia A (35 severe, five moderate, median age 30 years [range: 18–61]) were recruited. Thereof, 20 patients had blood group 0. Fifty percent of all patients (n = 20) had an inversion in the factor FVIII gene as underlying mutation (19: inversion 22, 1: inversion 1), 16 a point mutation, and one each had a deletion, a nonsense mutation, a splice mutation and no identified mutation, respectively. The median BMI was 25.7 (17.9–35.5) and the median FVIII dosage used was 23.7 IU/kg (10.5–50.0). Regarding the treatment regimen, 58% (n = 23) were on prophylaxis and 42% (n = 17) on demand. The majority of patients (n = 29) received recombinant and 11 a plasma-derived FVIII product. The median FVIII recovery was 2.4/dL/U/kg (1.0–3.7). Patients with higher BMI (> 25) showed a significantly higher FVIII recovery (P = 0.013). No correlation was found between FVIII recovery and blood group or age. The FVIII half-life varied from 5.8 to 19.2 h (median 10 h) and the median clearance was 0.27 L/h/kg (0.12–0.65). In patients with blood group 0, FVIII half-life was significantly shorter than in patients with non-0 blood group (median half-life: 9.5 h, range: 6.3–14.8 h vs. median: 11.8 h, range: 5.8–19.2 h, P = 0.046). Patients aged > 30 years had a longer median half-life compared to those 18–29 years of age (median: 12.4 h, range: 6.3–19.2 h vs. median: 9.2 h, range: 5.8–17 h, P = 0.004). Moreover, von Willebrand antigen and activity levels were associated with FVIII half-life, patients with higher levels had a longer FVIII half-life (r = 0.608 and r = 0.402, respectively).The mutation type (inversion vs. other mutations) had no impact on FVIII recovery, half-life or clearance.

Summary/Conclusions: FVIII pharmacokinetics, performed in adult patients in routine clinical practice, using the usual medication and dosage of an individual patient, revealed blood group, von Willebrand factor antigen and age as major determinants for FVIII half-life, whereas the underlying F8 gene mutation had no influence. Results can be used for individualization of the prophylactic treatment regimen.

PA 2.07-1

A retrospective observational multicenter cohort study on peri-operative Factor IX consumption in Hemophilia B ('OPTI-CLOT' studies)

M Hazendonk HCA[1], Lock J[1], Fijnvandraat KJ[2], Meijer K[3], Tamminga YJ[3], Kruip JHA[4], Leebeek FWG[4], Mathôt RAA[2] and Cnossen MH[1]

[1]Erasmus Medical Center Sophia Childrens Hospital Rotterdam, Rotterdam; [2]Academic Medical Center, Amsterdam; [3]University Medical Center Groningen, Groningen; [4]Erasmus Medical Center, Rotterdam, The Netherlands

Background: Hemophilia B is an X-linked bleeding disorder, caused by a deficiency of clotting factor FIX (FIX). Treatment of hemophilia with coagulation factors is costly. Previous studies have demonstrated that FIX consumption in prophylactic treatment can be significantly reduced by individualized dosing regimens. However, data on peri-operative FIX consumption, clearance and modifying factors are scarce.

Aim: To evaluate peri-operative FIX consumption and achieved FIX levels in hemophilia B with attention to patient- and surgical characteristics.

Patients and Methods: In this multicenter retrospective observational study, we included patients with severe and moderate hemophilia B (FIX levels < 0.05 IU/mL), without an inhibitor, undergoing elective and low or medium risk surgery from January 2000 until July 2012, from three Dutch Hemophilia Treatment Centers. The study was not subject to the Medical Research Involving Human Subjects Act and was approved by the Medical Ethics Committee. FIX concentrates were administered with the aim to achieve the following target levels advised by the Dutch Hemophilia Consensus: day 1: 0.8–1.0 IU/mL; day 2–5: 0.5–0.8 IU/mL; > day 6: 0.3–0.5 IU/mL. The achieved FIX plasma levels were generally checked daily. Data were collected on clinical and surgical characteristics, peri-operative dose and mode (bolus infusion: BI or continuous infusion: CI) of FIX concentrate administration, achieved FIX levels and bleeding complications.

Results: A total of 43 surgical procedures was performed in 21 patients; 16 adults (36 surgeries; median age 49 years; median weight 80 kg) and five children (seven surgeries; median age 4 years; median weight 18 kg). In adults, mainly orthopedic surgeries were performed (63%); in children insertion or removal of intravenous catheters and abdominal surgery was most frequent (57%). Peri-operative bleeding complications were reported in six procedures (14%); in three patients (7%) reoperation was required for persistent bleeding.

Median amount of infused FIX concentrate during hospitalisation was 44,575 IU (686 IU/kg) per surgical procedure. Forty-seven percent of achieved peri-operative levels was above highest required level (median + 0.17 IU/mL) according to the Consensus; 41% was within target range and 11% of levels was below targeted range (median −0.11 IU/mL). CI was used more frequently (63%) than BI (37%); children received only FIX by BI.

CI and BI did not differ in bleeding complications or achieved FIX levels. For adults the median amount of infused FIX concentrate was

significantly higher when treated by CI (788 IU/kg) compared to BI (408 IU/kg) ($P < 0.001$). After correction for duration of hospitalisation this difference did persist; CI 60 IU/kg/day and BI 44 IU/kg/day ($P = 0.01$). The severity of surgery was not associated with the amount of FIX concentrate administered per day. Further analyses are ongoing to differentiate between indications for surgery.

Conclusion: Forty-seven percent of peri-operative FIX levels was above the predefined target levels. These data support that there is room for improvement in the efficacy of peri-operative dosing. PK-guided dosing with iterative pharmacokinetic modelling in the peri-operative period is therefore promising.

PA 2.07-2

Is hemophilia B less severe than hemophilia A in young children with same level of factor deficiency?

Clausen N[1], Mancuso ME[2], Claeyssens-Donadel S[3], Petrini P[4], Liesner R[5] and Gouw S[6]

[1]University Hospital of Aarhus at Skejby, Aarhus N, Denmark; [2]Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, Milan, Italy; [3]Centre Regional d'Hemophilie, Toulouse, France; [4]Karolinska Hospital, Stockholm, Sweden; [5]Great Ormond Street Hospital for Children, London, UK; [6]Emma Children's Hospital, Amsterdam, The Netherlands

Background: Several studies, mainly in adults, have suggested that the bleeding phenotype in hemophilia B (HB) is milder compared with hemophilia A (HA) at similar residual clotting factor VIII or IX activities. More knowledge on children's bleeding phenotype in both HA and HB, especially at the start of treatment, is important in order to optimize childhood patient care.

Aims: This study was designed to describe and compare the severity of the bleeding phenotype and the variation in bleeding sites in young patients with severe or moderate HA and HB.

Methods: Consecutive untreated children with severe HA and HB (factor VIII/IX < 0.01 IU/mL) or moderate HA and HB (factor VIII/IX 0.01–0.05 IU/mL) born between January 1st 2000 and January 1st 2010, who were diagnosed in one of the participating hemophilia treatment centers were included. Approval from every centre's review board and written informed consent was obtained from the parents or guardians of all participants. The primary outcome of the study was the clinical phenotype expressed as the severity of bleeding tendency, i.e. the age when bleeding necessitating treatment occurred. The secondary outcome was variation in bleeding sites. The determinant was the type of hemophilia, HA and HB. Patients were censored when they started on prophylactic treatment.

Results: Among 582 patients with severe HA and 76 with severe HB there were no differences in age at diagnosis (median 0.42 vs. 0.43 years [$P = 0.65$]), age at first exposure to clotting factor (0.81 vs. 0.88 years [P 0.20]), age at first bleed (0.82 vs. 0.88 years [$P = 0.36$]), and age at first joint bleed (1.18 vs. 1.20 years [$P = 0.59$]), respectively. As expected, these respective ages were higher in patients with moderate hemophilia. Also in moderate hemophilia there were no clear differences between HA and HB. The age at start of prophylaxis in HA and HB were similar. Target joints occurred with similar frequencies. The proportion of children without bleeding before the age of 2 years was equal.

Summary/Conclusions: The present study demonstrates that the severity and the variation in bleeding phenotype of hemophilia A and hemophilia B are similar during the early stage of the disease in children with severe and moderate hemophilia. Young children with hemophilia B should be observed and treated as intensely as those with hemophilia A.

PA 2.07-3

Identification of 11 new mutations in the factor IX gene in patients with haemophilia B

Trento TH[1], Siqueira LH[2], Santos A[2], Veiga M[3], Thomas S[4], Streva A[5], Prezotti A[6], Medina S[2] and Ozelo MC[2]

[1]State University of Campinas, Campinas; [2]INCT do Sangue Hemocentro UNICAMP, University of Campinas, Campinas, SP; [3]Hemocentro do Paraná, HEMEPAR, Curitiba, PR; [4]Hemocentro do Mato Grosso, Cuiabá, MT; [5]Hemocentro da Bahia, HEMOBA, Salvador, BA; [6]Hemocentro do Espírito Santo, HEMOES, Vitória, ES, Brazil

Introduction: Haemophilia B (HB) is an X-linked hereditary bleeding disorder caused by factor IX (FIX) deficiency. The FIX gene (*F9*) is located at Xq27.1 with eight exons and seven introns and encodes a 2.8 kb mRNA molecule, resulting in the mature serine protease FIX with 461 amino acids. Mutations that cause haemophilia B are restricted entirely to the *F9* and include point mutations, such as missense, nonsense and splice site mutation, and deletions or insertions. Point mutations are regarded as cause of approximately 85% of the haemophilia B cases.

Objective: The aim of this study was to determine the genotype of patients with the diagnosis of haemophilia B, correlating it with their phenotype, and to evaluate the most frequent mutations in our population.

Patients and Methods: Patients with HB from six Haemophilia Centers located in different regions inBrazil were included in this study. DNA samples extracted from peripheral blood leukocytes were used for direct sequence analysis, using the reference NCBI Ref Seq NM_000133.3 and the King's College London Haemophilia B database.

Results: A total of 154 patients with haemophilia B of 88 unrelated families were included in this study, with 11 cases of sporadic haemophilia B. Sixty-nine patients (47 families) were classified as severe haemophilia B (FIX ≤ 1 IU/dL). Sixty-one *F9* distinct mutations were identified, including 11 mutations not previously described. Novel mutations included two frameshift mutations (c.31044_31046delC and c.31298_31303ins) and the point mutations p.L326R, p.D359H, p.R116P, p.H221N, p.I382T, p.P193L, promoter -21 T>A, p.E17D and p.Q246R. Forty-seven unrelated families had severe haemophilia B, among them we observed 32 (68%) missense mutation, 8 (17%) of nonsense mutation, 3 (6%) splice site mutation and 4 (9%) frameshift mutation. In 41 unrelated families with moderate and mild haemophilia B (34 moderate and seven mild) we observed 1 (2.5%) frameshift mutation, 1 (2.5%) splice site mutation and 39 (95%) missense mutations. Regarding the most frequently observed mutations in this population we can highlight two codons in exon 8 recognized as hotspots in *F9* (p.R248 and p.R333). The mutation p.R248Stop (30863 C>T) was present in three families with severe haemophilia B. Four distinct families with haemophilia B presented the mutation p.R333Q (31119 G>A) and in one family with severe haemophilia B the mutation p.R333Stop (31118 C>T) was identified.

Discussion: The present study identified the causal mutation of 154 Brazilian haemophilia B patients. Sixty-one different *F9* mutations, including 11 novel mutations, were detected. Identification of the mutations related to haemophilia B allows the carrier detection and prenatal diagnosis. This study is of great interest for genetic counseling of HB carriers and to better understand the pathophysiology of the disease.

PA 2.07-4

Long-lasting recombinant factor FIX Fc fusion (rFIXFc) for perioperative management of subjects with haemophilia B in the phase 3 B-LONG study

Powell J[1], Apte S[2], Chambost H[3], Hermans C[4], Jackson S[5], Josephson N[6], Mahlangu J[7], C Ozelo M[8], Peerlinck K[9] and Allen G[10]
[1]University of California at Davis, Davis, CA, USA; [2]Sahyadri Hospital, Mahara, India; [3]Centre Régional de Traitement des hémophiles, Marseille, France; [4]Cliniques Universitaires Saint-Luc, Bruxelles, Belgium; [5]Saint Paul's Hospital, Vancouver, Canada; [6]Puget Sound Blood Center, Seattle, WA, USA; [7]Haemophilia Comprehensive Care Centre, Johannesburg, South Africa; [8]INCT do Sangue Hemocentro UNICAMP, Campinas, Brazil; [9]Apotheek, UZ Gasthuisberg, Leuven, Belgium; [10]Biogen Idec, Weston, MA, USA

Background: A long-lasting recombinant factor IX Fc fusion protein (rFIXFc) was developed to improve current treatment of haemophilia B. A monomeric rFIX molecule was fused directly to the Fc domain of immunoglobulin G_1(IgG_1) to utilise an endogenous pathway that delays lysosomal degradation by cycling these proteins back into circulation, resulting in a longer plasma half-life. The prolonged activity of rFIXFc was confirmed in the recently completed phase 3 B-LONG study to provide prophylactic protection at 1–2 week dosing intervals and effective management of bleeding episodes.
Aim: To evaluate the efficacy of rFIXFc for haemostatic control in the setting of major surgery.
Methods: Male subjects with severe haemophilia B (≤ 2 IU/dL [2%] endogenous FIX), ≥ 12 years old, with no current or previous FIX inhibitors, and a history of ≥ 100 documented prior exposure days (ED) to FIX were enrolled in one of four treatment arms: Arm 1, weekly prophylaxis; Arm 2, individualised interval prophylaxis; Arm 3, episodic (on-demand) treatment; and Arm 4, perioperative management. Subjects requiring major surgery (newly recruited or from Arms 1–3) participated in Arm 4. Treatment for subjects in Arm 4 was chosen by the investigators and surgeons based on considerations of the subject's rFIXFc PK profile, the type of planned surgery, and clinical status of the subject. Endpoints for Arm 4 included investigators'/surgeons' assessments of subjects' response to surgery with rFIXFc; number of injections and dose required to maintain haemostasis during the surgical period; estimated blood loss during and after surgery; and number of transfusions required for surgery.
Results: Overall, 14 major surgeries were performed in 12 subjects, including arthroscopic meniscectomy of knee (n = 1), arthroscopic ankle fusion (n = 1), knee replacements (n = 5), and other (n = 7). Haemostasis was rated as excellent (13/14) or good (1/14) by the investigator/surgeon. The median estimated blood loss was 65.5 mL (range: 0.0–300.0 mL) during surgery and 0.0 mL (range: 0.0–500 mL) post-operatively. No blood transfusions were required during surgery, but two subjects received transfusions in the postoperative period. A single injection of rFIXFc was required in 85.7% of surgeries to maintain haemostasis during surgery, at a median dose of 90.9 IU/kg per injection. Most procedures required 1–2 injections the day preceding and day of surgery and most subjects required 2–3 injections during post-operative Days 1–3. On the day of surgery, post-operative Days 1–3, and post-operative Days 4–14, the median rFIXFc consumption (summarized over all injections during the time period) was 146.1, 164.6, and 277.1 IU/kg, respectively. Overall, one or more adverse events (AE) were reported for 10 (83.3%) of the 12 subjects, and three subjects reported six serious AEs, all of which resolved and were judged as unrelated to rFIXFc treatment.
Summary/Conclusions: In this study, long-lasting rFIXFc maintained perioperative haemostasis in patients with haemophilia B. High perioperative efficacy was reported by investigators/surgeons, suggesting that haemostasis achieved after infusion of rFIXFc was comparable to that for similar surgeries in subjects without haemophilia B.

PA 2.07-5

Clinical implications of population pharmacokinetics of rFIXFc in routine prophylaxis, control of bleeding and perioperative management for haemophilia B patients

Li S[1], Diao L[1], Powell J[2], Shapiro AD[3], Josephson N[4], Pasi J[5], Perry D[6], Ragni M[7], Kulkarni R[8], Valentino LA[9], Brennan A[1], Pierce GF[1], Nestorov I[1] and Jiang H[1]
[1]Biogen Idec, Waltham, MA; [2]University of California Davis Health System, Sacramento, CA; [3]3Indiana Hemophilia and Thrombosis Center, Indianapolis, IN; [4]Puget Sound Blood Center, Seattle, WA, USA; [5]Barts and the London School of Medicine and Dentistry, London; [6]6Department of Haematology, Addenbrookes Hospital, Cambridge, UK; [7]University of Pittsburgh and the Hemophilia Center of Western Pennsylvania, Pittsburgh, PA; [8]Breslin Cancer Center, East Lansing, MI; [9]Rush University Medical Center, Chicago, IL, USA

Background: Clinical dosing of factor IX (FIX) in treatment of haemophilia B is well established based on empirical practice and clinical outcomes. Since pharmacokinetics (PK) of FIX activity is a surrogate efficacy marker, we utilised population PK (popPK) modelling and simulation to evaluate dosing regimens of long-lasting recombinant FIX Fc fusion protein (rFIXFc). The PK of rFIXFc, in 12 phase 1/2a and 123 phase 3 study subjects from 12 to 76 years old (body weight (BW): 45–186.7 kg), was best described by a three-compartmental model, which showed modest inter-individual variability (IIV) of 17.7% for clearance (CL) and 21.7% for volume of central compartment (V1). The proportional residue error of 10.6% approximates the variability of the one-stage clotting assay for FIX activity. The only covariate that showed a weak association with rFIXFc PK was BW, which accounted for approximately 3% of IIV for CL and V1, suggesting that BW-independent (i.e. flat) dosing of rFIXFc may be feasible for treating adult haemophilia B patients.
Aims: To simulate the BW-based and flat dosing regimens for routine prophylaxis, control of bleeding and perioperative management in the haemophilia B population.
Method: The validated three-compartmental popPK model, including inter-occasion variability and BW as the covariate on CL and V1, was used for dosing simulations. For each regimen, PK profiles were simulated for 1000 subjects with BW distribution representative of the phase 3 study, and for three populations (n = 1000 each) stratified by BW: low (≤ 10th percentile), typical (10th–90th percentile) and high (≥ 90th percentile). Variability of exposure parameters, percentage of population maintaining target C_{max} and trough, and deviations of median exposure parameters in extreme BW groups were compared between BW-based and flat dosing regimens.
Result: Consistent with the observations from the phase 3 study, popPK simulation of 50 IU/kg once weekly or 100 IU/kg every 10–14 days predicted peak FIX activity within the physiologic range (C_{max} < 150%) and trough ≥ 1% in the majority of the population. Analysis of 12 major surgeries found that the FIX activities measured during the perioperative period were largely consistent with the prediction by popPK based on subjects' pre-surgery PK characteristics, indicating no substantial factor consumption in these surgeries. Furthermore, BW-based and flat dosing resulted in comparable PK profiles, eg, 50 IU/kg and 4000 IU once weekly predicted a median (5th, 95th percentile) C_{max} of 52.6 (32.1, 89.3) IU/dL and 56.1 (36.2, 90.9) IU/dL, respectively. Both dosing regimens predicted that > 95% of the population maintains C_{max} < 150% and trough ≥ 1%. However, BW-based and flat dosing showed differential effects on the exposure parameters in extreme (≤ 10th or ≥ 90th percentile) BW populations.
Conclusion: PopPK provides a robust and effective means to evaluate potential dosing regimens. The predictions by popPK simulation for rFIXFc corroborate the results from the phase 3 study. The simulations of BW-based and flat dosing of rFIXFc achieved similar PK pro-

files. Considering the wide therapeutic range for factor replacement therapy, flat dosing of rFIXFc and rFIX products may be a viable approach in adult haemophilia B patients that warrants further clinical investigation.

Treatment of bleeding episodes in subjects with haemophilia B with the long-lasting recombinant factor IX Fc fusion protein (rFIXFc) in the phase 3 B-LONG study

Pasi J[1], Josephson N[2], Mahlangu J[3], Perry D[4], Powell J[5], Ragni M[6], Valentino LA[7], Krassova S[8], Nugent K[8], Brennan A[8], Innes A[8], Luk A[9], Pierce GF[8] and Allen G[8]

[1]Barts and the London Comp Care Center, London, UK; [2]Puget Sound Blood Center, Seattle, WA, USA; [3]Haemophilia Comprehensive Care Centre, University of the Witwatersrand, Johannesburg, South Africa; [4]Addenbrooke's Hospital, Cambridge, UK; [5]University of California at Davis, Davis, CA; [6]University of Pittsburgh and the Hemophilia Center of Western Pennsylvania, Pittsburgh, PA; [7]Rush University Medical Center, Chicago, IL; [8]Biogen Idec; [9]Biogen Idec Hemophilia, Weston, MA, USA

Background: Fc fusion technology has been utilised to develop a long-lasting recombinant factor IX (rFIXFc) for the treatment of haemophilia B. Recombinant FIX was covalently linked to the Fc domain of human immunoglobulin G_1 (IgG) to utilise an endogenous pathway that delays lysosomal degradation by cycling Fc-containing proteins back into circulation, resulting in a longer plasma half-life. The improved PK of rFIXFc was demonstrated in the recently completed phase 3 B-LONG study, in which rFIXFc provided sustained protection from bleeding with prophylaxis regimens of injections every 1–2 weeks, and excellent control of bleeding episodes.

Aim: To evaluate the treatment of bleeding episodes with rFIXFc in the B-LONG study.

Methods: Male subjects with severe haemophilia B (≤ 2 IU/dL [2%] endogenous FIX), ≥ 12 years old, with no current or previous FIX inhibitors, and a history of ≥ 100 documented prior exposure days (ED) to FIX products were included in one of four treatment arms: Arm 1, weekly prophylaxis (starting at 50 IU/kg; PK-driven dose adjustments); Arm 2, individualised interval prophylaxis (100 IU/kg starting at every 10 days; PK-driven interval adjustments); Arm 3, episodic (on-demand) treatment (20–100 IU/kg); and Arm 4, perioperative management. The number of bleeding episodes, number of injections, and median dose required to resolve bleeding episodes were evaluated. Subject and physician subjective assessment of efficacy were recorded.

Results: One hundred and twenty-three subjects were enrolled at 50 centres (Arm 1 = 63, Arm 2 = 29, Arm 3 = 27, Arm 4 = 12 [including eight from Arms 1–3]), and 93.5% completed the study. A total of 636 bleeding episodes (Arm 1 = 167, Arm 2 = 67, Arm 3 = 402) in 89 subjects were treated, 90.4% of which required a single dose of rFIXFc for resolution of the bleed and 97.3% required ≤ 2 injections. The median dose per injection was 46.1 IU/kg and the median total dose for the bleeding episodes was 47.0 IU/kg. Overall, subject assessment of response to treatment with rFIXFc was excellent or good for 76.4%, 77.0%, and 85.4% of injections in Arms 1, 2, and 3, respectively. Physicians' global assessment of subject response to their rFIXFc regimen was rated as excellent or effective for 98.9%, 99.2%, and 97.9% of visits in Arms 1, 2, and 3, respectively.

Summary/Conclusions: Results of this analysis indicate that long-lasting rFIXFc offers a robust option for treatment of bleeding episodes in persons with severe haemophilia B. Most bleeding episodes in this study required one injection only to resolve the bleed. Assessments of haemostatic response reflect high subject ratings of treatment response to breakthrough bleeding and high physician ratings of the efficacy of rFIXFc injections.

PA 2.08-1

Clinical efficacy and safety of DDAVP with or without tranexamic acid in inherited VWD: final results of the prospective and international study on 229 patients

Federici AB[1], Castaman G[2], Iorio A[3], Bonduel M[4], D'Amico EA[5], Oliovecchio E[6], Santoro C[7], Siboni SM[1], Zieger B[4] and Mannucci PM[8]

[1]University of Milan, Milan; [2]S. Bortolo Hospital, Vicenza; [3]University of Perugia, Perugia, Italy; [4]Pediatric Hospital, Buenos Aires, Argentina; [5]Internal Medicine, San Paulo, Brazil; [6]Unversity of Perugia, Perugia; [7]University of Rome, Rome; [8]Policlinico Hospital, Milan, Italy

Background: Desmopressin (DDAVP) is the treatment of choice for most patients with mild-moderate forms of von Willebrand disease (VWD) because it can induce the release of von Willebrand factor (VWF) from cellular compartments. However, despite the large use of DDAVP since 1977, there are only a few prospective clinical trials aimed at determining benefits and limits of this therapeutic approaches.

Aims and Design of the Study: To correlate efficacy and safety with biological response of DDAVP in inherited VWD, 268 patients were enrolled and exposed to 0.3 μg/kg DDAVP intravenous injection and to blood withdrawal for measuring VWF/FVIII activities before and after 0.5, 1, 2 and 4 h (biological response). Then efficacy and safety of DDAVP were evaluated prospectively during 24 months when VWD were exposed to bleedings and minor/major surgeries.

Methods: The following criteria were used for analyses: VWD = VWF:RCo < 55 U/dL; VWD2 = VWF:RCo/Ag ratio ≤ 0.6; VWD1 accelerated clearance: VWF:RCo/FVIII increase after 0.5–1 h with return to baseline after 2–4 h.

Results: 229/268 (85%) patients met inclusion criteria as VWD1 (n = 196), VWD2A (n = 18), VWD2B (n = 1), VWD2M (n = 14), VWD2N (n = 3). Biological response was complete, partial and absent in 89%, 10% and 1% of VWD and correlated with baseline levels of VWF:RCo < 30 U/dL (Fisher's exact = 0.001). VWD1(n = 15) with C1130F and R1205H mutations showed accelerated clearance. During the 24-month follow-up, 62/86 (72%) patients received > 1 injection of DDAVP for bleedings (n = 102), deliveries (n = 13), dental extractions (n = 27), minor/major surgeries (n = 46). Total injections were 652 with median, range/episode during bleedings (2.1–12), deliveries (3.1–3), dental extractions (1.1–10), surgeries (3.61–16). Tranexamic acid (TA) was used together with DDAVP not only in most bleeding episodes [GI bleeds (100%), epistaxis (77%), menorrhagia (71%)] and in most dental extractions (83%) but also in minor (53%) and major (57%) surgeries. Clinical efficacy was excellent/good in bleedings (92.1%), deliveries (84.6%), dental extractions (100%), surgeries (90.6%) being poor in six cases with VWD2A (n = 4) during GI bleedings (n = 3) or abdominal surgery (n = 1) and VWD1(n = 2) during deliveries and surgery. The rate of efficacy were not significantly different in the two groups receiving DDAVP with or without TA. Side effects (16 cases) were mainly minor, such as headache, facial flushing and tachycardia with water retention reported in two cases (one delivery, one surgery) after > 6 injections.

Conclusions: Based on the results of this large prospective study, we confirm that DDAVP is an effective and safe drug at low costs for

managing patients with VWD1, VWD2A, VWD2M and VWD2N once tested for their biological response: therefore it should be always recommended as the treatment of choice in responsive patients with moderate-mild VWD.

The merging project: a machine learning approach to merge and analyze data from four different bleeding questionnaires

Mollah S[1], Grabell J[2], Rand ML[3], Clarke D[3], Christopherson P[4], Mauer A[5], Montgomery R[4], T. Zimmerman Program Investigator[4], Coller B[1] and James PD[2]

[1]Rockefeller University, New York, NY, USA; [2]Queen's University, Kingston, ON; [3]The Hospital for Sick Children, Toronto, ON, Canada; [4]Blood Research Institute and Medical College of Wisconsin, Milwaukee, WI; [5]Massachusetts General Hospital, Boston, MA, USA

Background: The accurate assessment of hemorrhagic symptoms is a critical component in the diagnosis of mild bleeding disorders including von Willebrand disease (VWD). The value of standardized bleeding histories and quantitative bleeding scores has been recognized and multiple bleeding assessment tools have been developed, validated and published for use in both adult and pediatric populations.

Aim: To create a bioinformatics system for merging and analyzing data derived from different bleeding assessment tools.

Methods: Data obtained from index cases (IC) with VWD and healthy controls (defined as having no known problem with bleeding or bruising) using one of four different bleeding questionnaires [MCMDM1-VWD Bleeding Questionnaire (Tosetto, JTH, 2006;4:766–73), the Condensed MCMDM1-VWD Bleeding Questionnaire (Bowman, JTH, 2008;6:2062–6), the Pediatric Bleeding Questionnaire (PBQ) (Bowman, JTH, 2009;7:1418–21) and the ISTH-BAT (Rodeghiero, JTH, 2010;8:2063–5)] were normalized and cleaned prior to merging. Attribute selection was performed to determine features best able to distinguish individuals affected with VWD from unaffected. Information Gain and Rank search methods were used to determine the score to assign to each attribute with a score of 1.0 having perfect predictive value. The validity of the top 25 attributes was confirmed using classification analysis (Naïve Bayes Decision Tree Classifier) with 5-fold cross validation. Performance of the classifier was assessed by calculating sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV).

Results: Data from 2073 subjects were cleaned and merged (774 MCMDM1-VWD Bleeding Questionnaire, 735 Condensed MCMDM1-VWD Bleeding Questionnaire, 401 PBQ and 163 ISTH-BAT) comprising 679 cases of VWD and 1394 controls. The average age was significantly different between the affected subjects and controls [22.1 (range 1–81) and 34.8 (range 0.4–90), respectively ($P \leq 0.001$)]. The gender distribution did not differ [$n = 432$ females (64%) among cases and $n = 902$ (65%) among controls ($P = 0.785$)]. Of the 679 VWD cases, 612 are Type 1 VWD, 23 are Type 2 VWD and 44 are Type 3 VWD. The overall bleeding score from all four of the bleeding questionnaires included is the best predictor of affected status (score = 0.43) followed by the score for the bruising category (0.23), whether excessive bruising occurs or not (score = 0.23), size of the average bruise (score = 0.19) and location of bruises (exposed vs. unexposed) (score = 0.19). The sensitivity, specificity, PPV, and NPV of the top 25 attributes are 91%, 87%, 0.83 and 0.94 respectively. The analysis did not substantially differ when performed for only cases with Type 1 VWD and controls, with the exception of an increase in PPV to 0.93.

Conclusions: We found that the overall bleeding score is better than any single attribute at predicting the presence of VWD. Thus, an accurate assessment of bleeding symptoms must be comprehensive in order to have the greatest predictive value. Finally, our results highlight the strength in pooling existing datasets to improve our knowledge about diagnostic accuracy in VWD.

PA 2.08-3

Hemophilia arthropathy occurs in a significant percentage in von Willebrands disease

Van Galen KPM[1], Sanders YV[2], Schaefer TM[1], Eikenboom HCJ[3], Van Der Bom JG[3], Fijnvandraat KJ[4], Meijer K[5], Leebeek FWG[2] and Mauser-Bunschoten E[6]

[1]UMC Utrecht, Utrecht; [2]Erasmus University Medical Center, Rotterdam; [3]Leiden University Medical Center, Leiden; [4]Academic Medical Center Amsterdam, Amsterdam; [5]University Medical Center Groningen, Groningen; [6]University Medical Center Utrecht, Amsterdam, The Netherlands

Background: In von Willebrand disease (VWD), the occurrence of joint bleeds has been well described, but no valuable information on joint status and outcome is currently available. The objective of this study is to learn more about the occurrence and impact of arthropathy in VWD.

Methods: The Willebrand in the Netherlands (WiN) study is a large nation-wide cross-sectional study that collected data on adults and children with moderate and severe VWD (VWF of 30 IU/dL or lower) from all 13 Haemophilia Treatment Centers in the Netherlands between October 2007 and October 2009. Participants were asked to complete an extensive self-administered questionnaire, including questions on bleeding episodes, treatment, concomitant disease, joint damage, joint surgery and Quality of Life. Furthermore, at inclusion, blood was drawn from most patients for measuring von Willebrand parameters in a central laboratory.

Results: Twenty-three percent of the 664 included adult VWD patients suffered from haemarthrosis ($n = 147$). Sixty-one patients (61 out of 664, 9%) self-reported treatment with DDAVP or coagulation factor for joint bleeds. FVIII:C was a strong determinant and joint bleeds were mostly seen in VWD patients with FVIII:C < 5 IU/dL. Joint bleeds had significant impact on their health related quality of life (physical component summary of the SF36 in men, $P = 0.044$, 95% CI [−5.37, −0.07] and in women, $P = 0.007$, 95% CI [−5.20, −0.85]. Mental component summary of the SF36 ns in men, in women $P = 0.004$, 95% CI [−5.71, −1.10]). Joint damage related to joint bleeding was reported by 80 of the 147 patients who reported joint bleeds (54%), which was most often joint damage of the knee (31%). Ninety-four patients had been admitted to the hospital for orthopedic joint surgery (94 out of 664, 14%) and in up to 33% of these patients the orthopedic surgery was probably related to the JB.

Conclusion: This study shows that the problem of arthropathy in VWD clearly exists and is not marginal. Self reported joint damage related to joint bleeds occurred in a significant percentage of moderate and severe VWD patients and a significant percentage of the patients needed orthopedic surgery related to the joint bleeds. Joint bleeds affect health related quality of life in VWD patients and it could be speculated that arthropathy due to joint bleeds partly explains this finding. Further research is needed to learn more about the severity and onset of arthropathy in VWD patients, its impact on daily functioning and on health-related quality of life.

PA 2.08-4

Validation of a micro assay for the diagnosis and characterisation of Von Willebrand disease

Baaij M[1], Schutgens REG[2], Urbanus RT[2], Leung W[2], Laros BAP[3], Van Heerde WL[3], Sanders YV[4], Leebeek FWG[4], De Groot PG[2] and Roest M[2]

[1]UMC Utrecht; [2]University Medical Center Utrecht, Utrecht; [3]St. Radboud University Medical Center, Nijmegen; [4]Erasmus University Medical Center, Rotterdam, The Netherlands

Background: Von Willebrand disease (VWD) is the most common inherited bleeding disorder, defined by a quantitative or qualitative defect in the Von Willebrand Factor (VWF). Conventional diagnosis of VWD is based on quantification of VWF antigen levels and assessment of its activity and composition. These tests are laborious, require at least 15 mL of blood and can only be performed by specialised technicians in equally specialised laboratories. We have developed a simple VWF function micro assay which requires only 40 μL of blood for the diagnosis and characterisation of VWD.

Aims: Our aim was to develop and validate a simple, accurate and fast single step assay to distinguish healthy donors from VWD and characterise VWD subtypes, using a mere 40 μL of blood.

Methods: This study was approved by the Medical Ethics Committee of the University Medical Center Utrecht. The procedures followed were in accordance with the Helsinki Declaration. After oral informed consent, blood samples were collected from 60 healthy adult volunteers and 60 adult patients with established diagnosis of VWD (ten of each subtype 1, 2A, 2B, 2M, 2N, 3). The micro assay consists of an eight serial dilution of ristocetin (0–0.75 mg/mL) containing a fixed concentration of FITC labelled anti-VWF antibody. Five microllitre of citrated blood was added to each well and VWF binding was assessed with fluorescent activated cell sorting. Results were plotted in a dose response graph. Analysis of the control vs. VWD groups and the characterisation of the sub groups was performed using ROC analysis.

Results: VWD can be distinguished from healthy subjects in two steps. First, type 2B patients can be distinguished from other patients and controls by increased binding of VWF to the platelet at a low ristocetin concentration (0.13 mg/mL ristocetine, $P < 0.0001$, sensitivity 100.0%, specificity 99.0%). All other VWD types show a significantly lower area under the dose response curve (AUC) compared to healthy controls ($P < 0.0001$, sens 93.1%, spec 100.0%). We have developed an algorithm to further distinguish between type 1 and type 2A (P 0.0056, sens 88.9%, spec 90.9%), type 2M and type 3 ($P < 0.0001$, sens 100.0%, spec 99.1%). As expected, type 2N patients were not identified, which is in accordance with its assumed unaffected ristocetin induced binding capacity.

Summary/Conclusion: We have developed a simple, accurate and fast new assay to diagnose and characterise VWD in unprocessed blood using flow cytometry. This is a major step forward in the current complex and laborious diagnostic process of VWD.

PA 2.08-5

Comparison of two automated latex-based VWF activity assays of differing principles with a standard VWF:RCo platelet aggregometry technique

Moore G[1], Mayger K[1] and Madan B[2]

[1]Guy's & St. Thomas' NHS Foundation Trust/GSTS Pathology; [2]Guy's & St. Thomas' NHS Foundation Trust, London, UK

Background: Assessing VWF activity is a crucial diagnostic tool in detection and sub-typing of VWD. The VWF:RCo platelet aggregometry assay has been the mainstay technique for decades yet it is a technically demanding manual method with low sensitivity and high inter-assay and inter-laboratory variability. Newly available, fully automated assays potentially offer improved diagnostic performance.

Aims: To compare two new generation automated VWF activity assays with a VWF:RCo platelet aggregometry technique.

Methods: VWF:RCo was performed using locally-prepared formalin-fixed platelets on a PAP4 aggregometer (Alpha Laboratories). Both automated assays employ latex beads coated with a recombinant fragment of GpIbα through a monoclonal antibody. In the HemosIL VWF:RCo assay (Instrumentation Laboratory), VWF in the sample binds to the GpIbα fragment via ristocetin and the degree of agglutination is directly proportional to VWF activity, determined by decreased light transmittance due to aggregation. The Innovance® VWF activity assay (Siemens) similarly employs latex-bound GpIbα fragment but it contains two gain-of-function mutations and agglutination is ristocetin-independent. The HemosIL assay was performed on an ACL TOP® 500 (Instrumentation Laboratory) and the Innovance® assay on a CS2100i (Sysmex). Fifty nine samples from patients with various VWD sub-types and 14 samples with normal VWF activity levels were tested with all three assays.

Results: Both automated assays had sensitivity limits of approximately 7.0 IU/dL, compared to 12 IU/dL for the aggregometry technique. Intra-assay CVs with a commercial normal and an abnormal control were 4.21% and 3.20% respectively for HemosIL and 4.20% and 3.20% respectively for Innovance®. Forty three of the known VWD samples gave results within the measurable range for the aggregometry technique, which along with the normal samples gave good correlation with the automated techniques. Mean and median values and ranges for aggregometry, HemosIL and Innovance® were 40.7, 38.5, 12.0–114.0; 47.7, 45.8, 4.6–106.7 IU/dL and 46.6, 47.4, 4.0–132.2 IU/dL respectively. Coefficients of determination (R^2) for aggregometry vs. HemosIL, aggregometry vs. Innovance® and HemosIL vs. Innovance® were 0.86, 0.86 and 0.89 respectively. A positive proportional bias was noted with HemosIL and Innovance® when compared to aggregometry, the mean bias for HemosIL was 6.5 IU/dL and for Innovance® was 5.9 IU/dL, which interestingly improved concordance with VWF:Ag values in type 1 patients. Of the 16 samples reported as < 12 IU/dL by aggregometry, 11 gave quantitative results < 12 IU/dL with both automated assays. Mean and median values and ranges for HemosIL and Innovance® respectively were 6.1, 6.3, 3.3–9.6 IU/dL and 6.5, 5.6, 4.0–10.0 IU/dL. The remaining samples gave the following HemosIL/Innovance® paired results (IU/dL): 11.7/12.4, 12.9/16.8, 12.5/14.6, 12.9/12.3, 13.8/13.0. Based on an activity:antigen ratio of < 0.7 indicating a type 2/multimeric abnormality, six samples from type 1 patients would have been misclassified as type 2 (four with aggregometry and two with HemosIL), and two samples from type 2 patients misclassified as type 1, one each with aggregometry and HemosIL.

Conclusions: New automated, latex-based VWF activity assays offer increased precision and diagnostic accuracy compared to standard VWF:RCo platelet aggregometry.

PA 2.08-6

RNA analysis for Von Willebrand disease; it has a role but it's not the answer

Hadonou MA[1], Austin S[2], Cutler J[1] and Mitchell M[1]

[1]GSTS Pathology; [2]St George's Hospital, London, UK

Type 1 and type 3 von Willebrand disease (VWD) are quantitative deficiencies of von Willebrand factor (VWF) in plasma. Diagnosis of VWD requires phenotypic data (VWF:Ag; WVF:RCo, VWF:CBA) to support the clinical symptoms of muco-cutaneous bleeding and bruising. Low levels or absence of VWF and proportionate activity define type 1 or type 3 VWD. Unfortunately, many factors other than the VWF gene affect VWF levels in plasma, including ABO blood group. Molecular analysis of the VWF gene can assist diagnosis but is complex as it is large (approximately 175 kb spread over 52 exons), highly polymorphic and has a highly homologous partial pseudo-gene. Anal-

ysis of VWF cDNA, reverse transcribed from leukocyte RNA, significantly reduces the size (approximately 9 kb) and removes the issue of the pseudo-gene.
We report three cases which illustrate the benefit and limitations of an RNA approach to genetic screening of quantitative VWD and its contribution to our understanding of the disease.
In the first case, analysis confined to the genomic level suggested the lack of a pathogenic mutation, clearly visible at the RNA level. Heterozygosity for a 41 base-pair insertion after exon 5 was detected in a mother and daughter each with type 1 VWD. In silico analysis identified this sequence as originating within intron 5. Analysis of this region in gDNA identified a heterozygous G>A substitution within a region containing a possible cryptic splice site. In this case, RNA analysis provided a definitive result, missed by gDNA analysis.
The second case is a demonstration of additional information provided by RNA analysis. A male with severe type I VWD was shown, at the gDNA level, to have a homozygous c.5455+2T>C substitution. cDNA analysis demonstrated a transcript lacking exon 31, but also some expression of normal transcript. This explains the patient having higher levels (VWF:Ag 14 IU/dL) than would be predicted by the DNA result.
These cases argue the case for a role for cDNA analysis in the investigation of VWD. However a third example raises concerns. The only variant detected in the RNA from a female with 'severe type I' VWD was a heterozygous c.4751A>G mutation. As this was not consistent with the diagnosis, DNA samples from her two children, both with type 3VWD, were analysed. Neither had the c.4751A>G mutation but both were homozygous for a c.7130delC mutation. Further analysis of the maternal gDNA confirmed her to be heterozygous for the c.7130delC mutation. Preferential reverse transcription of the normal RNA species or selective amplification of the wild type cDNA obscured detection of this mutation in the heterozygous state and led to a false negative result.
Non reproducible sequence data from cDNA transcripts have been observed in several other cases. These are suggestive of the presence of aberrant leucocyte VWF transcripts.
In conclusion, genetic analysis of both gDNA and RNA has a role in VWD diagnosis. However, neither represents a totally effective tool, and a combined approach may resolve a maximum number of cases.

Von willebrand factor as a surrogate marker for coronary artery calcification: the rotterdam study

Sonneveld MAH, Kavousi M, Van Loon JE, Van Der Lugt A, Leebeek FWG, Hofman A, Witteman JCM, Franco OH and De Maat PM

Erasmus University Medical Center, Rotterdam, The Netherlands

Background: Increased levels of von Willebrand factor (VWF) are associated with increased risk of coronary heart disease (CHD). As VWF mediates platelet adhesion, there might be an association with atherosclerosis and plaque formation. Understanding the association between atherosclerosis and VWF levels will help us further understand the pathogenesis of CHD.
Aims: We studied the association between coronary atherosclerosis and VWF levels in a population-based cohort study.
Methods: This study was part of the Rotterdam study, a population-based cohort study among subjects ≥ 55 years. We included 3485 subjects of whom blood samples and electron-beam computed tomography (EBT) or multidetector computed tomography (MDCT) were available and who were free from CHD at baseline. VWF antigen (VWF:Ag) levels were measured using ELISA and the coronary artery calcification (CAC) score was quantified according to the Agatston score. CAC scores were divided into four categories: 0–10, 11–100, 101–400 and > 400 Hounsfield Units. The association between the CAC score categories and VWF:Ag levels was assessed using a linear regression analysis. Analyses were adjusted for potential confounders including age, sex and cardiovascular risk factors.
Informed consent was obtained and the study was approved by a recognised medical ethics committee.
Results: The CAC score was significantly and positively associated with VWF:Ag levels (*P* for trend 0.007). VWF:Ag level (Mean ± SD) was lowest among individuals in the 0–10 CAC score category (1.10 ± 0.44 IU/mL) and highest among the individuals with the > 400 CAC score category (1.25 ± 0.54 IU/mL).
Summary/Conclusion: Our findings demonstrate an association between the coronary artery calcification score and VWF:Ag levels in the older subjects, without coronary heart disease. This suggests that the well-known association between VWF and risk of coronary heart disease may be determined by atherosclerosis.

PA 2.09-2

Von Willebrand factor propeptide (VWFpp) a marker useful for identifying adverse platelet activation in murine blood phlebotomy samples

Jacobi PM[1], Kanaji S[1], Gehrand A[1], Jakab D[1] and Haberichter SL[2]

[1]BloodCenter of Wisconsin; [2]BloodCenter of Wisconsin and Medical College of Wisconsin, Milwaukee, WI, USA

Background: Von Willebrand factor (VWF) and its propeptide, VWFpp, are secreted in an equimolar ratio into plasma. Since the VWFpp has a shorter half-life than VWF (2–3 vs. 8–14 h), the concentration of plasma VWFpp is less than VWF although each is defined as 1.0 U/mL with a VWFpp/VWF ratio of 1.0. After DDAVP administration, the plasma concentration of both proteins is increased due to release from endothelial cell (EC) Weibel-Palade bodies (WPB), but VWFpp/VWF is elevated (range of 4–10), reflecting regulated release on an equimolar, but not 'equi-unit' basis. Platelet activation should result in an increased VWFpp/VWF ratio.
Aims: To determine the most reliable method for blood sampling in mice and to identify the source of exocytosed VWFpp and VWF (platelet or endothelial cell).
Methods: 'Platelet-only' and 'EC-only' mice were generated by bone-marrow transplant between C57BL/6J and VWF−/− mice. As control, murine VWF expression was induced in the livers of VWF−/− mice by hydrodynamic tail vein injection (HDTV) which lack regulated VWF release. Blood sampling methods used include single retro-orbital (single capillary tube), multiple retro-orbital (multiple successive capillary tubes), cardiac puncture, submandibular, and vena cava bleeds. Blood collection after injection of heparin into the mouse was assessed. VWFpp and VWF levels were determined by ELISA.
Results: Assay of VWFpp/VWF demonstrated that single retro-orbital bleed, and multiple retro-orbital or cardiac puncture after heparin injection resulted in a VWFpp/VWF range of 0.6–1.6. Multiple retro-orbital bleeds without heparin injection had an elevated VWFpp/VWF of 4.5, suggesting activation of regulated release. Cardiac puncture and submandibular bleeds demonstrated variable results with VWFpp/VWF ranging from 1.0 to 18.4. Vena cava bleeds consistently showed the least activation with average VWFpp/VWF of 0.5. HDTV mice that lack regulated VWF secretion had VWFpp/VWF of 0.2 regardless of collection method. The low ratio in vena cava bled mice and HDTV mice compared to our VWF standard collected by cardiac puncture indicates the standard itself suffers from a degree of platelet/EC activation. To determine the source of released VWFpp and VWF, we compared vena cava and multiple retro-orbital bleeds of 'platelet-only', 'EC-only', and HDTV mice, measuring VWFpp and VWF released into plasma. In EC-only mice, VWF and VWFpp levels after vena cava collection averaged 0.5 U/mL with a ratio of 1.0. In contrast, after multiple retro-orbital bleeds, VWF and VWFpp were ele-

vated (0.9 and 2.3 U/mL, respectively) with average ratio of 3.1. In platelet-only mice, no VWFpp or VWF could be detected in plasma after vena cava sample collection as expected. In contrast, after multiple retro-orbital bleeds, VWFpp and VWF were elevated (3.5 and 0.12 U/mL) with VWFpp/VWF of 25.8 indicating substantial platelet activation.

Conclusions: Activation of platelets appears to be the more predominant mechanism than EC activation. Vena cava blood collection in mice appears to be the most reliable method, although a single retro-orbital bleed is a non-terminal method with only moderate platelet activation. Assay of VWFpp has a clear utility in determining the acceptability of murine plasma samples.

PA 2.09-3

Isolation of blood outgrowth endothelial cells from early infantile epileptic encephalopathy 4 (EIEE4) and familial hemophagocytic lymphohistiocytosis 5 (FHL5) patients

Bierings R[1], Van Breevoort D[1], Hofman M[1], Van den Berg T[1], Weckhuysen S[2], De Jonghe P[2] and Voorberg J[1]

[1]Sanquin-AMC Landsteiner Laboratory, Amsterdam, The Netherlands; [2]University of Antwerp, Antwerp, Belgium

Background: Syntaxin binding proteins (STXBPs) are Sec1/Munc18-like (SM) proteins which allow the docking of secretory granules to the plasma membrane and regulate the formation of the SNARE-complex prior to exocytosis. Recently, a number of putative binding partners of STXBP1, such as synaptotagmin-like protein 4-a (Slp4-a) and the small GTPase Rab27A, have been implicated in regulation of secretion of Von Willebrand factor (VWF), which is released from endothelial-specific secretory organelles called Weibel-Palade bodies (WPBs). Mutations or deficiencies in some STXBP proteins are linked to diseases characterized by a secretory defect: Early infantile epileptic encephalopathy type 4 (EIEE4) is a severe neurological disorder caused by de novo mutations in the gene encoding syntaxin binding protein 1 (STXBP1). Familial hemophagocytic lymphohistiocytosis type 5 (FHL5) is severe immunological disorder caused by mutations STXBP2.

Aims: In this study we will address a potential role of STXBP1 and STXBP2 in regulation of VWF secretion and WPB exocytosis using endothelial cells isolated from individuals carrying disease causing mutations in STXBP1 or STXBP2.

Methods: Blood outgrowth endothelial cells (BOECs) were isolated from peripheral blood. Expression of STXBP1 and STXBP2 was determined by Western blotting. VWF antigen plasma levels were determined by ELISA.

Results: We have isolated BOECs from a 16-year old EIEE4 patient carrying a de novo mutation in STXBP1 [c.963+ ?.(1967+?); p.Thr322_Glu603 del], which is predicted to result in a truncated protein. Moreover we isolated BOECs from two siblings homozygous for a splice-site mutation [c.1247-1G>C] in STXBP2, which results in a 17–19 residue substitution and one patient compound heterozygous [c.1247-1G>C; c.1621G>A], the latter resulting in a Gly541Ser substitution. By Western blotting we found that FHL5 BOECs had severely reduced levels of STXBP2, whereas STXBP1 levels in EIEE4 BOECs were relatively unperturbed. Both EIEE4 and FHL5 BOECs contained normal numbers of morphologically normal WPBs. VWF plasma levels in the EIEE4 patient and the FHL5 siblings were reduced, but normal in the compound heterozygote FHL5 patient.

Summary/Conclusions: Our findings suggest a moderate effect of clinically relevant mutations in STXBP proteins on VWF plasma levels, in line with the absence of immediate hemostatic abnormalities in the pathology of EIEE4 and FHL5. Further characterization of the secretory function of EIEE4 and FHL5 BOECs is necessary and ongoing to determine a role for STXBP1 and/or STXBP2 in regulation of WPB exocytosis.

PA 2.09-4

Active VWF predicts 4 week mortality in patients with SIRS

Hyseni A, Kemperman H, De Lange DW, Linssen M, Kesecioglu J, De Groot PG and Roest M

University Medical Center Utrecht, Utrecht, The Netherlands

Background: Systemic Inflammatory Response Syndrome (SIRS) and sepsis are among the leading causes of death in industrialized nations and adequate early diagnosis is a major challenge. Endothelial cell function is a major determinant of thrombosis in patients with SIRS and sepsis and might be used to identify high risk patients or guide the treatment. Von Willebrand factor (VWF) released from Weibel-Palade bodies of endothelial cells is different from the majority of VWF in plasma because it is present in a GPIb binding conformation ('active' von Willebrand factor, aVWF).

Aims: The aim of this study was to determine if the amount of circulating aVWF is able to predict mortality in patients with SIRS.

Methods: A prospective cohort study of 275 consecutive SIRS patients, aged 18 years or older and an anticipated Intensive Care Unit (ICU)-stay of at least 24 h. Blood samples on admission and the following 9 days were collected. aVWF was measured in plasma with an ELISA that recognizes aVWF but not VWF[1]. The end-point of the study was 4-week hospital mortality.

Results: aVWF levels were higher in non-survivors on admission (0.47 vs. 0.69 μg/mL, $P = 0.019$) on day 1 (0.52 vs. 0.78 μg/mL, $P = 0.011$) and on day 2 (0.50 vs. 1.03 μg/mL, $P < 0.01$). On day 3, non-survivors tended to have higher levels of VWF (0.51 vs. 0.76 μg/mL, $P = 0.055$) but subsequently, these levels were comparable to those of survivors. Kaplan Meier Curves showed that patients in the highest tertile of aVWF levels on admission had a lower cumulative survival than patients in the lower two tertiles (75% vs. 86%, $P = 0.017$) and a 2-fold increased risk of mortality [HR = 1.98; 95% CI: 1.1–3.5]. When adjusted for the APACHE IV score, this association remained significant [adjusted HR = 1.82; 95% CI: 1.03–3.3]. Total VWF levels were higher in patients who developed septic shock (53 μg/mL; IQR = 31.5–76.3 μg/mL) and severe sepsis (47.8 μg/mL; IQR = 35.3–63.3 μg/mL) than in patients with only SIRS or sepsis (42.2 μg/mL; IQR = 30.3–61.9 μg/mL), but these differences did not reach significance ($P = 0.071$).

Conclusions: Higher levels of circulating VWF in its GpIb binding conformation predict 4-week mortality in SIRS patients, independently of the APACHE IV Score. Our results show that biomarkers that reflect endothelial activation are of value in SIRS and sepsis patients.

PA 2.09-5

Matrix metalloproteinase-13 influences thrombus formation through the cleavage of VWF

Howes JM, Pugh N, Smethurst P, Bihan D and Farndale RW

University of Cambridge, Cambridge, UK

Background: Following atherosclerotic plaque rupture, the exposure of flowing blood to collagen-rich surfaces triggers platelet activation and aggregation. The engagement of GPIb-IX-V/GPVI by VWF and collagen is pivotal to thrombus formation on the exposed endothelium. MMP-13 is a collagenolytic metalloproteinase that is up-regulated in the vulnerable plaque and released upon rupture.

Aim: Here we aim to determine the effects of MMP-13 on platelet receptor and VWF function.

Methods: Solid phase binding assays, receptor-specific compounds and blocking single-chain variable fragment antibodies (scFvs) were used

to determine the interaction of MMP-13 with platelet receptors. The degradation of recombinant human platelet receptors by MMP-13 was assessed by SDS-PAGE and corresponding assays performed *in vitro*. Aggregation experiments were used to elucidate the effect of MMP-13 and catalytically inactive (E204A)MMP-13 on washed platelet activation in response to CRP-XL, A23187, thrombin and fibrillar Type I collagen. The degradation of VWF by MMP-13 was confirmed via SDS-PAGE and Edman degradation. MMP-13 on coated and plasma-borne VWF proteolysis on platelet adhesion, rolling and thrombus size were analysed under flow conditions in whole blood. The effect of MMP-13 on VWF multimerisation was assessed via agarose gel electrophoresis.

Results: Both latent and active forms of MMP-13 bind to washed platelets via GPVI and αIIbβ3 and can be inhibited by scFvs and RGD peptides respectively. Although MMP-13 is able to cleave rhGPVI, no evidence was found for sheddase activity *in vitro*. These interactions, while resulting in some degree of platelet shape change, do not impede the activation of platelets or a significant inhibition of aggregation in response to any agonist tested. Pre-incubation of active MMP-13 and (E204A)MMP-13 with whole blood however resulted in a differential reduction in surface coverage and volume of the thrombi formed on fibrillar collagen. Pre-treatment of whole blood with MMP-13 resulted in a decrease in thrombus height and platelet rolling on intact coated VWF. In contrast, surface coverage and height of thrombi formed on MMP-treated VWF were increased. SDS-PAGE following incubation of MMP-13 with VWF confirmed cleavage of the glycoprotein between the D3 and A1 domains. This MMP-mediated proteolysis resulted in an impairment of VWF multimer assembly as assessed by agarose gel electrophoresis.

Summary/Conclusions: Under high shear VWF is unfolded and is cleaved by the protease ADAMTS13. Here we report that the collagenase MMP-13 is also able to cleave VWF; albeit at a different site than ADAMTS13. Further studies will determine how pro- and anti-thrombotic flow conditions affect VWF cleavage by MMP-13.

PA 2.09-6
Von Willebrand factor and ADAMTS-13 in hypertensive disorders of pregnancy

Bayoumy N, Al-Sharaidh A, Babay ZAH and Abdulgader AM
King Saud University, Riyadh, Saudi Arabia

Background: Normal pregnancy is associated with hypercoagulability, endothelial activation and suppression of fibrinolysis. Haemostatic changes are, mostly, exaggerated when pregnancy is complicated with hypertensive diseases of pregnancy (HDP). HDP are a common cause of maternal morbidity and mortality, but much remains to be known about the underlying pathophysiology. Earlier studies have shown that HDP are accompanied, and occasionally preceded, by significant endothelial cell damage, platelet activation and enhanced intravascular thrombin generation. von Willebrand Factor (VWF) is an adhesive glycoprotein that plays a major role in primary haemostasis. Increased levels are commonly reported in normal pregnancy. The main mechanism regulating VWF molecular size and function is its cleaving protease ADAMTS13 (A disintegrin and metalloprotease with thrombospondin) that controls the release of the highly thrombogenic ultra large ULVWF multimers. Factors disturbing this balance may cause pathologic conditions ranging from bleeding to thrombosis.

Aims: We aimed to study the changes in plasma antigen levels of VWF, and ADAMTAS-13 in Saudi patients with HDP in the antenatal and postnatal periods in comparison with normal pregnancy.

Methods: This case-control cross-sectional study included 109 patients with HDP; 49 preeclampsia (PE), 60 gestational hypertension (GH) and 100 women with normal pregnancy as control group. Subjects were recruited in the third trimester and 24 h post-delivery at a tertiary care facility in the capital Riyadh. Commercially available Enzyme immunosorbant assay (ELISA) kits were used to measure plasma antigen concentrations of VWF and ADAMTS-13.

Results: The plasma levels of VWF were significantly higher in PE and GH in both the antenatal and postnatal periods as compared to normal pregnancy ($P < 0.001$). The levels of ADAMTS-13 were significantly lower in PE and GH in both the antenatal and postnatal periods, as compared to normal pregnancy ($P = 0.001$, $P = 0.002$ respectively). VWF levels were elevated, 24 h after delivery, in all three groups and reached statistically significant levels in GH patients ($P = 0.02$). However, ADAMTS-13 did not change significantly in the postnatal period. No significant correlation was found between VWF and ADAMTS-13 plasma levels in all groups. Also, levels were not associated with O and non-O blood groups.

Conclusion: PE and GH and associated with significant increase of VWF and decrease of ADAMTAS-13 antigen levels which reflect an exaggeration of the prothrombotic state that characterizes normal pregnancy. Also, the further elevation of VWF levels after delivery and with no change in of ADAMTS13 levels add to the heightened hypercoagulability which is believed to underlie the pathogenesis of HDP. All level changes seem to be independent of ABO blood groups.

Novel VKORC1 variants are associated with the higher acenocoumarol requirements

Ana A[1], Cerezo-Manchado JJ[2], Constantino M[2], Jose P[2], Perez-Andreu V[2], Javier C[2], Vicente V[2], Vanesa R[2] and Gonzalez-Conejero R[2]
[1]Centro Regional de Hemodonacion; [2]Centro Regional de Hemodonación, Hospital Morales Meseguer, UMU, IMIB, Murcia, Spain

Background: Algorithms combining both clinical and genetic data have been developed to improve oral anticoagulant therapy. All of them have confirmed that three polymorphisms in two genes, *VKORC1* and *CYP2C9*, are the main coumarin dose determinants. Additional genetic elements have to be involved in the response to oral anticoagulant, although no further polymorphisms (SNPs) with a relevant pharmacogenetic importance have been identified, and according to recent GWAS analysis is not expected.

Aim: To identify new pharmacogenetic variations involved in oral anticoagulant therapy in *VKORC1*, the main element of this pathway.

Methods and Results: Our retrospective study recruited 3949 consecutive Caucasian patients taking acenocoumarol. Patients were eligible to take part in the study if aged 18 years or over and were steadily anticoagulated (defined as a period of at least 3 weeks with three or more consecutive INR measurements with < 10% change within the target range in the acenocoumarol dose). Exclusion criteria were a diagnosis of cancer, alcohol or drug abuse, acenocoumarol allergy/intolerance, terminal disease, known or suspected pregnancy and intake of amiodarone, antifungal drugs, anti-platelet drugs and/or statins. Clinical and demographical data were obtained from the medical records and the database: 1947 males (49%); median age, 74 ± 10 years; median body mass index, 29.5 ± 7.4. Most patients (90%) were anticoagulated with an INR target range of 2.0–3.0% and 10% of them had an INR target range of 2.5–3.5. All 3949 patients were genotyped for the *VKORC1* rs9923231 and *CY2C9** polymorphisms. These polymorphisms defined 18 genetic profiles. For each profile, we identified the average dose of carriers. Patients with dose requirements outside the mean ± 2 SD value according to their genetic profile were identified as *"outlier"* patients ($N = 145$). Patients with clinical factors that explained the abnormal dose requirements (i.e., autoimmune diseases, liver failure, severe heart failure, severe chronic obstructive pulmonary disease, acenocoumarol interacting drugs, new thrombotic events, obesity and

associated tumoral diseases) as well as those patients with no available clinical data were excluded ($N = 88$). In the remaining 57 patients (all with higher doses than expected) the promoter and coding regions of *VKORC1* were sequenced. We identified *VKORC1* genetic changes in 14 patients. Four patients carried *VKORC1* variants previously related to high coumarin doses (L128R, $N = 1$ and particularly D36Y, $N = 3$).Three polymorphisms were also detected: rs17878544 ($N = 5$), rs55894764 ($N = 4$) and rs7200749 which was in linkage disequilibrium with rs17878544 ($N = 2$). Finally, 2 patients had lost the rs9923231/rs9934438 linkage. The prevalence of these variations was higher in these patients than in the whole sample. Multivariate linear regression analysis revealed that only D36Y and rs55894764 variants significantly affect the dose, although the improvement in the prediction model is small (from 39% without their inclusion to 40% if the analysis included these mutations).

Conclusion: Our strategy identified *VKORC1* variants associated with higher acenocoumarol doses. Further studies are necessary to test their influence on the *VKORC1* function and the cost/benefit of their inclusion in pharmacogenetic algorithms.

PA 2.10-2

Ensuring an efficient transition from rivaroxaban to warfarin: a pharmacodynamic study in healthy subjects

Moore T[1], Vaidyanathan S[2], Natarajan J[1], Ariyawansa J[1], Turner KC[1] and Byra W[1]

[1]Janssen Pharmaceutical Research & Development LLC; [2]Janssen Research and Development LLC, Raritan, NJ, USA

Background: Clinical scenarios may arise when it is necessary to transition patients from rivaroxaban to a vitamin K antagonist such as warfarin. Maintaining appropriate anticoagulation, without increasing the risk of thrombosis or adverse bleeding events, is key when transitioning patients between anticoagulants.

Aims: The primary objective of this study was to evaluate the pharmacodynamic changes when transitioning healthy subjects from steady-state rivaroxaban 20 mg once daily (od) to warfarin, dose-adjusted to an international normalized ratio (INR) range of 2.0–3.0.

Methods: This was an open-label study conducted in 46 healthy adults. This study was comprised of a screening phase and two treatment periods (TP1 and TP2) with a ≥ 14 day wash-out in-between. During TP1, subjects received rivaroxaban monotherapy 20 mg od for 5 days followed by rivaroxaban 20 mg od + warfarin 10 mg od for 2–4 days (warfarin dose could be adjusted after 2 days based on the trough INR value on Day 8), co-administered each morning. When a trough (pre-dose) INR ≥ 2.0 was achieved during this transition phase, subjects were switched to warfarin monotherapy (dose range: 0 [no dose] to 15 mg od) for 4 days to achieve/maintain an INR range of 2.0–3.0 by the last day of warfarin monotherapy. TP2 involved just a warfarin monotherapy control arm, in which subjects received the same warfarin regimen administered in TP1. Each TP was followed by a single oral dose of vitamin K.

Results: During the TP1 transition phase, when rivaroxaban was co-administered with warfarin, INR and peak prothrombin time (PT) values were higher than those observed with either agent administered alone. The mean maximum effect (E_{max}) for INR values ranged from 2.79 to 4.15 (mean PT E_{max} values ranged from 41.0 to 62.7 s), with individual INR values reaching as high as 5.90. In comparison, warfarin monotherapy during TP2 produced mean INR E_{max} values ranging from 1.41 to 1.74 (mean PT E_{max} values ranged from 20.1 to 25.2 s). However, rivaroxaban had a minimal effect on INR values at trough drug levels during the TP1 transition phase (mean trough INR values during co-administration were similar to those observed with warfarin monotherapy). Maximum plasma concentrations (C_{max}) for both rivaroxaban and warfarin seemed to be unaffected when the drugs were co-administered: a finding that is consistent with results obtained from a previously conducted drug-drug interaction study. Study drugs were generally well tolerated (alone or combined), although three subjects withdrew owing to adverse events. No significant bleeding events were observed, even in subjects with elevated INRs during the transition phase, and no discontinuations or serious adverse events occurred because of bleeding events.

Summary/Conclusions: This study showed that healthy adult subjects can be safely transitioned from steady-state rivaroxaban to warfarin based on a target INR of 2.0–3.0. Importantly, when transitioning patients, the INR value used to determine the next warfarin dose should always be taken at a trough (24 h after the last rivaroxaban dose) in order to minimize the transient additive INR effect of rivaroxaban.

PA 2.10-3

Postdischarge mortality risk and risk factors for mortality in acutely ill medical patients following hospitalization

Mahan CE[1], Fields LE[2], Mills RM[3], Stephenson J[4], Fu AC[4], Fisher D[4] and Spyropoulos AC[5]

[1]University of New Mexico, Albuquerque, NM; [2]Janssen Scientific Affairs, LLC, Raritan, NJ; [3]Janssen Research and Development, LLC, Raritan-Titusville, NJ; [4]HealthCore, Inc., Wilmington, DE; [5]North Shore/LIJ Health System; Lenox Hill Hospital; Hofstra School of Medicine, New York, NY, USA

Background: Conflicting evidence exists regarding the benefit of venous thromboembolism (VTE) prophylaxis on mortality in hospitalized acutely ill medical patients, who may also be at-risk after discharge. We identified characteristics associated with receiving thromboprophylaxis after discharge and compared the risk of within-90-day mortality among those patients who did or did not receive thromboprophylaxis.

Aims: To evaluate post-discharge antithrombotic drug use, risk of short-term mortality, and risk factors for mortality.

Methods: We conducted a retrospective healthcare claims analysis of patients aged ≥ 40 years hospitalized ≥ 2 days for nonsurgical reasons between 2005 and 2009 using the HealthCore Integrated Research Database. VTE and rehospitalization were identified by ICD-9-CM codes while use of antithrombotics was captured from pharmacy claims. All-cause mortality was ascertained using the Social Security Death Index and cause of death was identified utilizing the National Death Index. Hazard ratios (HR) for mortality risk factors were estimated using multivariate survival analysis and Cox proportional hazards models.

Results: A total of 327,578 patients were included (median age, 65 years; mean hospital stay, 4.6 days). Of those, 11.6% received at least one post-discharge antithrombotic medication, with 3.9% receiving anticoagulants only. The final post-discharge mortality cohort consisted of 11,922 patients with a median age at death of 80 years compared to 64 years for patients that did not die ($P < 0.001$). Cancer was the most common cause of death ($n = 4695$; 39.4%) followed by overall cardiovascular disease ($n = 3293$; 27.6%). Only 24 and 171 of patients had VTE or major bleeding indicated as a cause of death (0.2% and 1.4%, respectively). Compared with patients that survived within 90 days, significantly fewer patients in the mortality cohort received post-discharge antithrombotics (5.3% vs. 11.9%, $P < 0.001$), and for a significantly shorter mean [SD] duration of time (29 [19] vs. 59 [24] days, $P < 0.001$). In general, mortality rates of patients who did not receive any antithrombotics were significantly higher than those of patients who did. Absence of antithrombotic use (HR 1.6252, 95% Confidence Interval [CI] 1.4999–1.7610), stroke (HR 1.1275, 95% CI 1.0489–1.2120), severe lung disease (HR 1.0693, 95% CI 1.0293–1.1108), age (HR 1.0049, 95% CI 1.0032–1.0065) and index hospitalization length of stay (HR 1.0077, 95% CI 1.0054–1.0100) were significant predictors of post-discharge mortality. Absence of anticoagulants and antiplatelets were also predictors for

mortality (HR 1.5573, 95% CI 1.4003–1.7320 and 1.6774, 95% CI 1.4967–1.8798, respectively). For patients receiving anticoagulants, cancer was a significant risk factor for mortality (HR 1.0620, 95% CI 1.0120–1.1146).

Conclusions: Patients prescribed antithrombotic medications in a heterogeneous medical population had a lower risk of short-term mortality. The described risk factors for mortality may guide future studies assessing potential mortality benefits with thromboprophylaxis in specific subsets of medical patients and are hypothesis generating.

PA 2.10-4

A high risk of falls is associated with an increased risk of medically-relevant non-major bleeding in elderly patients receiving anticoagulants

Méan M[1], Aujesky D[1], Limacher A[2] and Kämpfen P[3]
[1]Inselpital; [2]University of Bern; [3]Inselspital, Bern, Switzerland

Background: Whether a high falls risk significantly increases the risk of bleeding in patients receiving anticoagulants is still a matter of debate.

Aims: We aimed to evaluate whether a high falls risk is associated with an increased risk of bleeding in elderly patients receiving anticoagulants for acute venous thromboembolism (VTE).

Methods: In a multicenter prospective Swiss cohort, we prospectively enrolled consecutive patients aged ≥ 65 years who received anticoagulants (low-molecular-weight heparin, fondaparinux, and/or vitamin K antagonists) for acute VTE between September 2009 and March 2012. We prospectively assessed the falls risk by asking patients two validated questions: (i) 'Did you fall during the last year?', (ii) 'Did you notice any problems with gait, balance or mobility?'. If at least one of these questions was answered positively, the falls risk was considered high. The primary outcome was the occurrence of a first major bleeding, defined as fatal bleeding, symptomatic bleeding in a critical site, or bleeding causing a fall in hemoglobin ≥ 20 g/L or leading to the transfusion ≥ 2 units of red blood cells. The secondary outcome was the occurrence of a first non-major bleeding requiring medical attention. To examine the association between falls risk and bleeding, we used a Cox proportional hazards model, adjusted for age, gender, history of major bleeding, anemia, thrombocytopenia, cardiac disease, diabetes mellitus, arterial hypertension, active cancer, chronic liver disease, chronic renal disease, overt pulmonary embolism, surgery in the last 3 months, polypharmacy, concomitant treatment with antiplatelet agents, and history of stroke or transient ischemic attack.

Results: Of 991 enrolled patients, 458 (46.2%) had a high risk of falls. The mean ± SD follow-up duration was 17 ± 10 months. The overall incidence rate of major and medically-relevant non-major bleeding was 7.9 events per 100 person-years and 12.0 events per 100 person-years, respectively. Patients with a high falls risk had a somewhat higher rate of major bleeding (9.6 vs. 6.6 per 100 patient-years; $P = 0.06$) and a significantly higher rate of medically-relevant non-major bleeding (16.7 vs. 8.3; $P < 0.001$) than patients with a low falls risk. After adjustment, a high falls risk was significantly associated with non-major bleeding (hazard ratio [HR] 1.67, 95% confidence interval [CI] 1.18–2.36; $P = 0.004$) but not with major bleeding (HR 1.18, 95% CI 0.78–1.77; $P = 0.43$).

Discussion: In this prospective cohort of elderly patients with acute VTE, patients at high falls risk had a significantly increased risk of medically relevant non-major bleeding. A high falls risk may be an argument against prolonging anticoagulation duration beyond 3 months in such patients.

PA 2.10-5

Reversal of the effects of new oral anticoagulants by administration of FEIBA

Schiviz A, Verdino D, Schrenk G, Resch M, Neyens I, Dietrich B, Turecek PL, Scheiflinger F, Muchitsch EM and Höllriegl W
Baxter Innovations GmbH, Vienna, Austria

Rivaroxaban and dabigatran, a direct factor Xa inhibitor and a direct thrombin inhibitor, respectively, are new oral anticoagulants (NOACs) used in a large number of patients to prevent thromboembolic disease following orthopedic surgery and non-valvular atrial fibrillation. In the event of a major bleed, however, there is no specific way to reverse their anticoagulant effect. The presented studies evaluated the potential of FEIBA, a licensed activated prothrombin complex concentrate, to reverse the anticoagulant effect of rivaroxaban or dabigatran.

Six male NZW rabbits per group received an i.v. dose of 25, 50, or 100 IU/kg FEIBA. Saline was used as a negative control item. Efficacy was defined as a correction of the animals' thrombelastogram (*R*-time) compared with saline-treated controls. Other coagulation variables were assessed for additional information.

After assessment of baseline coagulation parameters, animals received 1.2 mg/kg of the respective NOAC. Buffer was used as a negative control item to validate the model. Ten minutes later, coagulation was assessed followed by i.v. administration of test or reference item. Another 5 min and 1 day later, coagulation was assessed again.

Administration of NOACs led to an increased median *R*-time (from 21.5–35.5 to 67.3–120.0 min), aPTT, PT and reduced thrombin generation in all groups. Administration of saline showed no effect on coagulation parameters.

Treatment with 25, 50, or 100 U/kg FEIBA led to a dose-dependent correction of the prolonged *R*-time (28.6, 24.9 and 12.6 min with rivaroxaban; 46.5, 42.0 and 33.8 min with dabigatran). *R*-time on day 1 was similar to baseline values.

This procoagulant effect of FEIBA was also seen in other coagulation variables: Treatment with 25, 50 or 100 U/kg FEIBA led to a correction of the prolonged PT (9.15, 8.3 and 9.1 s with rivaroxaban; 9.90, 7.70 and 6.80 s with dabigatran) and dose-dependent increase in thrombin generation (56.0, 81.1 and 103.6 nM with rivaroxaban; 77.5, 167.5 and 406.7 nM with dabigatran) 5 min after administration. Intravenous administration of FEIBA also corrected aPTT after pretreatment with rivaroxaban (39.55, 38.80 and 40.40 s). After pretreatment with dabigatran, however, aPTT remained above baseline 5 min after treatment with FEIBA (56.40, 62.90 and 62.00 s).

In summary, the results of our studies show that FEIBA effectively and quickly corrects NOACs' anticoagulant effect, and thus may be a suitable antidote for bleeding complications after treatment with NOACs.

PA 2.10-6

Methodological problems in network meta-analysis of studies with the new oral anticoagulants

Harenberg J[1], Weiss C[2] and Weiss C[2]
[1]Clinical Pharmacology; [2]Biometry and Statistics, Mannheim, Germany

Background: The efficacy and safety of the new oral anticoagulants (NOACs) dabigatran, rivaroxaban and apixaban have been demonstrated for prevention of venous thromboembolism following total knee- (TKR) and hip-replacement surgery (THR), and of ischemic stroke and systemic embolism in atrial fibrillation (AF). Direct comparisons of the NOACs on these indications are unlikely to be conducted in the near future. Patients and practioners may wish a scientific rationale for which NOAC to preferentially use on a specific indication. Network meta-analyses (NMA) are statistical tools feasible to compare indirectly the NOACs on their efficacy and safety outcomes. Several network NMAs have recently been presented. The statistical methods of the indi-

rect comparisons differ to some extend and there is a need for standardized procedures to document more precisely endpoints in the studies and to follow rules for conducting NMAs.
Aim: The aim of the present study is to identify the methodological differences of the NMAs performed with NOACs in THR/TKR surgery and in patients with AF and to relate their methods to the published guidelines for Preferred Reporting Items for Systematic reviews and Meta-aAnalyses (PRISMA) and for conducting NMAs published by the International Society for Pharmacoeconomics and Outcome rResearch (ISPOR).
Methods: The NMAs were subjected to the adherence to the PRISMA and ISPOR guidelines. NMAs were checked (i) for presentation of data on risk of bias of each trial regarding the definition and documentation of bleeding and thromboembolic events (PRISMA item 12 and 19, (ii) for handling of potential statistical biases, the on relative-effect estimates (odds ratio, relative risk, hazard ratio, differences in change from baseline), levels of significance and differences across studies that may violate similarities (ISPOR).
Results: PubMed and internet search strategies identified seven NMAs with NOACs for prevention of venous thromboembolism following TKR and THR and 10 NMAs for prevention of stroke and systemic embolism in patients with AF. As major differences between the NMAs were identified: (i) analyzed only efficacy and not safety endpoints, (ii) combined results of NOACs, (iii) combined results of control groups, (iv) analysed subgroups without access to original data, (v) not analysed differences in biographic trial-data, (vi) or determined hazard ratio without access to the original data (time of event relevant), (vii) not reported *P*-values, (viii) not reported the use of ISPOR criteria.
Conclusion: We conclude that further standardization of the definition and reporting of efficacy and safety endpoints in trials on anticoagulants are required as well as how to adopt PRISMA and ISPOR criteria in NMAs before drawing definite conclusions on which NOAC that is preferable in a given situation. Guidelines based on a wider matrix of scientific information than purely trial-data should be recommended until an international standard on all key levels of the anticoagulant drug development process has been agreed. Until such guidelines are available only results of NMAs should be recommended which used the rigorous methods published by PRISMA and ISPOR.

Thrombin generation monitored in capillary blood with a calibrated automated thrombogram-based assay

Krishnamoorthy G[1], De A[2], Ninivaggi M[1], Apitz-Castro R[1], Carlen ET[2], Ten Cate-Hoek AJ[3], Hemker CH[1], De Bas L[1] and Lindhout T[1]
[1]Synapse b.v., Maastricht; [2]University of Twente, Enschede; [3]University Medical Center, Maastricht, The Netherlands

Background: The calibrated automated thrombogram (CAT) assay in plasma is a versatile tool to investigate patients with hypo- or hypercoagulable phenotypes. Recently we have published a thrombin generation (TG) method applicable to whole blood.
Aim: The aim of the current study was to develop a method capable of measuring thrombin generation from capillary blood (via finger-puncture) enabling near-patient testing.
Method: To study TG in capillary blood we have developed a miniaturized bedside device that consists of a microfluidic chip, handheld dual-channel fluorometer, and foil heater. The device is connected to a handheld computer. The device has been technically validated using citrated blood and finger prick blood from healthy volunteers and patients taking oral anti-coagulants. Thrombin generation was initiated with 5 pM tissue factor (TF). The read-out thrombogram parameters were endogenous thrombin potential (ETP), thrombin peak (TP), lagtime and time to peak.
Results: In the newly developed miniaturized device, repeated TG measurements ($n = 8$) with citrated blood from one healthy volunteer gave inter-assay coefficients of variation (CV) for ETP and TP of 7% and 11%, respectively (in whole blood CAT, CV of 12% for ETP and 11% for TP).
Applying this technique to samples from patients on warfarin treatment in the range INR 1–6 we found a good correlation between INR and ETP ($R^2 = -0.97$, $P < 0.01$) as well as between INR and TP ($R^2 = -0.91$, $P < 0.01$).
Validation with blood from a finger puncture (capillary blood) showed an inter-assay CV for ETP and TP of 5% and 14%.
Conclusions: We have developed a small portable device capable to measure with high precision TG in a single drop of (capillary) blood.

PA 2.11-2

Optical tracking of acoustic radiation force induced motion in plasma to estimate viscoelastic measurements of blood coagulation

Wang C, Perez MJ, Viola F and Lawrence MB
University of Virginia, Charlottesville, VA, USA

Background: Several viscoelastic measurements of blood coagulation have been used in clinical care to diagnose and guide the treatment of bleeding or thrombotic disorders. The current devices have been shown to improve patient outcome while reducing the use of blood products. Sonorheometry is a novel viscoelasticity measurement technique that assesses the relative stiffness of a sample by application of acoustic radiation force from ultrasound pulses. The returning echoes are analyzed to determine a relative measure of displacement of the material in response to the applied force. The algorithm used in sonorheometry depends on time delay estimation of the ultrasound pulse, an indirect measure of particle displacement, in order to make its viscoelastic measurements.
Aims: Our work investigates the viscoelastic measurement capabilities of direct optical.
Methods: of measuring particle displacement by acoustic radiation force in order to verify that sonorheometry measurements are indeed representative of changes in stiffness. We hypothesize that (i) optical tracking of bead movement due to acoustic radiation force can detect the viscoelastic changes that occur in the coagulation of plasma, and (ii) that the optical measure of viscoelasticity will provide comparable displacement measurements to those obtained with sonorheometry.
Methods: We utilized 15 μm polystyrene beads in plasma as a source of acoustic reflectors and targets for motion tracking. The bead motion in response to the applied ultrasound pulses was observed by microscopy and quantified using a particle tracking program implemented in Image J. The end point displacements of the bead after 1 s of ultrasound pulse sequence were plotted over the course of up to 40 min of sample coagulation to give a relative compliance curve.
Results: In this study, we show that plasma in which coagulation was initiated with kaolin developed significantly increased stiffness over the course of minutes. Bead displacement reduced from initial velocities of 30 μm/s to near zero 20 min after initiation of clotting. The relative compliance curves collected had the same shape as the curves produced by thrombelastography or sonorheometry. At 15 min after clot initiation, inhibition of $\alpha_{IIb}\beta_3$ by the Fab fragment abciximab reduced platelet rich plasma clot stiffness by 43% relative to control plasma. Bulk clot stiffness was reduced 48% relative to control for platelet rich plasma treated with cytochalasin D, an inhibitor of platelet cortical actin polymerization.
Conclusions: We observed a time dependent change in stiffness due to clotting based on tracking microparticles under the influence of acoustic radiation force. In addition we observed reduced stiffness of platelet-inhibited plasma as compared to control platelet rich plasma. In summary, motion of microparticles in response to the application of acoustic radiation force by ultrasound can be used to measure changes in viscoelasticity of the blood plasma.

PA 2.11-3

Six novel missense mutations causing factor X deficiency and application of thrombin generation test

Liang Q[1], Chen Q[1], Ding Q[2], Wu F[3], Wang X[2], Xi X[1] and Wang H[1]
[1]*State Key Laboratory of Medical Genomics, Shanghai Institute of Hematology;* [2]*Department of Laboratory Medicine, Ruijin Hospital;* [3]*Department of Geriatric, Ruijin Hospital, Shanghai, China*

Background: Inherited factor X (FX) deficiency is a rare hemorrhagic condition characterized by a variable clinical presentation poorly correlating with laboratory phenotype and genotype. Thrombin generation test (TGT) is a newly developed global coagulation assay, which offers potential clinical advantages in the evaluation of hypocoagulable states, but its application in FX-deficient patients is rarely reported.
Aims: In the present study, we investigated the role of thrombin generation as a tool for assessing bleeding tendency in four unrelated pedigrees with FX deficiency.
Methods: Five FX assays were performed using clotting, chromogenic and immunological methods. FX gene defects were analyzed by direct sequencing. Thrombin generation was measured using a standard procedure in platelet-poor plasma of patients and normal control using 1 and 5 pM of tissue factor (TF), respectively.
Results: Seven missense mutations were identified in four probands, six of which (Ser425Pro, Ala-29Pro, Phe324Leu, Ala235Thr, Cys111Arg and Met362Thr) were novel and associated with type I FX deficiency. Arg347Cys was previously reported by us and accounted for type III FX deficiency (proband 3). Peak and Rate parameters measured at 1 pM TF were closely correlated with the clinical manifestations of the patients and the results revealed a higher sensitivity for FX deficiency at 1 pM TF compared with 5 pM TF.
Conclusion: TGT may serve as a useful laboratory tool to assess the individual clinical manifestation of patients with FX deficiency. Lower TF concentration (1 pM) is suggested to make the assay more sensitive to discriminate clinical severity of patients.

PA 2.11-4

Fibrinogen activity determined by rotational thromboelastometry is affected by high haematocrit

Westbury S[1], Lee K[2], Reilly-Stitt C[2], Tulloh R[1] and Mumford AD[1]
[1]*University of Bristol;* [2]*University Hospitals Bristol NHS Foundation Trust, Bristol, UK*

Background: Whole blood viscoelastometry may help selection of appropriate coagulopathy treatments in settings such as cardiac surgery. However, viscoelastometry assay end-points are influenced by the red cell concentration in whole blood which may affect interpretation of test results.
Aim: To investigate the effect of high haematocrit (HCT) on whole blood clot formation and clot viscoelastic strength, by comparing ROTEM® thromboelastometry and plasma coagulation test results in patients with cyanotic congenital heart disease (CCHD) and in model high HCT blood.
Methods: Blood samples from adults with CCHD and stable HCT (> 0.55 L/L) were collected into tubes containing HCT-adjusted volumes of 0.105 M tri-sodium citrate during routine clinic phlebotomy.
Model *high* (0.44–0.62 L/L) and *very high* (0.63–0.75 L/L) HCT blood was generated by adding autologous packed red cells to blood samples from healthy controls with *normal* HCT (0.35–0.43 L/L). The HCT, platelet count, prothrombin time (PT), activated partial thromboplastin time (APTT) and Clauss fibrinogen (CF) were determined using standard techniques. The whole blood fibrinogen concentration (WBFC) was calculated using the formula WBFC = (1−HCT) × CF (g/L). The clot time (CT), clot formation time (CFT), α-angle and maximum clot firmness (MCF) were determined by ROTEM viscoelastometry using the EXTEM® and FIBTEM® reagents.
Results: Compared to normal HCT controls, high HCT blood samples from CCHD patients displayed prolonged EXTEM CT and CFT, reduced EXTEM α-angle and MCF, prolonged FIBTEM CT and reduced FIBTEM MCF. The platelet count and WBFC were reduced in the CCHD blood samples compared to controls. The PT, APTT and CF were similar to controls.
The model *high* and *very high* HCT blood samples displayed the same pattern of ROTEM changes as the CCHD patients, which were greatest in the *very high* HCT group (median EXTEM CT *normal* 50 s vs. *very high* 81 s; EXTEM CFT *normal* 75 s vs. *very high* 151 s; EXTEM α angle *normal* 75° vs. *very high* 62°; EXTEM MCF *normal* 64 mm vs. *very high* 52 mm; FIBTEM CT *normal* 47 s vs. *very high* 85 s; FIBTEM MCF *normal* 14 mm vs. *very high* 5 mm, all $P < 0.0001$). The WBFC was reduced in the model high HCT blood compared to controls (median WBFC *normal* 1.59 g/L vs. *very high* 0.85 g/L; $P < 0.0001$). There were no differences in PT, APTT or CF between model groups and controls. Across all model groups, the FIBTEM MCF correlated linearly with WBFC ($r^2 = 0.59$; $P < 0.0001$) but not with CF ($r^2 = 0.03$; $P = 0.18$).
Summary and Conclusions: We show for the first time using blood samples with HCT-adjusted anticoagulant volume, that high HCT in blood samples from CCHD patients and in model blood causes changes in ROTEM test results suggestive of hypocoagulability. Although the FIBTEM MCF predicts plasma fibrinogen concentration (CF) at normal HCT, this relationship is disrupted at high HCT. However, FIBTEM MCF remains correlated with WBFC irrespective of HCT suggesting that high HCT reduces FIBTEM MCF by a simple dilution effect of the increased red cell concentration. The influence of HCT should be considered carefully during interpretation of ROTEM results in clinical settings.

Evaluation of the activated partial thromboplastin time assay for clinical monitoring of PEGylated recombinant factor VIII (BAY 94-9027) for hemophilia A

Gu J-M, Ramsey P, Evans V, Tang L, Apeler H, Leong L, Murphy JE, Laux V and Myles T
Bayer HealthCare Pharmaceuticals, San Francisco, CA, USA

Background: BAY 94-9027, a site-specific PEGylated factor VIII (FVIII) with a longer plasma half-life than native FVIII, is currently in clinical development for prophylactic treatment of hemophilia A. Clinical monitoring of FVIII:C activity in patients with hemophilia (PWH) is performed using the activated partial thromboplastin time (aPTT) assay.
Aim: It is highly important for diagnostic and patient care that aPTT results are interpreted correctly. Therefore, we evaluated the aPTT for clinical monitoring of BAY 94-9027.
Methods: BAY 94-9027 and the World Health Organization 8th International Standard for FVIII (WHO-8) were spiked into pooled and individual severe hemophilia A plasma samples at 1.0, 0.25, and 0.05 IU/mL. Five commercial aPTT reagents widely used in clinical laboratories were compared and evaluated for BAY 94-9027 activity in plasma from PWH using the ACL TOP and STAGO STA compact analyzers.
Results: BAY 94-9027 and WHO-8 bestow similar clot times (CTs) and excellent precision in both analyzers when ellagic acid aPTT reagents (SynthAFax, Dade Actin, and Cephascreen) are used. In contrast, BAY 94-9027 shows significantly prolonged CT and poor precision compared with WHO-8 using silica aPTT reagents (APTT-SP and STA-PTT5). Furthermore, free polyethylene glycol (PEG)-60 kD used for the conjugation of FVIII shows dose-dependent prolongation of CT in the APTT-SP assay. There was no effect on the SynthAFax-aPTT, the prothrombin time, or the activated factor XI-initiated

thrombin generation assay, demonstrating that the PEG moiety on FVIII has no general effect on coagulation cascade and most likely interferes with contact activation on the silica surface.
Conclusion: Ellagic acid aPTT reagents (SynthAFax, Dade Actin, Cephascreen) are most suitable for evaluating potency of BAY 94-9027 and should be used in clinical laboratories for monitoring FVIII activity after infusion of BAY 94-9027 to PWH.

PA 2.11-6
Investigation of the use of a proteomic approach to detect intravascular coagulation

Goodwin C, Scully MF and Kakkar A
Thrombosis Research Institute, London, UK

Background: At present, intravascular coagulation is diagnosed by measuring the level of activation markers such as Prothrombin fragments F1 + 2, thrombin-antithrombin complex and D-dimer. However in other areas of medicine (e.g. cancer), the use of proteomic fingerprinting is under development since it can be used to characterise the underlying mechanism driving the disease, to detect disease at the early stages and to determine therapeutic efficacy, as part of the movement towards personalized medicine.
Aim: To compare the proteomic fingerprint of plasma to that of serum to determine the potential of proteomic fingerprinting for the diagnosis of intravascular coagulation.
Method: Forty-five microlitre of citrated NHP at 37 °C was mixed with 5 μL of diluted tissue thromboplastin (IL)/$CaCl_2$ 100 mM mixture. At 0, 4 and 180 min following recalcification, reactions were terminated by the addition of 950 μL of 0.1% trifluoroacetic acid (TFA). After removal of the clot, the sample was centrifuged at 13,000 r.p.m. for 2 min. Peptides were extracted from the sample by the addition of 80 μL of RPC-18 beads (Dynabeads) to 200 μL of the TFA treated sample. After 5 min incubation, the beads were washed and extracted with 10% acetonitrile (AcN). The AcN extract was pipetted onto the surface of a Bio Rad Protein Chip NP-20 array, the chip was allowed to dry and Sinapinic acid according to the manufacturer's instructions. Chips were read using a Ciphergen Protein Biological Systems II Ca ProteinChip reader (Bio-Rad). The detector was optimized in the range of 1–8 kDa and mass spectrometry profiles were generated at three different laser intensities. Peak detection was performed using ProteinChip Biomarker Wizard software version 3.1 and the intensity of each compared between each of the three groups (NHP and 4 and 180 min after initiation of clotting, respectively) using Biomarker Wizard.
Results: Around 70 separate peaks of mass between 1022 (M/Z) to 7154 (M/Z) were detected in the AcN extracts. From the profile of the change in intensity over the time course of clotting, the peaks could be divided into four groups. The majority of the peaks were in Group 1 in which the intensity of the peak remained unchanged from plasma apart from a slight fall at 180 min. Group 2 contained seven peaks which increased abruptly and significantly ($P < 0.02$) at 4 min but then dropped at 180 min (e.g FpA which decays to des Ala FpA). Three peaks were in Group 3 which showed a progressive decrease at 4 and 180 min. Group 4 contained 20 peaks which exhibited an increase from low levels at $t = 0$ and 4 min to high levels at 180 min.
Conclusion: The large number of peptides (in the range of 1189–4403 M/Z) which have been shown to change in level during the clotting of plasma suggests that this approach can be used to develop proteomic fingerprints for the diagnosis of intravascular coagulation using statistical approaches such as decision tree analysis or neural networks.

PA2.12 – Coagulation Factor VIII – III

PA 2.12-1
Enhancing expression of coagulation factor VIII through bioengineering: strategic introduction of Asn-linked glycan improves secretion

Selvaraj SR, Miao H and Pipe S
University of Michigan, Ann Arbor, MI, USA

Coagulation factor VIII (FVIII) is an essential cofactor of the intrinsic blood coagulation pathway and its deficiency results in hemophilia A. Commercial production of recombinant FVIII (rFVIII) in heterologous expression systems is 2–3 orders of magnitude lower than similarly sized proteins owing to multiple factors. FVIII is a complex glycoprotein containing upto 25 asparagine (N)-linked glycans and deletion of the entire B domain, that contains the bulk of these oligosaccharide structures, does not affect either expression or its procoagulant activity. Our preliminary results from site-directed mutagenesis of the non-B domain N-linked glycans indicated that N-239, present in the A1 domain, was the most crucial and N239Q reduced secretion by 35–50%. N-239, positioned at the A1–A2 interface, is situated just upstream of the putative BiP-binding site. BiP, a peptide dependent ATPase is known to interact with FVIII and retain unfolded protein within the endoplasmic reticulum. We therefore hypothesized that additional N-linked glycans in the vicinity of this region could improve efficiency of protein folding and improve secretion. Potential N-linked glycosylation sequons (K213N, L216S, A222N, M231N, and Y237S) were introduced into the A1 domain of full length wild type (WT), B domain deleted (BDD) and 226/N6 (bioengineered FVIII variant with enhanced secretion efficiency) FVIII backbones, through site-directed mutagenesis techniques. Transient transfections in COS-1, CHO and HEK-293t cells showed a 2-fold higher expression of K213N and L216S mutants across all three FVIII variant backbones. While the expression of A222N mutant was not significantly different from that of native FVIII, the mutants M231N and Y237S were poorly secreted. A similar increment in expression was observed for the K213N and L216S mutants over BDD (2.4 vs. 1.1 U/mL) and 226/N6 (11.6 vs. 5.4 U/mL) following hydrodynamic tail vein injections into $F8^{-/-}$ hemophilia A mice. An additional twofold enhancement in expression was observed upon incorporation of F309S, an A1 domain mutation which improves secretion possibly by diminishing FVIII association with BiP, into the 226/N6-L216S variant. Confirmation of the presence of an additional N-linked glycan structure in the L216S mutant through mass spectrometric analysis is currently underway. Previous studies have shown that porcine BDD-FVIII is secreted more efficiently than human BDD-FVIII. While the precise mechanism is still unclear, it has been suggested that structural variations between the A1, ap (activation peptide) and A3 domains of human and porcine FVIII might contribute to this secretion differential. Sequence alignment analysis revealed that porcine FVIII contains a potential glycosylation site at N-213 that is not conserved in human FVIII and is analogous to the K213N and L216S mutants engineered in this study. This additional N-linked glycan in the porcine A1 domain could partly account for the enhanced expression levels observed for recombinant porcine BDD-FVIII in cell culture systems. Also this region of the A1 domain was observed to be the most divergent between human and porcine BDD-FVIII with respect to the primary sequence.
Such targeted bioengineering strategies may facilitate more efficient secretion of rFVIII thereby enhancing commercial production for lower cost factor replacement therapy.

Functional consequences and founder effect of a recurrent mutation of F8 (c.6046C>T, p.R2016W) in patients with hemophilia A from Northern Italy

Garagiola I[1], Mortarino M[1], Mancuso ME[1], Fasulo MR[1], Seregni S[1], Santagostino E[1], Lotta LA[2] and Peyvandi F[1]

[1]*Fondazione IRCCS Cà Granda – Ospedale Maggiore Policlinico;* [2]*Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, Milan, Italy*

Background: Hemophilia A, the most common hereditary bleeding disorder, is caused by mutations in coagulation Factor VIII gene (*F8*). Knowledge on recurrent *F8* mutations may facilitate screening and genetic diagnosis in patients from specific geographic areas. By screening more than 300 haemophilia A patients from Northern Italy who referred to the Angelo Bianchi Bonomi Hemophilia and Thrombosis Center (Milan, Italy), we identified a recurrent mutation occurring in exon 19 of *F8*.

Aims: To characterize the functional effect of the mutation and determine the existence of a founder effect for the c.6046C>T (p.R2016W) mutation in exon 19 of *F8*.

Methods: Mutations of *F8* were searched for by PCR and Sanger sequencing in 335 patients with hemophilia A referred to the Angelo Bianchi Bonomi Hemophilia and Thrombosis Center (Milan, Italy). The functional effects of the c.6046C>T (p.R2016W) mutation were assessed by *in silico* annotation on *F8* gene models (URL:http://conseq.bioinfo; URL: http://bioinf.cs.ucl.uk/psipred) as well as on Polyphen 2 and SIFT prediction software (URL: http://genetics.bwh.harvard.edu/pph2/; http://sift.jcvi.org/). Analysis of *F8* mRNA was performed by reverse transcription (RT)-PCR and subsequent Sanger sequencing. Haplotype analysis using three intragenic (STR13, STR22 and STR24) and three extragenic (DXS1108, DXS1073, and DXS7423) polymorphic microsatellites markers was employed to investigate a potential founder effect. DMLE+2.3 software was used to estimate mutation age using linked markers.

Results: A c.6046C>T (p.R2016W) mutation occurring in exon 19 of *F8* was identified in 35 of 335 haemophilia A patients from Northern Italy (prevalence 10.4%; 95% confidence intervals 7.6–14.2%). The mutation was the second most frequent in our cohort, after the intron 22 inversion. Patients carrying the c.6046C>T (p.R2016W) mutation had moderate to severe clinical phenotype. *In silico* annotation predicts that the substitution of an Arginine by a Tryptophan introduces a polar residue within the A3 domain of FVIII, which may alter the conformation of the protein. Polyphen 2 and SIFT software predicted the mutation to be potentially deleterious for FVIII function. RT-PCR and sequencing of the *F8* mRNA region spanning exons 17–22 clearly showed that the C>T substitution also induces an impairment of the splicing process causing the skipping of exon 19. Characterization of splicing patterns of *F8* in patients' leukocytes identified both in- and out-of-frame *F8* transcripts. Haplotype analysis found a peculiar haplotype (H1) in 21/35 (60%) haemophilia A patients with the recurrent mutation. The haplotype was not identified in 52 Italians without hemophilia (Fisher's exact test, $P < 0.0001$). These data strongly suggest a founder effect, supporting the existence of a single mutation event. DMLE+ software estimated that c.6046C>T (p.R2016W) mutation likely arose approximately 300 years ago.

Conclusions: We identified a mutation of *F8* that is highly prevalent among haemophilia A patients from Northern Italy. The variant, which likely arose from a single mutation event occurring approximately three centuries ago, acts by the dual mechanism of affecting the protein sequence of FVIII and inducing abnormal splicing of *F8*.

PA 2.12-3

Characterization of missense mutations in the B domain of coagulation factor VIII reported to be associated with mild/moderate hemophilia A

Selvaraj SR and Pipe S

University of Michigan, Ann Arbor, MI, USA

Background and Significance: Factor VIII (FVIII) serves an essential role as a co-factor in the intrinsic coagulation pathway and its deficiency leads to hemophilia A. FVIII is a complex glycoprotein with the domain structure A1-a1-A2-a2-B-ap-A3-C1-C2. The B domain is dispensable for procoagulant activity and is not involved in von Willebrand factor affinity or phospholipid binding. However, several missense mutations within the B domain have been reported in patients with hemophilia A of varying clinical severity. We have demonstrated earlier that missense mutations within the B domain are unlikely to cause severe hemophilia A (Ogata, J Thromb Haemost 2011). This study focuses on missense mutations in the B domain reported in patients with mild/moderate hemophilia A. A total of 17 such missense mutations were identified from the HAMSTeRS and CHAMP hemophilia mutation databases and current literature. These include T751S, P851R, D944N, E1038K, M1074I, N1091Y, S1095S, P1134A, F1175V, R1260K, T1295P, R1310H, Q1317K, L1450S, S1511T, E1623G and N1639H. Four of these were unpublished submissions to the HAMSTeRS database. While T1295P and M1074I were reported in female patients, R1260K was found in conjunction with the well known polymorphism D1241E in four patients of the same family. Interestingly, S1095S, a synonymous substitution has also been reported to be associated with mild hemophilia. M1074I and Q1317K were excluded from the study since they were secondary mutations found in addition to causative lesions.

Methods: *In silico* analysis using online tools predicted that while the majority of these mutations were considered benign, P851R and E1623G were considered likely to affect protein function. The B domain contains several Asparagine (Asn)-linked glycans that might influence FVIII expression and intracellular transport, but none of the missense mutations reported so far have been shown or predicted to interfere directly with the Asn-linked glycosylation process. Plasmid vectors containing the B-domain missense mutations were generated using site-directed mutagenesis techniques and were analyzed through transient transfections into COS-1, CHO and HEK-293t cell lines. FVIII activity and antigen levels were assayed by aPTT and ELISA respectively and compared to FVIII-wild type (WT). Previously well-defined mutations, R2150C, R593C and C179G were utilized as controls for mild, moderate and severe clinical phenotypes respectively.

Results: FVIII activity and antigen levels of all the mutants studied were similar to that of FVIII-WT levels in all three cell lines indicating that these B domain missense mutations did not significantly impact FVIII expression or activity.

Conclusion: In accordance with our previous observations for FVIII B domain missense mutations associated with severe hemophilia, our findings in the present study indicate that missense mutations reported to be associated with mild/moderate hemophilia also do not have an impact on expression or activity of FVIII. It is therefore unlikely that any of these mutations could be causative of hemophilia A. These reported amino acid changes are more likely to represent polymorphisms or non-pathological mutations. This will be important to recognize as genotyping gains momentum globally through new research initiatives, particularly as it pertains to genetic counseling and genotype/phenotype correlations.

PA 2.12-4

In vivo and hepatocellular distribution of FVIII in rats is independent of high affinity binding to VWF

Øie CI[1], Karpf M[2], Behrens C[2], Kristensen JB[2], Kjalke M[2], Karlsson J[2], Stennicke HR[2], Smedsrod B[1] and Appa RS[2]

[1]University of Tromsø, Tromsø, Norway; [2]Novo Nordisk A/S, Maaloev, Denmark

Background: FVIII is predominantly cleared in the liver. In circulation, the majority of FVIII is bound to VWF. Tyrosine sulfation of FVIII-Y1680 is required for high affinity VWF binding[1] and FVIII-Y1680F lacking high affinity VWF binding displays a shorter half-life *in vivo*. Currently, it is not known if high affinity VWF binding influences the clearance pathways of FVIII.

Aims: To determine the *in vivo* anatomical and hepatocellular accumulation of wild type FVIII and FVIII-Y1680F in rats, in order to investigate the contribution of high affinity VWF binding in FVIII clearance.

Methods: Anatomical distribution of a biostable radio-iodinated human recombinant FVIII and FVIII-Y1680F was assessed following i.v. tail injection in rats. At time points up to 24 h for native FVIII and 1 h for FVIII-Y1680F plasma samples were collected, blood removed by systemic perfusion with saline, and organs harvested. Radioactivity in plasma and organs was counted. At time points up to 7 h, cells were harvested from the liver by collagenase perfusion followed by isopycnic density gradient centrifugation in Percoll®. Hepatocellular distribution was assessed by comparing amount of radioactivity per million cells in parenchymal (PCs), Kupffer (KCs) and sinusoidal endothelial cells (LSECs). The uptake per total cell population was calculated according to the ratio between KCs, LSECs and PCs in rat livers of 1:2.5:7.7.[2]

Results: More than 94% of radioactivity remained bound to FVIII and FVIII-Y1680F for the duration of the study and < 1% of radioactivity was found in the thyroid demonstrating sufficient stability of the iodine-labeled FVIII proteins to analyze not only the initial distribution of FVIII, but also accumulation in organs for up to 2–3 half-lives. As expected, the clearance of FVIII-Y1680F was significantly faster than for FVIII but the relative distribution between organs was the same for both FVIII molecules with the liver being the organ primarily responsible for clearance. Radioactivity was observed in the intestines after 1 h, in concordance with FVIII degradation via the liver. In hepatocellular studies, both FVIII molecules were predominantly taken up by PCs with approximately 64 ± 5% of total radioactivity, while 34 ± 4% radioactivity was found in LSECs. Calculations of radioactivity per cell showed that LSEC had slightly higher capacity than PC to take up FVIII or FVIII-Y1680F. Minimal radioactivity was seen in KC for both molecules. The relative pattern of cellular distribution did not change over time (between 1–7 h for FVIII or 0.5–2 h for FVIII-Y1680F).

Conclusion: In rats, the liver is the predominant organ showing accumulation of FVIII and FVIII-Y1680F. Hepatocellular distribution was also similar for both FVIII molecules with PC and LSEC having a major role. Thus, the lack of high affinity VWF binding does not alter the distribution of FVIII.

A combinatorial library approach to generate rFVIII variants with multiple XTEN insertions and improved pharmacokinetic properties

Liu T[1], Kulman J[1], Chang P-YB[2], Patarroyo-White S[1], Drager D[1], Ding S[2], Chhabra ES[1], Kumar S[1], Pape B[1], Moore N[1], Bardan S[1], Goodman A[1], Acosta M[1], Pierce GF[1], Schellenberger V[2], Mei B[1], Peters RT[1] and Jiang H[1]

[1]Biogen Idec Hemophilia, Waltham, MA; [2]Amunix, Mountain View, CA, USA

Background: XTEN is an unstructured polypeptide that has been shown to increase the circulating half-lives of a number of proteins. The impact of XTEN on the clearance and function of rFVIII molecules can be optimized by varying the location, composition, length and number of XTEN insertions, all of which can be achieved by recombinant technology. With the identification of locations in rFVIII that can accommodate intra-domain insertions of XTEN, a multivariate approach towards XTEN modification of FVIII was explored to develop novel long-lasting rFVIII-XTEN variants.

Aim: To evaluate the effects of multiple XTEN insertions on the activity and pharmacokinetics of rFVIII.

Methods: rFVIII-XTEN combinatorial libraries were constructed comprising over 400 rBDD-FVIII variants with 2–6 XTEN insertions within the A domains, at the B domain junction, and at the C-terminus. Variants were expressed in HEK293 cells by small-scale transient transfection, and FVIII activity in conditioned medium was measured by FVIII chromogenic assay. The pharmacokinetic (PK) properties of variants with ≥ 0.3 IU/mL FVIII activity in culture medium were evaluated in FVIII knockout (HemA) and FVIII/VWF double-knockout (DKO) mice by monitoring plasma FVIII activity over time. DKO mice were used for initial ranking purposes to eliminate the influence of endogenous VWF on half-life. Concentrated conditioned medium or partially purified rFVIII-XTEN preparations were used in PK studies to increase the throughput of PK screening, since the PK profile obtained is comparable to those of the purified proteins.

Results: Based on the FVIII chromogenic activity, the rFVIII variants remained functional with up to five XTEN insertions. In DKO mice, which lack the protective benefit of VWF, the half-lifeimprovement conferred by XTEN was insertion site-dependent, with single XTEN insertions in the A1, A2 and A3 domain extended half-live up to 3.5, 2.5, and 4.5 h, respectively, as compared to 0.25 h for unmodified rBDD-FVIII. The optimal composition and length of XTENs for activity and half-life at each intra-domain insertion site is site-dependent, and the effects on PK of multiple XTEN insertions were generally additive when insertion sites were in different domains. rFVIII with three XTEN insertions achieved a half-lifeof 16 h in DKO mice, representing a 64-fold increase relative to rBDD-FVIII, but the introduction of additional XTENs resulted in only a nominal increase to 18 h, indicating that half-life extension with XTENs is additive but saturable. Selected rFVIII-XTEN variants that had exhibited half-lives of 3–18 h in DKO mice all had similar half-lives in HemA mice (approximately 14 h).

Conclusions: Multiple intra-domain XTEN insertions are tolerated by rFVIII and provide greater protection for rFVIII compared to the endogenous VWF multimers. The normalizing effect of VWF on the half-lives of these variants observed in HemA mice highlights a limit on half-life extension imposed by VWF. Protein engineering of a rFVIII-VWF fusion protein for which the clearance is independent from endogenous VWF will be necessary to exceed this limit on half-life extension by the modification of XTEN.

PA 2.12-6

B domain-deleted FVIII lacking mannose-ending glycans at Asn239 and Asn2118 retains pro-coagulant activity and corrects bleeding in FVIII-deficient mice

Rayes J[1], Delignat S[2], Cherel G[3], Dasgupta S[4], Kaveri SV[2], Denis C[5], Lacroix-Desmazes S[2] and Christophe OD[3]
[1]Inserm 770, UMRS 872; [2]Inserm UMRS 872, Paris; [3]Inserm Unit 770, Le Kremlin-Bicêtre; [4]UMRS 872 equipe 16, Paris; [5]Inserm, Le Kremlin-Bicêtre, France

Background: Hemophilia A (HA) is a rare inherited bleeding disorder due to the absence of the coagulation protein factor VIII (FVIII). Administration of therapeutic FVIII to severe hemophilia A patients induces, in up to 30% of the cases, inhibitory anti-FVIII antibodies. Previously, we have shown that blockage of mannose receptor on human monocytes-derived dendritic cells reduces FVIII uptake and presentation to a human FVIII-specific T-cell line. The data suggested that a recombinant FVIII lacking mannose-ending would be less immunogenic.
Aim: The aim of this study was to validate in a mouse model of hemophilia A the production and procoagulant activity of recombinant human FVIII lacking oligomannose carbohydrates at Asn239 and Asn2118.
Methods: FVIII-deficient mice were injected with 100 μg of pLIVE encoding wild-type (WT) human B domain-deleted FVIII (Δ2-FVIII, LFB, Les Ulis), and the corresponding single Asn239Gln mutant, single Asn2118Gln mutant or double Asn239Gln/Asn2118Gln mutant (DM). FVIII:Ag, FVIII:C and hemostatic function were assessed 4 days after hydrodynamic injection using Asserachrom, functional coagulation assay and tail vein clip assay, respectively.
Results: Our results show reduced levels of circulating demannosylated FVIII compared to WT FVIII in hydrodynamic injection-treated mice. Indeed, the expression of Δ2-FVIII mutated at position Asn2118Gln was slightly reduced compared to that of WT (FVIII:Ag 3.61 ± 1.11 IU/mL and 1.60 ± 1.53, respectively), whereas the expression levels of the Asn239Gln and DM FVIII mutants were significantly decreased (FVIII:Ag 0.25 ± 0.05 and 0.63 ± 0.28 IU/mL). Similar observations were made when FVIII:C was measured in plasma. Interestingly, the specific activity of the different mutants did not drastically differ from that of the WT Δ2-FVIII: 1.02 ± 0.1, 2.09 ± 0.54, 1.4 ± 0.4, 1.66 ± 0.44 IU/mL for WT Δ2-FVIII, and the Asn239Gln, Asn2118Gln, and DM, respectively.
In agreement with the latter findings, the amount of blood loss by hemophilia A mice expressing the DM Δ2-FVIII was significantly lower following tail clipping than that loss by untreated hemophilic mice (226 ± 94 vs. 63 ± 56 μL, respectively, $P = 0.013$), and was not statistically different from the blood loss by wild-type mice.
Conclusion: The absence of mannose-ending sugars at Arg239 and/or Arg2118 does not alter the specific pro-coagulant activity of FVIII. It however affects the levels of circulating FVIII, probably by reducing the secretion yield by hepatocytes. Mutation at Arg239 was found to affect FVIII secretion the most. Importantly, the double mutant corrects bleeding in an acute model of hemorrhage.

Structure-function analysis of prothrombin-D519E, a causative mutation in a type 1/2 prothrombin deficient patient with a severe bleeding tendency

Schrijver R[1], Kuijper P[2], Rosing J[1], Dors N[3] and Nicolaes GAF[1]
[1]Cardiovascular Research Institute Maastricht, Maastricht; [2]Máxima Medical Centre Veldhoven, Veldhoven; [3]Catharina Hospital Eindhoven, Eindhoven, The Netherlands

Background: Recently we have described two mutations in the prothrombin gene of a young boy of Caucasian descent from non-consanguineous parents who presented with a serious bleeding disorder as a neonate. Functional analysis showed that the patient had a prothrombin activity below the detection level (< 1%). Genetic analysis revealed the presence of two mutations: one introducing a premature STOP codon at position Arg296, the other coding for a Asp519Glu missense mutation, together giving rise to a compound heterozygous prothrombin deficiency phenotype.
Since complete prothrombin deficiency results in embryonic and neonatal lethality in mice, and furthermore given that amino acid 519 in prothrombin is crucial to enzyme catalysis by thrombin, being located at the base of the catalytic pocket, we hypothesized that the relative conservative mutation of Asp into Glu has prevented embryonic lethality, yet causes a severe bleeding tendency.
Aims: We performed a detailed structure-function analysis of the human prothrombin Asp519Glu mutant molecule.
Methods: Human wild-type prothrombin, PT-Asp519Glu and PT-Asp519Ala were stably expressed in HEK293 cells. Prothrombin was subsequently purified from conditioned serum-free medium to homogeneity. Activation of prothrombin was achieved with the prothrombin activator from *Oxyuranus Scutellatus*, after which thrombin was purified. Wet laboratory experiments were supported by *in silico* structural bioinformatics. Methods involving 3D structure analyses of (pro) thrombin and its *in silico* prepared variants, molecular dynamics simulations and docking studies.
Protein analysis was performed via SDS-PAGE analysis and spectrophotometry. Prothrombin variants were tested for their ability to function as substrates in the prothrombinase complex both in reaction systems composed of purified components and in plasma. Membrane binding was assessed via surface plasmon resonance. Thrombin variants were analysed by quantitation of their amidolytic activities towards the chromogenic substrate S2238, and for their ability to activate physiological thrombin substrates such as FV, fibrinogen and platelets.
Results: *In silico* analysis predicted no major folding effects of mutation of Asp519 to either Glu or Ala. Analysis of substrates docked into the S1 site for each of the thrombin variants indicates that the Asp519Glu mutation clearly distorts the interaction between the guanidium group of the P1 Arg residue and residue 519, while the Asp519GluAla mutation results in a complete loss of essential interactions between enzyme and substrate.
Protein expression typically yielded 4–8 mg of purified prothrombin (> 95 purity as judged by SDS-PAGE analysis). Electrophoretic mobility of all prothrombin variants was identical as was their ability to bind to phospholipid membranes. All prothrombin variants were converted to thrombin by the snake venom activator. However, the amidolytic activities of purified wt thrombin and Asp519Glu and Asp519Ala thrombin were 100; 1.3% and 0.1%, respectively. The low but detectable activity of the Asp519Glu mutant as compared to the Asp519Ala mutant was also observed with other thrombin substrates (FV, fibrinogen and platelets).
Summary: We have shown that the Asp519Glu mutation in human prothrombin results in a serious bleeding phenotype and we hypothesize that the conservative Asp®Glu mutation allows for this mutation at position 519 to be compatible with life.

Identifying novel thrombin interactions: alpha-synuclein binds to thrombin exosites and inhibits thrombin-mediated platelet aggregation

De Filippis V, Acquasaliente L, Pontarollo G, Frasson R, Maset F, Banzato A, Pengo V and Negro A
University of Padova, Padova, Italy

Background: Alpha-synuclein is involved in the pathogenesis of Parkinson's disease (PD). It is expressed in the presynaptic neuron terminals and constitutes the major component of protein deposits in PD. Alpha-synuclein is essentially unfolded in solution and assumes a partially helical conformation when bound to phospholipid vesicles. The protein consists of three distinct regions: a positively charged N-terminal region (amino acids 1–60), a hydrophobic region encompassing the highly aggregation-prone Non-Amyloid sequence (65–90) and the C-terminal 103–140 region, rich in acidic amino acids and prolines. Alpha-synuclein is also expressed in T and B lymphocytes and platelets, where it is associated with the membrane of secretory alpha-granules. Thrombin, the final effector protease in the coagulation cascade, is the most potent activator of platelets and this function is exerted through cleavage of type-1 Protease Activated Receptor (PAR1), which results in alpha-granule release and platelet aggregation. Conversely, platelet degranulation is inhibited by alpha-synuclein (Park et al. 2002). Moreover, clinical evidences show that patients with Parkinson's disease are less susceptible to ischemic stroke and exhibit a significantly reduced tendency to aggregate platelets (Sharma et al. 1991).
Aims: Establish whether or not alpha-synuclein interacts with thrombin; study the effect of alpha-synuclein on thrombin procoagulant (fibrin generation and platelet aggregation) and anticoagulant (generation of active protein C) functions.
Methods: Wild-type and His-tag full-length alpha-synuclein were expressed in *E. coli* and purified. Thrombin mutants Arg73Aa and Arg101Ala were expressed in *E. coli*. Binding of alpha-synuclein to thrombin was studied by measuring the change of intrinsic fluorescence of thrombin and by Surface Plasmon Resonance on a Biacore X100 instrument. The effect of alpha-synuclein on fibrin generation was investigated by turbidimetric measurements, while the effect on platelet aggregation was evaluated on whole blood by Multiple Electrode Aggregometry (MEA). PC activation by thrombin was monitored by measuring the rate of S2366 hydrolysis.
Results: Fluorescence binding measurements yielded K_d = 2.6 ± 0.5 mM. Similar results were obtained after Biacore analysis (K_d = 4.2 ± 1.0 mM). Displacement experiments, carried out with specific binders of thrombin exosite-1 (hirugen and HD1 aptamer) or exosite-2 (fibrinogen g"- peptide and HD22 aptamer) and with thrombin mutants having exosite-1 (Arg73Ala) or exosite-2 (Arg101Ala) compromised, suggest that both exosites of the protease are involved in alpha-synuclein binding. Conversely, alpha-synuclein does not affect the affinity of the enzyme for some active-site inhibitors, like p-aminobenzamidine and the N-terminal domain 1–47 of hirudin, nor the efficiency of S2238 hydrolysis. Likewise, alpha-synuclein does not affect fibrin generation by thrombin and very preliminary results indicate that it is also ineffective on the thrombin-mediated PC activation. Strikingly, MEA measurements indicate that alpha-synuclein inhibits platelet aggregation by thrombin in a dose-dependent manner, whereas it only slightly reduces ADP-induced platelet aggregation.
Conclusion: alpha-synuclein binds to thrombin at both exosites, while leaving the protease active site accessible. These results rationalise previous work on the inhibitory effect of alpha-synuclein on thrombin-mediated platelet activation suggesting that alpha-synuclein impairs localization of thrombin on platelets by competing with the receptor GpIb-alpha for thrombin exosite-2. Our data also explain clinical evidences showing that patients with Parkinson's disease display lower incidence of thrombotic events.

PA 2.13-3

Amino acid sequence 473–487 of human prothrombin is required for timely activation by prothrombinase and optimal thrombin activity

Wiencek JR[1], Hirbawi J[2] and Kalafatis M[1]
[1]*Cleveland State University;* [2]*Cleveland Clinic-Lerner Research Institute, Cleveland, OH, USA*

Background: Prothrombinase is the important enzymatic complex that catalyzes the proteolytic conversion of prothrombin (Pro) to thrombin with rates compatible with survival. Prothrombinase is composed of the enzyme factor Xa (fXa), and the cofactor factor Va (fVa) associated on a procoagulant membrane surface in the presence of divalent metal ions. Timely prothrombinase formation results in the suitable formation of a fibrin clot and the arrest of bleeding because the interaction of fVa with the members of prothrombinase leads to a fivefold increase in the catalytic efficiency of fXa as compared to the activity of fXa alone. Prothrombinase produces thrombin following two sequential cleavages of Pro (at Arg^{320} followed by cleavage at Arg^{271}) with formation of an enzymatically active intermediate called meizothrombin. Although membrane-bound fXa is capable of activating Pro, the overall rate of thrombin formation is not compatible with survival, and activation proceeds through the opposite pathway (cleavage at Arg^{271} is followed by cleavage at Arg^{320}) with formation of prethrombin-2. fXa is known to exhibit a strong interaction with Pro in the presence and absence of fVa. Previous studies have suggested that fXa interacts with Pro within amino acid region 473–487 in a fVa-dependent manner.
Aim: To investigate the functional importance of amino acid region 473–487 of Pro.
Methods: We used site-directed mutagenesis to create a recombinant Pro molecule with the region 473–487 deleted ($rPro^{\Delta 473–487}$). Wild type Pro ($rPro^{WT}$) and the deletion mutant were stably transfected in BHK-21 cells. The two recombinant molecules were purified according to an already established protocol. During the last step of the purification procedure, we used Mono-Q chromatography and a calcium gradient to isolate properly carboxylated $rPro^{\Delta 473–487}$ and $rPro^{WT}$. Both recombinant molecules were assessed by gel electrophoresis for their capability to produce active thrombin by fully assembled prothrombinase or fXa alone. The recombinant molecules were also assayed for clotting and chromogenic activity.
Results: Gel electrophoresis revealed that consumption of $rPro^{\Delta 473–487}$ by prothrombinase and thrombin formation was drastically impeded when compared with thrombin formation following cleavage of $rPro^{WT}$ by prothrombinase. In contrast, membrane-bound fXa alone, in the absence of fVa, displayed a marked increase in the rate of cleavage at Arg^{271} and activation of $rPro^{\Delta 473–487}$ as compared to cleavage at Arg^{271} and activation of $rPro^{WT}$. A similar cleavage pattern within the recombinant proteins was observed, implying that no structural alterations took place in $rPro^{\Delta 473–487}$ following the mutation. Additionally, while clotting assays revealed that $rPro^{WT}$ had clotting and chromogenic activities comparable to human plasma-derived Pro, $rPro^{\Delta 473–487}$ was devoid of clotting activity and severely impaired in its amidolytic activity.
Conclusion: Our data demonstrate that amino acid sequence 473–487 of Pro is required for optimal rates of activation by prothrombinase. In addition, our data suggest that amino acid region 473–487 is required for proper thrombin activity. These data are providing a rationale to the fact that to date there is no natural mutation within this region of Pro reported since any changes within this crucial amino acid region would lead to dire circumstances and are not compatible with survival.

PA 2.13-4

A novel prothrombin c.1787G>A mutation in Serbian family with recurrent thromboembolism- another case of antithrombin resistance

Valentina D[1], Kovac M[2], Pruner I[3], Francuski D[3] and Radojkovic D[3]

[1]Institute of Molecular Genetics and Genetic Engineering; [2]Faculty of Medicine, University of Belgrade, Blood Transfusion Institute of Serbia; [3]Institute of Molecular Genetics and Genetic Engineering, University of Belgrade, Belgrade, Serbia

Background: Family thrombophilia is considered a multifactorial and polygenic disorder in which gene-environment and gene-gene interactions play a pivotal role. The most frequent thrombophilic genetic risk factors are FV Leiden and FII G20210A mutations. The FII G20210A (c.*97G>A) variant in the 3′-untranslated region of the prothrombin gene is associated with elevated plasma prothrombin level and increased burst in thrombin generation. Recently, new mutation (c.1787G>A) affecting the prothrombin Arg596 residue, has been identified in a Japanese family with juvenile thrombosis. This Arg596Leu substitution leads to impaired inhibition of mutant thrombin by antithrombin, resulting in antithrombin resistance and increased thrombophila risk.

Aims: Here we report a novel prothrombin mutation detected in three sisters, suffering from a severe recurrent thrombosis from a young age.

Methods: Contrary to our expectations, the routine thrombophilia testing did not show any inherited risk factors. Additional genetic analysis revealed the presence of a new FII c.1787G>A mutation in heterozygous form in all three sisters.

Results: The mutation is located in the last exon of the prothrombin gene resulting in Arg596Gln replacement. Residue Arg596 is positioned within the region that contains one of the antithrombin-binding sites involved in thrombin inactivation by antithrombin. Considering the clinical findings and *in silico* protein structure prediction, we assume the same thrombophilic mechanism for the herein presented Arg596Gln as in previously described Arg596Leu.

Conclusion: Our study reports the first data for Caucasian population supporting the newly proposed mechanism of hereditary thrombophilia called antithrombin resistance.

PA 2.13-5

Effects of prothrombin Yukuhashi mutation on thrombomodulin-protein C system

Takagi Y[1], Takagi A[1], Suzuki A[1], Murata M[1], Okuyama E[1], Ando Y[1], Kato I[1], Matsushita T[2], Saito H[3] and Kojima T[1]

[1]Nagoya University Graduate School of Medicine; [2]Division of Transfusion Medicine, Nagoya University Hospital; [3]National Hospital Organization-Nagoya Medical Center, Nagoya, Japan

Background: We have reported antithrombin (AT) resistance in the prothrombin Yukuhashi substituted arginine for leucine at position 596 (p.Arg596Leu). The mutant thrombin, an active form of the prothrombin Yukuhashi, showed moderately lower clotting activity than that of wild-type prothrombin, while substantially impaired complex formation with AT. However, effects of the mutation on thrombomodulin (TM)-protein C (PC) pathway was not yet analyzed.

Aims: We evaluated effects of the prothrombin Yukuhashi mutation on TM-PC anticoagulation system.

Methods: We prepared expression vectors of wild type and mutant (p.Arg596Leu) prothrombins using pcDNA 3.1(+), and transfected them to HEK293 cells. We established respective stable transformants by G418 selection, and obtained clones highly expressing recombinant prothrombins. We cultured stable transformants highly expressing recombinant prothrombins in serum-free medium containing vitamin K, and collected and concentrated their conditioned media. Antigen levels of prothrombins were determined by an enzyme-linked immunosorbent assay (ELISA). We used *Oxyuranus scutellatus* venom (Ox), a factor Xa-like enzyme, as a prothrombin-to-thrombin converting enzyme together with cephalin and calcium chloride. We measured clotting time for Ox-activated recombinant thrombins using fibrinogen as a substrate in the presence or absence of recombinant TM (rTM). We determined relative fibrinogen clotting activities using a standard curve of clotting time of normal pool plasma. We also used a chromogenic substrate (S-2238) to evaluate thrombin activity. We measured APC generation activity with or without rTM for Ox-activated recombinant thrombins using S-2366 as an APC substrate in the presence of Pefabloc-TH. We expressed APC generation activity as changes in absorbance/min (delta A/min) at 405 nm

Results: In the fibrinogen clotting time assay, relative activity of the mutant thrombin was 21.8% of that of the wild type in the absence of TM. TM treatment reduced relative fibrinogen clotting activity of the wild type thrombin to 34.3%, whereas that of the mutant to 20.4%. Reduction rates of fibrinogen clotting activity were 65.7% for the wild type thrombin and 6.4% for the mutant, respectively. In the chromogenic assay using S-2238, relative activity of the mutant thrombin was 47.2% of that of the wild type in the absence of TM. In the absence of TM, APC generation activity (delta A/min at 405 nm) were fairly low; 0.0089 for the wild type and 0.0048 for the mutant. TM treatment enhanced APC generation activity to 0.13145 (14.8 folds) for the wild type and to 0.05735 (11.9 folds) for the mutant respectively, although relative APC generation activity of the mutant was 43.6% of that of the wild type.

Summary: We evaluated effects of the prothrombin Yukuhashi mutation on TM-PC pathway. We demonstrated that fibrinogen clotting activity of the mutant was low but resistant to TM compared with the wild type. TM enhanced APC generation activity of the mutant substantially, but that was still lower than that of the wild type. These data suggested that the prothrombin Yukuhashi mutation might cause not only AT resistance, but also TM resistance in terms of fibrinogen clotting activity, resulting in susceptibility to thrombosis.

PA 2.13-6

Evaluation of a new chromogenic method based upon the prothrombinase complex for determination of the functional activity of prothrombin

Rosén P, Bryngelhed P and Rosén S

Rossix, Molndal, Sweden

Background: In clotting and chromogenic methods: for prothrombin (FII) activity based upon the use of Ecarin, FII activation occurs irrespective of the extent of g-carboxylation of Glutamic acid residues (Gla). One-stage clotting methods: involving FII activation by the extrinsic system reflect better biologically functional FII but are hampered by a limited resolution.

Aim: As an alternative to one-stage methods, a chromogenic method for FII activity has been developed.

Method: The method is based upon the prothrombinase (FII-ase) complex and utilizes purified FXa, FV, calcium ions and synthetic or highly purified phospholipids. Gamma-carboxylation of FII is mandatory for its binding and activation on phospholipid surfaces in the presence of calcium ions and accordingly no thrombin is generated in this FII-ase based method on analysis of acarboxy FII, which completely lacks Gla residues.

The method is intended for both plasma and FII containing factor concentrates. Plasma should be collected in citrate or EDTA and a dilution of 1:200 is used.

Results: The method offers a resolution of about 1.2 absorbance units between 0 and 1.5 IU/mL and the detection limit is 0.05 IU/mL. Due to the high dilution, which minimizes matrix interference, the method allows levels of Hb 10 mg/mL, triglycerides 10 mg/mL, bilirubin 0.8 mg/mL and heparin 4 U/mL.

The correlation vs. a chromogenic Ecarin based method on analysis of plasmas from 196 patients supposedly not receiving anticoagulant treatment was $FII_{FII\text{-}ase} = 1.14 \times FII_{Ecarin} - 0.15$ ($R^2 = 0.87$).
Analysis of 11 plasmas from individuals heterozygous for FII G20210A showed a complete agreement with FII-ase = 0.97 xEcarin + 0.03 ($R^2 = 0.99$) and a mean value (SD) for both methods of 1.33 (± 0.24) IU/mL. Thus, elevated FII levels in carriers of the G20210A mutation are verified also with the FII-ase based method.
Analysis of plasmas from patients on warfarin with an INR range of 2–4 ($n = 47$) showed 1.4–3.8-fold lower activities with the FII-ase based method vs. the Ecarin based method. Importantly, for plasmas with an INR between 2.0 and 2.2, the functional FII activity varied 2.6-fold as determined with the FII-ase method. In one of these cases, the FII activity was 0.18 IU/mL which is in the same range as for plasmas with an INR of 3.5, tentatively indicating an increased risk of bleeding. For three plasmas with INR 5, 5.4 and 6.5, the FII activities were 0.12, 0.11 and 0.075 IU/mL, respectively.
The proper applicability on analysis of FII containing factor concentrates with the FII-ase based method is illustrated from the calibration of the 4th IS FII, X concentrate (11/126) with the obtained activity 9.67 IU/ampoule being in good agreement with 9.53 IU/ampoule (GCV 2.9%) for PT-based FII methods.
Conclusion: In summary, this prothrombinase based method allows accurate determination of functional FII activity in plasmas and FII containing concentrates and it provides a new tool for evaluation of patients on antivitamin K treatment as well as on patients with compromised liver function.

PA 2.14-1
Inhibitory effects of LDL-associated tissue factor pathway inhibitor

Augustsson C, Hilden I and Petersen LC
Novo Nordisk A/S, Bagsvaerd, Denmark

Background: Tissue factor pathway inhibitor (TFPI) is present in plasma as full length TFPI (TFPI) and as a C-terminally degraded form associated with low-density lipoprotein particles (LDL-TFPI). Addition of TFPI to plasma induces a prominent dose-dependent prolongation of the clotting time (CT) when tested in a diluted prothrombin time (dPT) assay. In contrast, addition of LDL-TFPI or truncated recombinant TFPI ($TFPI_{1–161}$) was shown not to prolong CT when tested in a dPT assay. It was concluded that the anticoagulant function of TFPI in human plasma was limited to fl-TFPI. Since LDL-TFPI has preserved its factor Xa (FXa) inhibitory activity and also worked as an inhibitor of tissue factor/factor VIIa (TF/FVIIa) in FX activation assays it was unclear why LDL-TFPI failed to affect the dPT in a plasma environment; and it was suggested that a slower on-rate of LDL-TFPI in a rate limiting step might explain this phenomenon.
Aim: The aim was to further characterize kinetic properties of purified LDL-TFPI in plasma in a thrombin generation test (TGT) and in various chromogenic *in vitro* activity assays.
Methods: LDL-TFPI was purified from human plasma by sequential flotation ultracentrifugation. FXa activity was measured using a chromogenic assay. Inhibitor constant, K_I, was calculated using the Morrison tight binding non-linear curve fitting. Thrombin generation assay was performed in normal human plasma (NHP) or in FVIII-immuno depleted plasma using either 1 pM TF and 4 μM phospholipids (PLs) or 4 μM PLs and 0.5 nM FXa respectively.
Results: When TFPI inhibition was tested in a TF-induced TGT assay in NHP we observed, in line with findings by dPT experiments, that TFPI, but not LDL-TFPI prolonged the lag-phase of thrombin generation. The kinetics of thrombin generation were, however, not unaffected by LDL-TFPI. Similar to TFPI it decreased the peak height of thrombin generation. Steady state inhibition of FXa showed a faster inhibition with LDL-TFPI than TFPI ($K_I = 0.0071 \pm 0.003$ nM and $K_I = 0.15 \pm 0.006$ nM respectively). In addition, transient kinetic data on FXa inhibition showed thatLDL-TFPI was 2.5 fold faster than TFPI indicating that FXa inhibition was not rate determining for the lag phase, whereas it appeared to affect thrombin generation during the propagation phase. This was supported by FXa-inducedTGT in hemophilia A plasma showing thatLDL-TFPI more actively decreased the peak height of thrombin generation compared to TFPI.
Conclusions: Our results suggest that LDL-TFPI affects thrombin generation during the propagation phase. It may therefore play a more prominent physiological role *in vivo* than hereto anticipated from dPT measurements.

PA 2.14-2
The effect of fibrin(-ogen) on thrombin generation and decay

Kremers RMW, Wagenvoord R and Hemker CH
CARIM, Maastricht University, Maastricht, The Netherlands

Background: In clotting blood(-plasma) >95% of thrombin develops and decays after clot formation. Thrombin generation (TG) in clotting plasma can be assessed by measuring the conversion of an added thrombin substrate (eg. In calibrated automated TG measurement [CAT]). The removal of fibrinogen from plasma has been shown to reduce TG as assessed by CAT. On the contrary, in a subsampling procedure TG is increased. This is explained by the assumption that part of the thrombin is reversibly adsorbed onto fibrin and is protected from the action of antithrombins, and therefore remains longer amidolytically active. In human plasma, two variants of the fibrin(ogen) γ chain occur, γ' and γA, that both contain low affinity binding sites for thrombin. The γ' chain contains an additional exclusive high affinity binding site for thrombin. Plasma contains ~85% of fibrinogen that has two γA chains and ~15% with one γ' and one γA chain. Apart from slowing down thrombin decay, fibrin may also influence prothrombin conversion. We therefore investigated the effect of the presence of fibrin on thrombin decay and prothrombin conversion during thrombin generation (TG).
Aims: We wanted to quantify the effect of γA/γ'- and γA/γA fibrinogen on thrombin decay and to investigate whether or not the presence of fibrin also influences prothrombin conversion.
Methods: TG was measured with the CAT technique in normal pool plasma (NPP), defibrinated NPP, and defibrinated NPP resupplied with purified γA/γA fibrinogen, with γA/γ' fibrinogen or with the two types in their natural proportions. The rate constants of total thrombin decay and thrombin decay by α2Macroglobulin (α2M) were calculated from the TG curves and prothrombin conversion curves were constructed from the TG curves and these rate constants.
Results: The removal of fibrinogen significantly decreases TG and restoration of the original fibrinogen concentration reverses this effect; γA/γA fibrinogen does not restore TG completely (ETP 83% of normal), whereas γA/γ' fibrinogen increases TG to above its original level (ETP 141% of normal). Physiological fibrinogen has a significant dose-dependent attenuating effect on thrombin decay, which is primarily due to protection against the action of α2M (64% reduced, $P < 0.001$). Serpin dependent thrombin inactivation is significantly decreased by γA/γ' (24% reduced, $P < 0.001$), but not by γA/γA fibrin. The effects of fibrin on TG are not completely explained by these effects on thrombin inactivation alone. In the presence of fibrin prothrombin conversion is significantly higher than in its absence (127%, $P = 0.001$). This effect is independent of the type of fibrinogen added.
Conclusion: Fibrin(ogen) has an important positive effect on thrombin generation because it dose-dependently inhibits thrombin decay and fosters prothrombin conversion. Fibrinogen containing the γ' chain is more effective in protecting thrombin than the γA is and inhibition by α2M is more affected than that by other antithrombins. A high fibrin-

ogen concentration must be excluded as a trivial explanation for high TG values found in some diseased states.

PA 2.14-3

Role of the serpin protease Nexin-1, In tissue remodelling occurring during pulmonary fibrosis.

François D[1], Marchal-Sommé J[2], Crestani B[2] and Bouton M-Ch[1]
[1]*Inserm U698;* [2]*Inserm U700, Paris, France*

Background: Idiopathic pulmonary fibrosis (IPF) is a chronic diffuse lung disease characterized by excess fibrous material which accumulates in the lung via the modulation of proteolytic degradation of extracellular matrix (ECM) and/or fibrin deposition. Protease Nexin-1 (PN-1), also named SerpinE2, is a tissue serpin produced by many cell types and involved in the regulation of coagulation and fibrinolysis. PN-1 inhibits thrombin, plasminogen activators (tPA and uPA) and plasmin. Its ability to regulate coagulation and fibrinolysis factors makes it a good candidate as a regulator of tissue remodelling.
Aims: Since PN-1 is expressed in lung, a fibrosis target organ where the regulation of proteolytic activity is of great importance, we aimed to test the hypothesis that PN-1 is a key regulator in lung remodelling occurring during IPF.
Methods: Human lung fibroblasts were cultured from IPF patient biopsies. In some experiments, cells were incubated with recombinant TGFbeta before analysis of PN-1 expression by real-time PCR, immunoblotting and antiprotease activity assay. Lung tissue extracts, and Brochoalveolar Lavages (BAL) from IPF patients were also analyzed by immunohistochemistry and biochemical techniques. mRNA expression of ECM proteins like collagen and fibronectin were also analyzed by real time PCR. For this purpose, mRNA was obtained from fibrotic fibroblasts or control lung fibroblasts whose PN-1 expression was up-regulated by transfection of a PN-1 expression vector.
Results: PN-1 (mRNA and protein) was significantly expressed in control lung fibroblasts and up-regulated in a dose- and time-dependent manner by TGFbeta; maximal overexpression was reached after 24 h stimulation. Moreover, PN-1 expression was 3.5 fold increased ($P < 0.01$) in fibrotic compared to control pulmonary fibroblasts. PN-1 was not only observed on cell membrane but also in the conditioned medium, demonstrating that it can be secreted when overexpressed by the fibroblasts. Both secreted PN-1 present in conditioned media and PN-1 present on cell surfaces, from TGFbeta-stimulated control fibroblasts and fibrotic fibroblasts, were functional since both could inhibit thrombin catalytic activity. Moreover, PN-1 overexpression could be observed in lung extracts and BAL from IPF patients (1.8 fold increase, $P < 0.05$). In parallel to PN-1 over-expression, an mRNA up-regulation of ECM proteins like collagen1-alpha2 (1.8 fold increase, $P < 0.05$) and fibronectin (2.9 fold increase, $P < 0.01$) was observed in fibrotic fibroblasts. Interestingly such an overexpression of mRNA of the ECM proteins could be mimicked when controls fibroblasts were transfected with a PN-1 overexpression vector.
Conclusions: PN-1 is overexpressed in lung fibroblasts under fibrotic conditions at the messenger and protein levels. Overexpressed PN-1 is secreted in the pericellular environment where it has been shown to be able to inhibit thrombin. Interestingly, overexpression of PN-1 is accompanied by an overexpression of ECM proteins favouring a fibrotic phenotype of cells. PN-1 thus represents a new actor in the evolution of tissue remodelling.

Structural and functional studies of a monoclonal high affinity antibody against the human TFPI Kunitz-type protease inhibitor (KPI) 3 domain

Svensson A[1], Petersen LC[1], Kjær B[1], Krogh B[1], Breinholt J[1], Tzu-Yuan C[2], Wenjuan X[2], Li Y[2] and Petersen HH[1]
[1]*Novo Nordisk A/S, Måløv, Denmark;* [2]*Novo Nordisk China R&D, Beijing, China*

Background: Activated coagulation factor VIIa (FVIIa) in complex with Tissue factor (TF) initiates coagulation by proteolytically converting coagulation factors IX and X (FIX and FX) to their activated forms, FIXa and FXa. Tissue factor pathway inhibitor (TFPI) inhibits the initiation of the coagulation cascade by forming a proteolytically inactive FVIIa:TF:FXa:TFPI complex. The TF/FVIIa-mediated FXa generation is tightly regulated by TFPI in a process which, as a rate-limiting step, appears to involve TFPI inhibition of FXa, either when FXa is bound to the TF/FVIIa complex or in its near vicinity on the membrane.
Aims: Functional blocking of TFPI binding to FXa or the TF:FVIIa:FXa complex with a monoclonal antibody may facilitate haemostasis initiated by FVIIa:TF hereby compensating for impaired FIX/FVIII-dependent coagulation. We have studied high affinity monoclonal antibodies binding to the KPI-3 domain of human TFPI.
Methods: A murine monoclonal antibody, with high TFPI-KPI-3 affinity (K_D 260 pM), mAb 0001 and the corresponding Fab-fragment, Fab 0001, were cloned and expressed as mouse-human chimeric mAb/Fab and purified by affinity chromatography. A 1:1 complex of the Fab 0001 and TFPI-KPI-3 protein was purified and crystallized with the hanging-drop method using a precipitant solution containing 18% PEG 4000, 26% propanol and 100 mM sodium citrate, pH 5.5.
Thrombin activity was assessed by calibrated automated thrombin generation measurements (CAT) and was measured continuously after the conversion of the fluorogenic substrate Z-Gly-Gly-Arg-AMC.HCl. Fluorescence was measured in a microtiterplate Fluorskan Ascent fluorometer with excitation and emission wavelengths set at 368 and 460 nm, respectively.
Results: Binding of mAb 0001 to TFPI-KPI-3 shortened the clotting time in normal and hemophilia A plasma measured by a diluted prothrombin (dPT) assay. Binding also produced a prominent increase in tissue factor induced thrombin generation studied by CAT in FVIII immune-depleted plasma supplemented with 10 μM phospholipids (PS/PC; 25/75%).
The binding epitope of mAb 0001 on KPI-3 of TFPI was determined by solving the crystal structure at 2.1 Å resolution of the complex between KPI-3 and the Fab fragment, Fab 0001. There were two independent KPI-3/Fab 0001 complexes in the crystallographic asymmetric unit. Calculation of the areas excluded in pair-wise interactions gave for the soluble TFPI KPI-3/Fab 0001 molecular complex 680 and 669 Å^2 for TFPI KPI-3 and 532 and 536 Å^2 for Fab 0001 and the two crystallographic independent molecular complexes, respectively. Results from a site-directed mutagenesis Ala-scan study confirm the epitope determined by X-ray crystallography.
Summary: The epitope for mAb 0001 on TFPI KPI-3 was characterized. Activity data demonstrated that binding of a high affinity antibody to this epitope was capable of improving *in vitro* haemostasis under haemophilia A-like conditions.

PA 2.14-5

Apolipoprotein(a) inhibits the conversion of Glu-plasminogen to Lys-plasminogen on the surface of vascular endothelial and smooth muscle cells

Romagnuolo R, DeMarco K, Boffa MB and Koschinsky ML
University of Windsor, Windsor, ON, Canada

Lipoprotein(a) [Lp(a)] has been identified as an independent risk factor for cardiovascular diseases including coronary artery disease. Lp(a) has a complex structure consisting of a low-density lipoprotein (LDL) moiety and the unique glycoprotein apolipoprotein(a) [apo(a)]. Lp(a) possesses both proatherogenic and prothrombotic properties due to the LDL-like moiety and apo(a) component of the lipoprotein respectively. Molecular cloning of apo(a) revealed that it contains remarkable homology to the fibrinolytic zymogen plasminogen. Plasmin, generated through plasminogen activation, is a key component in cell migration and proliferation, angiogenesis, inflammation and wound healing. Binding of plasminogen to various cell surface receptors initiates the conversion of its native form, Glu-plasminogen, to its more readily activatable form, Lys-plasminogen. Conversion of Glu- to Lys-plasminogen is necessary for optimal stimulation of plasminogen activation on human umbilical vein endothelial cells (HUVECs). It has been previously shown that apo (a) can inhibit plasminogen activation, through the positive feedback Glu- to Lys-plasminogen conversion mechanism, on the fibrin surface. Current work from our group has shown that apo(a) can inhibit pericellular plasminogen activation on vascular cells. Therefore, we determined the potential role of inhibition by apo(a) of Glu- to Lys-plasminogen conversion.

A novel method was employed to detect plasmin-mediated Glu- to Lys-plasminogen conversion utilizing an inactive plasminogen mutant with a fluorescent tag. A recombinant apo(a) [r-apo(a)] variant, 17K, was found to inhibit Glu- to Lys-plasminogen conversion on the surface of HUVECs by 60%. A series of r-apo(a) variants containing deletions of specific domains or point mutations were utilized to asses which domains mediate the ability of apo(a) to inhibit conversion. Removal of the protease and kringle V domain of 17K results in a decrease in the ability to inhibit Glu- to Lys-plasminogen conversion on HUVECs. Removal of the strong lysine binding site (sLBS) in kringle IV type 10 abolishes the ability of 17K to inhibit conversion. Various isoforms of r-apo(a) (ranging in size from 3 to 21 kringle IV type 2 repeats) were utilized in order to assess whether isoform size contributes to the inhibitory effect of conversion. All isoforms were able to inhibit Glu- to Lys-plasminogen conversion to a similar extent.

The ability of apo(a) to inhibit Glu- to Lys-plasminogen conversion on smooth muscle cells (SMCs) was also evaluated. Apo(a) inhibited conversion to a greater extent (76%) on SMCs compared to HUVECs. Unlike HUVECs, removal of the sLBS in kringle IV type 10 only reduces, but does not abolish, the ability of apo(a) to inhibit conversion on SMCs. In the absence of cells, plasmin-mediated Glu- to Lys-plasminogen conversion is greatly reduced (by approximately 75%). Although apo(a) is able to further reduce this rate, the absolute magnitude of the decrease is correspondingly reduced, indicating that the effect of apo(a) in the presence of cells is in fact cell-dependent.

Our results indicate a novel mechanism in which apo(a) can inhibit pericellular plasminogen activation on HUVECs and SMCs. The kringle V domain, protease domain and sLBS in kringle IV type 10 of apo (a) are required to maximally inhibit Glu- to Lys-plasminogen conversion.

PA 2.14-6

TF/FVIIa mediated activation of FIX and PAR-2 escapes inhibition by TFPI under conditions of concomitant TFPI blockage of FX activation

Petersen LC and Hilden I
Novo Nordisk A/S, Måløv, Denmark

Background: The complex of FVIIa and TF triggers coagulation by recognizing its macromolecular substrates factors IX (FIX) and X (FX) through extended exosite interactions. In addition, TF mediates cleavage of protease activated receptor 2 (PAR-2) on e.g. MDA-MB-231 carcinoma cells. These activities are regulated by TF exposure, and various factors on the cell surface affecting its cofactor function. In addition TFPI works as a potent modulator of FX activation by TF/FVIIa. Initiation of coagulation is down-regulated by TFPI inhibition of TF/FVIIa in a feed-back mechanism requiring generation of FXa and subsequently formation of an inactive TF/FVIIa/FXa/TFPI complex. How TFPI inhibition affects TF-dependent FIX and PAR-2 activation reactions in absence and presence of concomitant TF/FVIIa/FXa/TFPI complex formation is less well described.

Aim: To study TFPI inhibition of the three TF/FVIIa substrates FX, FIX and PAR2 using MDA-MB-231 cells as a template.

Methods: FVIIa activation of FX and FIX on MDA-MB-231 cells was measured with chromogenic substrates. FVIIa activation of PAR-2 was determined as IL-8 expression measured by ELISA in the supernatant from MDA-MB-231 cells.

Results and Discussion: Measurements of TF-dependent activation of FIX and FX on the cells revealed that the two reactions were saturated at widely different concentrations of FVIIa with EC_{50} values of 4.4 ± 0.4 and 64 ± 7 pM. Maximal turnover of FX by TF/FVIIa was about 20 fold faster than that of FIX. Furthermore, FX and FIX activation were both subject to competitive inhibition by alternative substrates (IC_{50} approximately 200 nM).

TF/FVIIa mediated FX activation was inhibited by TFPI ($IC_{50} = 0.38 \pm 0.09$ nM) at markedly lover concentrations than FIX (IC_{50} approximately 26 nM). Inhibition by TFPI of FX activation was minimally affected by the presence of FIX in accordance with the importance of the interaction between FXa and TFPI for efficient inhibition of FX activation by TF/FVIIa. The presence of FX and concomitant TF/FVIIa/FXa/TFPI complex formation restricted the amount of TF available for FIX turnover without an appreciable effect on the IC_{50} for TFPI inhibition. This and data showing that FX and FIX activation were similarly neutralized by active site inhibited FVIIa seems to exclude that different pools of TF are involved in FX and FIX activation.

PAR-2 activation was saturated by FVIIa with $EC_{50} = 16 \pm 5$ nM. This decreased to $EC_{50} = 4.7 \pm 1.7$ nM with concomitant FX activation without an effect on turnover. Like FIX activation, inhibition of PAR-2 activation by TFPI required high concentrations of TFPI (IC_{50} approximately 26 nM). Formation of the TF/FVIIa/FXa complex increased TFPI inhibition of PAR-2 activation by decreasing IC_{50} to 3.7 ± 0.6 nM.

The data suggested that formation of the TF/FVIIa/FXa complex stimulated PAR-2 activation and its inhibition by TFPI. Still PAR-2 activation remained essentially unaffected by TFPI inhibition at physiological relevant sub-nanomolar TFPI concentrations where FX activation was fully blocked.

Increased mortality in SIRS patients with low levels of zymogen and high levels of activated coagulation factor VII

Hyseni A, De Groot PG, Kemperman H, De Lange DW, Linssen M, Kesecioglu J, Lisman T and Roest M

University Medical Center Utrecht, Utrecht, The Netherlands

Background: The Tissue Factor (TF)-Activated Factor VII (FVIIa) complex plays an important role in the inflammatory and coagulation responses in patients with Systemic Inflammatory Response Syndrome (SIRS) and sepsis. As zymogen FVII (FVII) and FVIIa compete for binding to TF, it is possible that the mutual relation of their plasma levels determines the extent of activity of the TF-FVIIa complex.
Aims: The objective of this research was to study the mortality in SIRS patients as a function of FVIIa and VII levels in plasma.
Methods: A prospective cohort study of 275 consecutive patients presenting with SIRS, aged 18 years or older and an anticipated Intensive Care Unit (ICU)-stay of at least 24 h. FVIIa was measured using a novel, quantitative ELISA that recognizes FVIIa but not its zymogen FVII. All-cause hospital mortality was followed over a period of 60 days.
Results: On admission, the percentage of circulating FVIIa over factor VII was significantly higher in non-survivors than survivors (2.8% vs. 1.5%, $P = 0.034$). High levels of FVIIa were associated with decreased survival (62% vs. 81%, $P = 0.030$) while high levels of FVII were associated with an increased survival (84% vs. 76%, $P = 0.039$). Patients with high FVIIa and low FVII levels had a three-fold increased mortality risk compared to the patients that had low FVIIa and high FVII levels (Hazard Ratio [HR] = 3.2, 95% Confidence Interval [CI] 1.4–7.3). This association persisted after adjustment for the APACHE IV score (adjusted HR = 2.7, 95% CI 1.2–6.2).
Conclusions: We found an increased mortality in SIRS patients with high FVIIa levels and low FVII levels, independently of the parameters included in the APACHE IV score. Our data indicate that FVIIa and FVII could be useful in stratifying SIRS patients with high mortality risk.

Targeting protein C activation to tissue factor: *In vivo* studies in human tissue factor knock-in mice

Schmidt MV[1], Wilmen A[1], Dittmer F[1], McLean K[1], Laux V[2] and Gerdes C[2]

[1]*Bayer Healthcare;* [2]*Bayer Pharma AG, Wuppertal, Germany*

Thrombus formation by coagulation due to tissue factor (TF) exposure is associated with high mortality rates provoked by cardiovascular diseases such as ischemia, infarction, edema and inflammation. So far, the marketed antithrombotics do prevent thrombus formation but are also associated with an increasing risk of bleedings. By combining the anticoagulant properties of a TF antibody and a fragment of the protein C activator thrombomodulin (TM), substantial anti-thrombotic efficacy directly at the site of TF exposure is conceivable. Therefore, a genetic fusion was accomplished between the dimeric form of TF neutralizing single chain (Sc) antibody Fc fragment and the TM EGF-like domains 4–6. Constructive *in vitro* prothrombin time (PT) studies, *ex vivo* characterization as well as *in vivo* thrombosis experiments in human TF knock-in (hTFKI) mice were performed to investigate the antithrombotic and hemorrhagic properties of the fusion construct in comparison to the TF antibody or soluble TM individually.
PT studies with human plasma revealed a dose-dependent amplification of clotting time of the fusion construct compared to the TF antibody or TM individually. Further, to prove the efficacy of the fusion construct on human TF functionality, TF-rich brain extracts of WT (mouse TF) and hTFKI (human TF) mice were analyzed in a plasma clotting assay. Therein the fusion construct dose-dependently prevented clotting of human TF-activated plasma but not mouse TF-activated plasma. Inducing carotid or cremaster arterial thrombosis by ferric chloride or laser injury, respectively, the fusion construct prevented thrombosis in a dose-dependent manner. However, tail bleeding times, were similar in all treatment groups and did not show an improved therapeutic window compared to TF antibody alone.
In summary, the fusion construct outclasses the single components in *in-vitro* clotting assays. Further, the construct proved to be human TF specific and reduces thrombus growth in a dose-dependent manner similar to the TF antibody in two independent thrombosis models. However, due to the bleeding time prolongation which corresponds to the antibody, the benefit-risk ratio is comparable to the marketed drugs, therefore no superiority of targeting protein C activation at the site of TF exposure is achieved.

PA 2.15-3

Lung cancer chemotherapy agents induce protein disulphide isomerase dependent tissue factor decryption resulting in increased procoagulant activity *in vitro* and *in vivo*

Lysov Z[1], Swystun L[2], Kuruvilla S[1], Arnold A[1] and Liaw P[1]

[1]*McMaster University, Hamilton, ON;* [2]*Queens University, Kingston, ON, Canada*

Background: Cancer patients undergoing chemotherapy have an elevated risk for thrombosis, with venous thromboembolism (VTE) being the second leading cause of death in cancer patients. However, the mechanism(s) by which chemotherapy increases the risk for thrombosis in lung cancer patients is not well understood. Previous studies have shown that endothelial cells treated with lung cancer chemotherapy agents promote coagulation through an increase in tissue factor (TF) procoagulant activity.
Aims: The purpose of this study was to determine the mechanism(s) by which anti-lung cancer therapy agents cisplatin, carboplatin, paclitaxel, and gemcitabine induce procoagulant effect *in vitro* and *in vivo* when used as single agents, or in clinically relevant combinations.
Methods: Human umbilical vein endothelial cells (HUVECs), blood monocytes, and A549 cells were treated for 24 h with clinically relevant concentrations of chemotherapy agents alone and in combination. Cell surface TF activity was measured by factor Xa (FXa) generation in the presence or absence of factor VIIa and $CaCl_2$ on treated cells. Cell surface TF antigen, phosphatidylserine (PS) levels, and protein disulphide isomerase (PDI) levels were measured by flow cytometry. Healthy Balb/C mice received intraperitoneal injections of lung cancer chemotherapy agents alone or in combination. Blood was collected 24 h post-treatment by carotid artery cannulation. Plasma levels of thrombin-antithrombin (TAT) complex were measured by ELISA.
Results: Treatment of HUVEC, A459 cells, and monocytes with single agent and combination chemotherapy significantly increased cell surface FXa generation. FXa generation was completely ablated in the absence of FVIIa or in the presence of HTF-1 (an anti-TF antibody), confirming that FXa generation is TF dependent. Flow cytometry demonstrated unchanged cell surface TF antigen levels suggesting increased FXa generation was due to TF decryption. There was a significant increase in PS levels on HUVEC treated with high-dose cisplatin and gemcitabine combinations, and significantly elevated levels of cell surface PDI on HUVEC and A549 cell surface treated with chemotherapy agents. Inhibition of PDI, but not PS resulted in a moderate decrease of FXa generation suggesting that TF decryption was PDI mediated. Treatment of cells with reducing

agents glutathione or dithiothreitol significantly reduced TF activity further suggesting that PDI mediated chemotherapy-induced TF decryption occurs through disulphide bond formation. Our *in vivo* results demonstrated that treatment of healthy mice with combination chemotherapy significantly increased plasma TAT levels in healthy mice.

Conclusions: Our studies are the first to explore the effects of lung cancer chemotherapy agents on monocyte and A549 cell TF activity levels, as well as the first to delineate the mechanisms by which lung cancer agents promote TF decryption on these cell lines. We are also the first to report *in vivo* increases in thrombin generation in response to treatment of healthy mice with anti-lung cancer agents. These studies reveal potential mechanisms by which lung cancer chemotherapy induce a hypercoagulable state.

PA 2.15-4

Tissue factor is not expressed in platelets activated by various agonists

Osterud B and Olsen JO

University of Tromso, Tromso, Norway

Introduction: Blood borne tissue factor (TF) has been implicated to be associated with monocytes as well as neutrophils and platelets. In humans monocytes may be the only blood cell expressing TF. When blood is stimulated, TF rich microvesicles may become fused with activated platelets. However, recent reports still claim that isolated activated platelets express TF activity and it has been suggested that the expression of TF is a result of rapid and dynamic process whereby TF activity may be detected as early as 3 min after stimulation and may be gone after 2 h.

Aim: To establish whether isolated platelets free of contaminating monocytes may generate TF activity after activation with TRAP, LPS, LPS/PMA, or complement (IgG antibody).

Methods: Platelet rich plasma (PRP) of blood collected in Fragmin was prepared by twice centrifugation at 150 ***g*** for 15 min. Contaminated monocytes were removed by using MS-columns with anti-CD14 antibody microbeads. Isolated platelets were re-suspended in plasma. The platelet samples were incubated with LPS/PMA (100 and 5 ng/mL) for 4 h or IgG (88/μg/mL final conc) from patient with Lupus anticoagulant for 3 h. Platelets activated with TRAP (10 μM final conc) was incubated for 10 min before testing for TF activity immediately after isolation and washed free of plasma.

Results: Platelet free of monocytes had a very small increase in TF like activity after being stimulated with LPS/PMA (0.2 ± 0.1 mU/10^8 plts), but this activity was not affected by anti-TF antibody. In contrast, platelets contaminated with monocytes had a 10 fold increase (2.0 ± 0.9 mU/10^8 plts) that was reduced to about the same TF activity as activated platelets free of monocytes. The IgG antibody had no TF activity inducing effect on platelets free of monocytes, but strongly induced TF activity in monocytes of whole blood (> 25 mU/10^6 cells). Platelets stimulated with TRAP for 10 min had no increase over the Background.

(0.9 ± 0.1 mU/10^8 platelets) for TF like activity in control. A rise in TF like activity was seen when anti-TFPI antibody was added (1.4 ± 0.4 mU/10^8 plts) and that was enhanced a little more when also anti-TF antibody was added (1.6 ± 0.4 mU/10^8 plts).

Discussion: Our results show clearly that TF activity is not expressed or associated with platelets activated in plasma by several platelet agonists, transiently or after longer stimulation. These results prove that platelets do not possess TF that can be converted to an active form or synthesized through a TF pre-mRNA system. It is mandatory to remove contaminating monocytes from platelet preparations when studying TF in platelets.

PA 2.15-5

PGE2 cigarette smoke-induced modulates endothelial tissue factor: role of EP1 receptor and SIRT1

Amadio P[1], Barbieri SS[2], Baldassarre D[2], Tarantino E[1], Amato M[2], Ravani A[2], Weksler B[3] and Tremoli E[2]

[1]*Università degli Studi di Milano;* [2]*Centro Cardiologico Monzino, IRCCS, Milan, Italy;* [3]*Weill Cornell Medical College, New York, NY, USA*

Background: Cigarette smoke exposure increases the risk of atherothrombosis, induces the expression of cyclooxygenase-2 (COX-2) and the release COX-2 derived eicosanoids, including Prostaglandin E2 (PGE_2). Moreover, cigarette smoke up-regulates the expression and activity of Tissue Factor (TF), the main initiator of the coagulation cascade. However, the relationship between PGE_2 and TF has not yet been elucidated.

Aims: In this study, we analysed the link between PGE_2 and TF, and the impact of their regulation on cigarette smoke-induced atherothrombosis.

Methods: The levels of PGE_2 and TF expression and activity in plasma were measured in 46 healthy active smokers (AS; 30 men and 16 women) and 19 non-smokers (NS; eight men and 11 women). In addition, PGE_2 and TF were also measured in aorta tissue of mice and in mouse cardiac endothelial cells (MCEC) treated with aqueous extracts of cigarette smoke (TS) plus IL-1β (TS/IL-1β) by EIA assay, real-time PCR and procoagulant activity, using one stage-clotting assay, and/or by Zymuphen MP-TF. Arachidonic acid-induced thrombosis was used to study the effect of TS/IL-1β in mice. The expression of SIRT1, the NAD^+-dependent protein deacetylase, was measured by Western blotting and by Immunofluorescence.

Results: Higher levels of both PGE_2 and TF were detected in plasma of AS compared to NS. Similar results were obtained in mice and in MCEC treated with TS/IL-1β. A highly significant correlation between PGE_2 and TF activity was observed in both human plasma and mouse tissue. Inhibition of PGE synthase (PGES) activity by CAY10526, or by specific PGES siRNA, markedly diminished both *in vitro* and *in vivo* the amount of TF and the mouse carotid artery thrombosis induced by TS/IL-1b. In contrast, treatment with exogenous PGE_2 increased both TF and arterial mouse thrombosis.

MCEC express three PGE_2 receptors: EP1, EP2 and EP4. In these cells, EP1 antagonists (AH6809 and SC51089) prevented the TF induced by TS/IL-1β. In contrast, an EP1 agonist (17-phenyl-trinor-PGE_2) increased TF. We excluded the involvement of other EP receptors because an EP4 antagonist (GW627368X) and EP2/EP4 agonists (misoprostol, butaprost) did not modify TF. The role of SIRT1 in the regulation of TF was also analysed. Both Sirtinol, an SIRT1 deactivator, and the specific SIRT1 siRNA increased TF expression and activity. In contrast, the SIRT-1 activators (resveratrol and CAY10591) reduced TF induced by both TS/IL-1β and EP1 agonist.

Finally, EP1 agonist or the selective PGES-1 siRNA prevented the inhibition of SIRT1 mediated by PGE_2 or byTS/IL-1β.

Summary/Conclusion: We conclude that PGE_2 increases TF expression and activity in both mouse carotid arteries and endothelial cells. The phenomenon involves the regulation of the EP1/SIRT-1 pathway. These findings suggest that EP1 may represent a target to prevent thrombotic events

PA 2.15-6

Proteomic analysis of tissue factor activation

Kask L[1], Jorsback A[2], Winkvist M[2], Ek B[3], Bergquist J[3] and Siegbahn A[1]

[1]*Department of Medical Sciences;* [2]*GE Healthcare;* [3]*Analytical Chemistry, Uppsala, Sweden*

Background: Tissue factor (TF), initiator of blood coagulation, is also a signalling receptor. Signalling involves activation of protease acti-

vated receptor (PAR) 2, but the platelet derived growth factor β receptor has also been shown to be transactivated and other receptors have been suggested to be involved.
Aims: We investigated possible downstream activators when TF is stimulated by its ligand activated factor VII (FVIIa) using a proteomic approach.
Methods: A proteomic study was performed with the use of the refined technique of 2-D difference gel electrophoresis (DIGE) which has many advantages compared to traditional 2-D electrophoresis. The samples are pre-labelled with three different fluorescent dyes that are well separated on the wave length scale. This makes it possible to run two samples on each gel together with an internal standard run on every gel. Since the samples are compared to the same internal standard the detection of differences down to 10% is achievable with high accuracy. We used porcine aortic endothelial cells transfected with tissue factor and stimulated with 50 nM FVIIa for 20 min, 1, 3 h and catalytically inactive FVIIa (FVIIai) for 3 h. The proteins of interest were identified by mass spectrometry and we used both Western blot and a protein synthesis assay and a second cell line (human fibroblasts, 1137Sk) to further confirm our results for one of our interesting findings.
Results: Forty one spots were regulated differently over time or compared to non-stimulated cells, and 23 out of these were identified by mass spectrometry as 13 different proteins. One of them, elongation factor 2 (EF-2), an enzyme that promotes the translocation step in the elongation of the protein chain in protein synthesis, was investigated in more detail. The phosphorylation of EF-2 was increased when tissue factor was stimulated by FVIIa, and thereby more inactivated. Analyzing the effect of FVIIai and the PAR-2 agonist, SLIGKV, indicated that the inactivation is not PAR-2 dependent. In a protein synthesis assay we could confirm the results of decreased protein synthesis in two different cell lines when TF is stimulated by FVIIa.
Conclusions: We demonstrate that the phosphorylation of EF-2 is increased when FVIIa is bound to TF. This phosphorylation regulates the activity of the protein and inactivates EF-2, which in turn slows down the protein synthesis. Our data suggest that this effect is not mediated through the PAR-2 receptor since the phosphorylation effect on EF-2 was also seen after FVIIai incubation, which cannot cleave the PAR-2 receptor. Moreover, the PAR-2 agonist SLIGKV did not induce phosphorylation of EF-2 and when deleting the cytoplasmic domain of TF the effect is abolished. Instead, the effect may be mediated via a novel receptor that interacts with TF or directly by a TF cytoplasmic domain induced pathway. The reason and mechanism behind the decrease in protein synthesis need to be further explored, but speculating, it could be an initial stress response.

PA 2.16-1

Incidence and predictive factors of symptomatic venous thromboembolism related to port-a-cath in cancer patients

Piran S[1], Ngo V[2], McDiarmid S[3], Le Gal G[1], Petrcich W[2] and Carrier M[1]
[1]Medicine, University of Ottawa; [2]Clinical Epidemiology Program, The Ottawa Hospital Research Institute; [3]The Ottawa Hospital, Ottawa, ON, Canada

Background: The use of indwelling central venous catheters, such as port-a-caths, has significantly improved the management of patients with malignancies receiving chemotherapy. Thrombosis is a common complication of catheters and is associated with significant morbidity. However, the true incidence of symptomatic port-a-cath-related deep vein thrombus (DVT) and its associated risk factors in cancer patients remains unclear.
Aim: To assess the incidence and risk factors associated with symptomatic venous thromboembolism (VTE) related to port-a-cath in cancer patients.
Methods: We performed a retrospective cohort study of consecutive cancer outpatients who have received an ultrasound guided port-a-cath insertion for the administration of chemotherapy between November 2010 and December 2011 in our institution. The primary outcome measure was symptomatic VTE. Venous thromboembolism was defined has symptomatic upper extremity port-a-cath related proximal (axillary vein or more proximal) DVT or pulmonary embolism (PE). Univariable and multivariable logistic regression analyses were used to identify risk factors for symptomatic VTE.
Results: A total of 400 cancer patients with a newly inserted port-a-cath for the deliverance of chemotherapy were included into the study. Median age was 58 years (range of 21–85 years) and 120 (30%) were males. All patients were followed for a median of 12 months and none received thrombophrophylaxis. Of the 400 patients included in the analysis, 34 patients (8.5%; 95% CI: 6.0–11.7%) had symptomatic VTE (16 DVTs, 16 PEs, and two with both). The median time from insertion of port-a-cath to VTE occurrence was 103 days (range of 13–371 days). In the univariate analyses, cancer type, metastatic disease, female gender and left sided port-a-cath insertion were significantly associated with the risk of VTE. The most common cancer types were GI tract cancer (62%) in patients with a symptomatic VTE and breast cancer (50%) was more frequent in patients without VTE. Ninety-four percent of patients with a symptomatic VTE had metastases compared to 60% in those without VTE. Other demographic factors including age, body mass index and smoking status were not significant contributors. Co-morbidities, including diabetes, coronary artery disease, hypertension, and chronic obstructive pulmonary disease (COPD) were also not significant contributors. In the multiple-variable analysis, female gender (OR 0.46, $P = 0.04$) and presence of metastases (OR 8.22, $P < 0.01$) were the two significant independent predictors of port-a-cath related VTE.
Conclusion: Symptomatic VTE is a frequent complication in cancer patients with port-a-cath receiving chemotherapy. Gender and presence of metastatic disease are independent risk factors for symptomatic VTE. Future trials assessing the role of thromboprophylaxis among these higher risk patients are needed.

PA 2.16-2

Prediction of venous thromboembolism in cancer patients by tissue factor dependent microparticle coagulant activity, biomarkers and a clinical score

Kleinjan A[1], Bossuyt P[1], Cesarman-Maus G[2], Di Nisio M[3], Kamphuisen PW[4], Kramer M[5], Mahé I[6], Nanayakkara P[5], Nieuwland R[1], Otten HM[7], Stephanian A[8] and Büller HR[1]
[1]Academic Medical Center, Amsterdam, The Netherlands; [2]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Mexico City, Mexico; [3]G.D'Annunzio University, Chieti, Italy; [4]University Medical Center Groningen, Groningen; [5]VU Medical Center, Amsterdam, The Netherlands; [6]Hospital Louis Mourier, Colombes, France; [7]Slotervaart Hospital, Amsterdam, The Netherlands; [8]Hospital Louis Mourier and Inserm, Colombes/Le Kremlin-Bicêtre, France

Background: Cancer patients receiving chemotherapy in an ambulatory setting are at risk of venous thromboembolism (VTE). Randomized controlled trials have shown that thromboprophylaxis with low-molecular-weight-heparin reduces the occurrence of VTE in cancer patients but the overall incidence of 4% is generally considered too low to justify thromboprophylaxis in all patients. A logical next step is to focus on tools for selecting cancer patients at the highest risk of VTE, in whom thromboprophylaxis is expected to have a more favorable risk-benefit ratio.

Aim: We aimed to determine the performance of tissue factor (TF)-dependent microparticle coagulant activity in predicting VTE, and to compare it to that of the Khorana score, and previously evaluated biomarkers.
Methods: In six hospitals blood was obtained from consenting ambulatory patients receiving chemotherapy for stage III or IV cancer. Patients were prospectively followed for 6 months for development of VTE. At inclusion, TF-dependent microparticle coagulant activity was measured in a fibrin generation test (FGT) on fresh plasma in the local laboratories. The outcome measure of this plasma recalcification test was the prolongation of the clotting time in the presence of antibody to factor VII/TF, expressed as percentage of the clotting time in the absence of antibody. The result was considered positive above 13%. Remaining plasma was frozen and stored for later central measurement of D-dimer, P-selectin, pro-thrombin fragment 1 + 2 (F1 + 2) and factor VIII; for these tests positivity cut-offs from the original publications were used. Clinical data were collected for calculation of the Khorana score, which assigns patients to three risk categories. Estimates of sensitivity and positive predictive value (PPV) were calculated, taking into account death as a competing risk, with 95% confidence intervals (CI) based on bootstrap re-sampling.
Results: The prospective cohort has recruited 443 patients, with a mean age of 61 years, of which 49% women. In total, 23 patients developed VTE, after a mean time of 2.1 months (5.2%); 77 patients died, after a mean follow-up of 3.3 months (18%). Sensitivity was estimated at 61% (95% CI: 31–84%) for FGT, 84% (61–97) for D-dimer, 85% (56–96) for P-selectin, 44% (61–97) for factor VIII, and 70% (36–89) for F1 + 2. The positive predictive value was 4.7% (1.9–9.3%) for FGT, 6.9% (3.5–12) for D-dimer, 14% (4.8–27) for P-selectin, 11% (4.5–21) for factor VIII and 5.9% (2.4–12) for F1 + 2. A high Khorana score had a sensitivity of 63% (28–83) and PPV of 5.1% (1.6–12). None of the differences were statistically significant.
Summary/Conclusions: There are no substantial differences in predictive performance between the studied biomarkers. None of the individual positive predictive values exceeded 15%. In this cohort of patients with advanced cancer, 18% died, which makes adjustment for death as competing risk of utmost importance. In our opinion single predictors will probably not solve the problem and combinations are likely to be helpful.

PA 2.16-3
High incidence of VTE despite electronic alerts for thromboprophylaxis in hospitalized cancer patients

Lecumberri R[1], Marqués M[1], Alfonso A[1], Fernández del Carril A[1], Nicolás M[1], García Mouriz A[1], Hermida J[2], Schulman S[3] and Páramo JA[1]

[1]University Clinic of Navarra; [2]Center for Applied Medical Research, University of Navarra, Pamplona, Spain; [3]McMaster University, Hamilton, ON, Canada

Background: Despite most cancer patients present high risk of venous thromboembolism (VTE) during hospitalization, thromboprophylaxis is frequently underused. Electronic alerts (e-alerts) have been associated with improvement in the use of thromboprophylaxis and a reduction of the incidence of VTE, both during hospitalization and after discharge, particularly in the medical setting. However, there are no data regarding the benefit of this tool in cancer patients.
Aim and Methods: Our aim was to evaluate the impact of a computer-alert system for VTE prevention on patients with cancer, particularly in those admitted in the Oncology/Hematology ward, comparing the results with the rest of inpatients at a university teaching hospital. The study included 32,167 adult patients hospitalized during the first semesters of years 2006–2010, 9265 (28.8%) of them with an active malignancy.
Results: Appropriate prophylaxis in medical patients, significantly increased over time (from 40% in 2006 to 57% in 2010) and maintained over 80% in surgical patients. However, while e-alerts decreased the incidence of VTE during hospitalization in patients without cancer (OR 0.31; 95% CI, 0.15–0.64), the impact was modest in cancer patients (OR 0.89; 95% CI, 0.42–1.86) and no benefit was observed in patients admitted for the Oncology/Hematology Departments (OR 1.11; 95% CI, 0.45–2.73). Interestingly, 60% of VTE episodes occurring in cancer patients in the last years developed despite appropriate prophylaxis.
Conclusion: Contrary to the impact on non-cancer hospitalized population, the implementation of e-alerts for VTE risk was insufficient to prevent the development of VTE during hospitalization among patients with malignancies.

PA 2.16-4
Clinical presentation, ADAMTS13-related measurements and outcomes in cancer-associated thrombotic thrombocytopenic purpura

Rossio R[1], Ferrari B[1], Pontiggia S[1], Lotta LA[2], Giuffrida G[3], Artoni A[1] and Peyvandi F[1]

[1]Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico; [2]Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, Milano; [3]Vittorio Emanuele Ferrarotto-S.Bambino Hospital, University of Catania, Catania, Italy

Background: Thrombotic thrombocytopenic purpura (TTP), a rare thrombotic disease of the microvasculature, may be idiopathic or secondary to various conditions. Idiopathic TTP is often characterized by plasmatic deficiency of von Willebrand factor (VWF) cleaving protease, ADAMTS13. Secondary TTP may be associated with autoimmune disorders, infections, drugs and cancer. Data on clinical features and ADAMTS13 levels in cancer-associated TTP are scanty.
Aims: To describe clinical presentation, outcomes and to analyze ADAMTS13- and VWF-related measurements in a cohort of cancer-associated TTP.
Methods: We analyzed clinical and laboratory data of 18 patients with cancer-related TMA referred to the Milan TTP Registry (URL: www.ttpdatabase.org) between 1999 and 2012. Inclusion criteria were: (i) clinical documentation of acute TTP and (ii) diagnosis of solid or hematologic malignancy, established by clinical, laboratory, radiological, histological findings. We measured ADAMTS13 antigen and activity, anti-ADAMTS13 antibodies by western blotting, VWF antigen and multimeric pattern on plasma samples collected before any transfusional therapy.
Results: Median age at presentation was 63 years (range: 29–83 years). Solid cancers affected stomach (n = 4, 22%), uterus (n = 2, 11%), liver (n = 1, 6%), prostate (n = 1, 6%), bladder (n = 1, 6%), skin (n = 1, 6%), rectum (n = 1, 6%); hematologic cancers were non-Hodgkin lymphoma (n = 2, 11%) and chronic myelomonocytic leukemia (n = 2.11%); three cases (16%) had metastatic tumors of unknown origin. TTP was the first sign of malignancy in 10 (55%) cases.
At presentation, nine patients (50%) had neurologic symptoms, 5 (28%) renal involvement, 13 (72%) bleeding diathesis. Median hemoglobin was 10.3 g/dL (range: 5.2–11.8 g/dL), platelets 16.5×10^9/mmc (range: 6–133 $\times$ 10^9/mmc), LDH 1664 IU/L (range: 286–7060 IU/L). Seventeen patients received plasma exchange or fresh-frozen plasma, associated with chemotherapy in two cases. Nine patients did not survive during the acute episode (data not available for four). ADAMTS13 and VWF values were tested in 14 patients: 28% had severe ADAMTS13 deficiency (activity below 10%), 21% had moderate deficiency (10–46%), 50% had normal ADAMTS13 activity (above 46%). Anti-ADAMTS13 antibodies were present in three out of four patients with severe ADAMTS13 reduction and in one out of three with moderate deficiency. VWF antigen resulted elevated in 64% of patients, independently of ADAMTS13 levels; 64% of patients had a consumption of ultralarge and large-size VWF multimers.
Summary/Conclusions: TTP may be the first manifestation of malignancy. ADAMTS13 activity may be normal or mildly reduced in can-

cer-related TMAs, suggesting that VWF-mediated thrombosis is not the only abnormality involved in this setting. Severely reduced ADAMTS13 levels associated with anti-ADAMTS13 antibodies do not rule out cancer-related TTP.

PA 2.16-5

TF expressed by microparticles is associated with mortality but not with thrombosis in cancer patients

Paramo JA[1], Orbe J[1], Roncal C[1], Alvarez-Hernandez M[2], Martinez de Lizarrondo S[1], Garcia-Mata J[3] and Hernandez C[3]

[1]CIMA, University of Navarra, Pamplona; [2]Facultad de Medicina, Granada; [3]Complejo Hospitalario Ourense, Ourense, Spain

Background: A prothrombotic state is one of the hallmarks of malignancy and a major contributor to morbidity and mortality. Tissue factor (TF) is often overexpressed in malignancy and is a prime candidate in predicting the hypercoagulable state. Moreover, increased number of TF-expressing microparticles (MPs) in cancer patients may contribute to venous thromboembolism (VTE).

Aim: We have conducted a prospective cohort study to determine whether elevated TF antigen, TF activity and TF associated to MPs (MPs-TF) are predictive of VTE and mortality in cancer patients.

Methods and Results: The studied population consisted of 252 cancer patients and 36 healthy controls. TF antigen and activity and MP-TF were determined by ELISA and chromogenic assays respectively. During a median follow-up of 8.9 months, 40 thrombotic events were recorded in 34 patients (13.5%) and 73 patients (27.9%) died. TF antigen and activity were significantly higher in patients than in controls ($P < 0.01$) specially in patients with advanced stages whereas no differences were observed for MPs-TF activity. We did not find a statistically significant association of TF variables with the risk of VTE, but they were associated with mortality in univariate analysis. Multivariate analysis adjusting for age, sex, type of cancer and other confounding variables showed that TF and MPs-TF activity were independently associated with mortality ($P < 0.01$).

Conclusions: While TF variables were not associated with future VTE in cancer patients, we found a strong association of TF and MPs-TF activity with a poor outcome, thus indicating they might be good prognostic markers in cancer patients.

PA 2.16-6

Association of endothelial protein C receptor (A6936G) haplotype with thrombotic events as a risk factor in acute myeloid leukemia

Azzazene D[1], Mirshahi S[2], Thawadi H[1], Al Farsi H[1], Besbes S[1], Mirshahi M[1], Therwath A[1], Tang R[3], Fava F[3], Ghedira I[4], Soria J[1] and Marie JP[5]

[1]Inserm, UMRS 872, CRC, Université Pierre et Marie Curie-Paris 6; Université Pari; [2]2 Hôtel Dieu Hospital; [3]Tumor Bank "Leukemia" Hôpital Saint-Antoine, Paris, France; [4]Faculté de Pharmacie, Monastir, Tunisia; [5]Département d'hématologie, Hôpital Saint-Antoine, Paris, France

Background: Previously we presented evidence of the presence of endothelial protein C receptor (EPCR or PROCR) in a large group of leukemic cell lines and high plasma level of soluble EPCR (s-EPCR) in plasma of patients with human hematologic malignancies, giving a powerful insight into thrombotic risk. Haplotype characterization of HL-60, a myelomonoblastic cell line, shows single nucleotide polymorphisms (SNPs) originally described in A1 and A2 haplotypes and some additional new SNPs in the promoter and intronic regions.

Objective: To assess whether A3 (A6936G) haplotype, which is a genetic regulator of s-EPCR, can be involved in procoagulant activity of hematologic malignancies.

Patients/Methods: In a retrospective case-control study, haplotype of the EPCR gene was performed in 205 patients with hematologic malignancies from Saint Antoine Hospital [76 Chronic Lymphocytic Leukemia CLL (median age 67; 39 men, 37 women), 68 Acute Myeloid Leukemia AML (median age 62.5; 41 men, women), 33 Acute Lymphoblastic Leukemia ALL (median age 36; 18 men, 15 women) and 28 other malignant diseases (median age 64.5; s19 men, nine women)] and in 63 healthy donors (controls)(median age 25; 30 men, 33 women) provided by Hôtel-Dieu and Saint-Antoine Hospitals blood banks. DNA was purified using Qiagen DNA extraction Kit. All subjects were genotyped by Genoscreen using allele specific amplification for the three haplotypes of EPCR gene according to 6963A/G polymorphism (AA, AG and GG nucleotides). Clinical association of AG polymorphism with thrombotic events was studied in 75 patients (CLL, $n = 21$, AML, $n = 42$ and other, $n = 12$).

Results:

1 The distributions of AA, AG and GG nucleotides in all subjects were identical in healthy donors and in patients: the distribution of alleles in healthy donors and in patients are respectively 84.2% and 84.9% for AA, 14.2% and 14.1% for AG and 1.6% and 1% for GG.
2 The percentages of the three haplotypes (AA, AG and GG) were 80.1%, 17.1% and 2.8% for AML-90.9%, 9.1% and 0% for ALL-85.5%, 14.5% and 0% respectively for CLL – 85.6%, 14.4% and 0% for the other malignant hematological diseases, and 84.2%, 14.2% and 1.6% for controls.
3 In 75 patients tested for thrombotic events, thrombosis occurred in 38.1–14.3–4.8% of patients with AML, CLL and others respectively. In addition, the incidence of thrombotic events is much higher in AG allele-patients than in AA-ones: 45.5% of AML patients and 20.% of CLL patients with AG phenotype had thrombotic event, whereas thrombosis occurred only in 7.5% of AML patients and in 12.5% of CLL patients with AA phenotype, suggesting a high incidence of thrombosis in patients with EPCR-AG haplotype.

Conclusion: In this pilot study, the results demonstrate a striking association of AG heliotype of EPCR with thrombotic events in AML. The presence of AG allele in AML patients may be a risk factor for thrombosis and its determination in patients can be crucial for thrombosis prevention in this malignancy.

TM5441, a novel PAI-1 antagonist, prevents hypertension and arteriosclerosis in an experimental model for vascular aging

Boe AE[1], Eren M[1], Murphy SB[1], Kamide CE[1], Miyata T[2] and Vaughan E[1]

[1]Northwestern University, Chicago, IL, USA; [2]Tohoku University, Sendai, Japan

Background: Long-term inhibition of nitric oxide synthase (NOS) by L-arginine analogues such as N^{ω}-nitro-L-arginine methyl ester (L-NAME) has previously been shown to induce systemic hypertension and arteriosclerosis in animal models. NOS inhibition is also known to augment the expression of plasminogen activator inhibitor-1 (PAI-1) in vascular tissue. Our laboratory previously reported that PAI-1 deficient mice (PAI-$1^{-/-}$) are protected against hypertension and vascular fibrosis due to long-term L-NAME treatment. These findings led to the hypothesis that pharmacological inhibition of PAI-1 activity is protective against the L-NAME-induced hypertension in wild-type (WT) mice. Addtionally, L-NAME has been shown to induce vascular senescence and aging. However, PAI-1's role in this process has yet to be investigated.

Aims: The aim of this study are to determine whether pharmacological inhibition of PAI-1 using the novel inhibitor TM5441 can protect mice from L-NAME induced hypertension, cardiac hypertrophy, arteriosclerosis, and vascular aging.
Methods: WT C57BL/6 mice were either fed a normal chow diet or TM5441 chow (20 mg/kg/day) starting at 6 weeks of age. These same animals were given either regular or L-NAME water (1 mg/mL). Animals were placed on their respective treatments for 8 weeks. Systolic blood pressure (SBP) measurements were taken every 2 weeks. Echocardiograms were performed at both baseline and after 8 weeks. After 8 weeks, the mice were sacrificed and organs were collected for histology and qRT-PCR analysis.
Results: After 8 weeks of treatment, we found that TM5441 attenuated the development of hypertension compared to animals that had received L-NAME alone (SBP 162.62 ± 21.18 vs. 182.99 ± 13.21 mm Hg, $P = 0.009$). We also observed significant reductions in left ventricle wall thickness ($P = 0.03$) and mass ($P = 0.02$). Additionally, TM5441-treated mice had a 34% reduction in periaortic fibrosis relative to WT animals on L-NAME ($P = 0.003$). Finally, we looked at the senescence marker $p16^{Ink4a}$ in the aorta and found that L-NAME-treated animals had a 2-fold increase in $p16^{Ink4a}$ expression over WT, and that this upregulation was prevented by TM5441.
Conclusions: Pharmacological inhibition of PAI-1 is protective against the development of hypertension, cardiac hypertrophy, and periaortic fibrosis in mice treated with the L-NAME. Furthermore, PAI-1 inhibition attenuates the arterial expression of $p16^{Ink4a}$. PAI-1 appears to play a pivotal role in vascular senescence, and these findings suggest that PAI-1 inhibitors may provide a novel approach in preventing vascular aging and hypertension.

PA 2.17-2

Vascular smooth muscle cells confer a prothrombotic phenotype within the vessel wall of spontaneously hypertensive rats

Regnault V[1], Ait Aissa K[1], Lagrange J[1], Max JP[1], Louis H[1], Thornton SN[1], Benetos A[1], Challande P[2], Wahl D[1] and Lacolley P[1]
[1]*Inserm U1116, Vandoeuvre-les-Nancy;* [2]*UMR CNRS 7190, Paris, France*

Background: Clinical and experimental evidence point towards an impairment of the hemostatic balance in blood conferred by change in individual coagulation factors in the presence of elevated blood pressure. The vascular wall is one of the elements that determine the thrombotic response. However, it is still unclear whether hypertension confers a prothrombotic state in blood and within the vessel wall.
Aims: This study investigated whether hypertension-induced changes in coagulation proteins cause an increase thrombin generating capacity both in blood and within the vascular wall and tested the respective contribution of vascular smooth muscle cell (VSMC) and endothelial cells (ECs).
Methods: We used 12-week-old spontaneously hypertensive rats (SHR) compared with age-matched Wistar rats. Two-millimeter ring segments, VSMCs or ECs were isolated form the descending thoracic aorta of both SHR and Wistar rats. Thrombin generation was monitored in platelet-rich PRP and platelet-poor plasma (PPP) as well as the surface of adherent VSMCs or endothelial cells (ECs) using calibrated automated thrombography (CAT) and quantified by the endogenous thrombin potential (ETP).
Results: The plasma of SHR had lower thrombin-forming capacity in response to a stimulation with 0.5 pM of tissue factor (TF) compared to Wistar rats (246 ± 16 vs. 338 ± 27 nM/min, $P = 0.007$), which was increased in the presence of platelets (594 ± 29 vs. 785 ± 51 nM/min, $P = 0.003$). This was related to lower prothrombin (58 ± 4 vs. 83 ± 4%, $P = 0.0004$) and higher tissue factor pathway inhibitor (TFPI) levels (6.9 ± 0.2 vs. 4.5 ± 0.4 U/mL, $P = 0.0002$) in SHR plasma. The addition of thoracic aorta rings to Wistar plasma pool increased thrombin generating capacity compared to 50 pM TF alone. These effects were more pronounced for SHR than Wistar rings (699 ± 19 vs. 637 ± 7 nM/min, $P = 0.007$ and 529 ± 17 nM/min for TF alone). Whereas no difference was observed for ECs, thrombin formation was higher at the surface of cultured SHR aortic SMCs than from Wistar (787 ± 5 vs. 824 ± 9 nM/min, $P = 0.003$). Exposure of negatively-charged phospholipids was higher on SHR than on Wistar rings (3.4 ± 0.4 vs. 1.9 ± 0.2 nM equivalent phosphatidylserine/g of ring, $P = 0.0007$) as well as on SMCs (747 ± 33 vs. 649 ± 222 nM equivalent phosphatidylserine/mL, $P = 0.03$). TF and TFPI activities were higher in SHR SMCs whereas no differences were observed for ECs between the two strains. In young, 5-week-old rats, before blood pressure increase, similar differences between SHR and Wistar are observed in plasma while there was no difference at the surface of aortic rings and SMCs.
Summary/Conclusion: These results show opposite thrombin generating capacity of plasma and vessel walls in SHR compared to Wistar. The higher prothrombotic phenotype of the SHR vessel wall was due to the ability of SMCs to support thrombin generation. These findings suggest that the hypertension-induced membrane phospholipid reorganization and synthesis of procoagulant molecules in SMCs provide substrates for increased thrombin formation within the vessel wall.

PA 2.17-3

Effect of hyperglycemia and hyperinsulinemia on platelet insulin signaling and coagulation pathways

Rao AK[1], Freishtat R[2], Jalagadugula G[1], Singh A[1], Mao G[1], Wiles A[2], Cheung P[1] and Boden G[1]
[1]*Temple University School of Medicine, Philadelphia, PA;* [2]*Children's National Medical Center, Washington, DC, USA*

Background: Type 2 diabetes mellitus (T2DM) is a prothrombotic and proinflammatory state with elevated plasma coagulation factors and evidence of platelet and monocyte activation. We previously showed that in healthy non-diabetic subjects that infusion clamp-generated hyperglycemia (HG) and hyperinsulinemia (HI) and the combination of HG+HI increased circulating membrane-bound tissue factor-procoagulant activity (TF-PCA). In addition, markers of thrombin generation and platelet/monocyte activation were induced.
Aims: To understand the mechanisms and pathways underlying these cellular perturbations.
Methods: We performed whole genome expression profiling (U133 Plus 2.0 Affymetrix GeneChips) of platelets (leukocyte-depleted) and monocytes before and after 24 h of HG+HI infusion clamping in a healthy non-diabetic subject. HG was maintained at approximately 200 mg/dL by glucose infusion, which elevates endogenous insulin to induce HI.
Results: We defined time-dependent differential mRNA expression [24 vs. 0 h fold change (FC) ≥ 2] common to both platelets and monocytes using Partek Genomics Suite. Ingenuity Pathways Analysis revealed alterations in canonical insulin receptor signaling and coagulation pathways in both cell fractions. For example, alterations were seen in platelet expression of insulin signaling pathway genes: *IRS1* (insulin substrate receptor 1, FC (24 vs. 0 h) = 0.14), *INSR* (insulin receptor, 0.23), *GSK3B* (glycogen synthase kinase 3 beta, 5.5), *VAMP2* (vesicle-associated membrane protein 2, 14.3), *STXBP4* (syntaxin binding protein 4, 0.13), *PIK3C3* (Phosphoinositide-3-kinase class 3, 0.31) and *PTPN11* (protein tyrosine phosphatase, non-receptor type II, SHP2, 13.0). In the coagulation pathway *F3* (tissue factor, 3.7) and *TFPI* (tissue factor pathway inhibitor, 4.5) were altered. These were selected for qRT-PCR confirmation. For additional validity in platelets the 24 h sample was compared to the 0 h sample plus four normal platelet controls. Notably, eight out of the nine selected transcripts listed above were confirmed in platelets and/or monocytes. In platelets, these include ↑*GSK3B*, ↓*STXBP4*, ↑*PTPN11* in insulin signaling, and ↑*F3*

and ↑*TFPI* in coagulation. In monocytes, *STXBP4, PIK3C3, PTPN11* and *TFPI* were downregulated. Due to the importance of F3 (TF) in T2DM related cardiovascular complications, we measured TF antigen in platelets and monocytes by ELISA. TF antigen increased 2- and 5-fold over 24 h in platelets and monocytes, respectively. Further, TF-PCA in whole blood increased from 7.9 to 69.7 μ/mL. Immunoblot analyses for platelet GSKb3 (↑ approximately 34%) and PTPN11 (↑ approximately 42%) showed increases. Finally, amplification (qRT-PCR) of platelet mRNA using F3 intron 4-specific primers showed that HG+HI leads to splicing of TF pre-mRNA *in vivo*.
Conclusions: HG+HI, even in the non-diabetic state, induces demonstrable changes in platelets, including alterations in insulin-signaling and coagulation pathways, with upregulation of *GSK3B* and *PTPN11* (important in insulin signaling) and in *F3* and *TFPI* in coagulation. Upregulation of platelet *F3* (i.e. TF) is an important finding associated with upregulation of TFPI (the principal TF inhibitor) and *GSK3B,* shown to be a negative regulator of TF synthesis. Further studies in healthy subjects and DM patients will better define the pathways altered in platelets and monocytes by HG, HI and HG+HI, and leading to the prothrombotic and proinflammatory state in diabetes mellitus.

PA 2.17-4
FVII-activating protease (FSAP) confers protection to primary astrocytes and neurons exposed to oxygen-glucose deprived conditions

Joshi AU
Justus Liebig University, Giessen, Germany

Background: Factor VII activating protease (FSAP) is a circulating plasma serine protease that is activated by factors released by dead cells such as histones, nucleosomes and nucleic acids. It inactivates tissue factor pathway inhibitor (TFPI) and activates single chain urokinase thus having potential roles in both the coagulation and fibrinolytic system. FSAP antigen and activity are increased in patients with ischemic stroke and single nucleotide polymorphisms (SNP) in the gene are risk factors for stroke. In this study, we investigated the role of endogenous FSAP in brain ischemia using an *in vivo* mouse model transient middle cerebral artery occlusion (tMCAO) and *in vitro* using neuronal-astrocytic cell culture model for oxygen-glucose deprivation injury (OGD).
Aim: To analyze the pathophysiological significance of FSAP in ischemic brain.
Methods: $FSAP^{-/-}$ mice were subjected to tMCAO for 90 min and reperfusion injury was assessed after 24 h using MRI scans and neurological scores. *In vitro*, primary cortical neurons and astrocytes were isolated from E16 mice and exposed to OGD. Neurons were treated with tissue plasminogen activator (tPA)/*N*-Methyl-D-aspartic acid (NMDA) under OGD conditions to analyze excitotoxic injury. LDH release, cellular metabolic activity assay, TUNEL assays and Caspase 3/7 activity assays were carried out to analyze cell death in the presence of exogenous FSAP. Casein zymography was used to analyze endogenous urokinase (uPA) and tPA activity while gelatin zymography was performed to analyze the MMP-2 and MMP-9 activity. Total RNA was isolated and expression for BCL-2, BCL-XL, tPA, uPA, MMP's and their inhibitors was analyzed. Protein lysates were prepared and analyzed for Akt, ERK phosphorylation and BCL-2.
Results: In the mouse stroke model, no difference was observed between the $FSAP^{+/+}$ and $FSAP^{-/-}$ mice in infarct volume or neuroscore. After stroke there was a 1.4-fold elevated FSAP activity in $FSAP^{+/+}$ mice. In primary cortical neurons FSAP treatment reversed NMDA mediated excitotoxicity by approximately 50% (P-value < 0.0001). FSAP increased endogenous tPA (approximately 1.5-fold) and uPA (approximately 2.5-fold) activity while decreased MMP-9 activity (approximately 1.5-fold) in primary cortical neurons. FSAP-treated astrocytes showed decreased TUNEL positive cells (approximately 2.9-fold) (P-value = 0.0019) and decreased Caspase 3/7 activity (approximately 1.5-fold) (P-value < 0.0001). Decreased LDH release (approximately 56%) and increased cellular metabolic activity (approximately 22%) were indicative of improved cell survival in FSAP treated astrocytes. FSAP up-regulated Akt phosphorylation (approximately 2.5-fold), up-regulated MMP-2 activity (approximately 1.5-fold), increased endogenous tPA (approximately 10-fold) and urokinase activity (approximately 15-fold) in primary astrocytes under OGD conditions. FSAP increased BCL-2 and BCL-XL mRNA expression by 2-fold and 2.5-fold respectively in astrocytes exposed to OGD.
Conclusions: Endogenous FSAP does not influence infarct volumes or functional recovery in the mouse tMCAO model. On the other hand a SNP that leads to reduced FSAP activity is associated with higher stroke-related mortality in humans. In neurons and astrocytes, FSAP protects from hypoxic and excitotoxic injury. These novel results provide insight into the protective role of FSAP in ischemic stroke.

PA 2.17-5
Antithrombin deficiency increases the severity of arterial thrombosis and promotes resistance to platelet antiaggregation *in vivo*

Guerrero JA
Centro Regional de Hemodonación, Hospital Morales Meseguer, UMU, IMIB, Murcia, Spain

Background: Despite genetic risk factors for venous thrombosis are also associated with arterial complications, antithrombin deficiency has only been considered in the framework of venous thrombosis. However, the key role of thrombin in atherothrombosis and platelet reactivity sustains a relevant function in this setting for antithrombin, the main endogenous inhibitor of thrombin.
Aim: To evaluate the role of antithrombin in arterial thrombosis and its potential effect on outcomes of antiplatelet therapy in a mouse model.
Methods: Wild type (WT) and antithrombin deficient (AT+/−) mice (with 50% plasma levels of antithrombin) were treated with vehicle, aspirin (single i.p. dose of 100 mg/kg of body weight) or clopidogrel (two doses of 2 mg/kg of body weight by oral gavage). At least nine animals per genotype and treatment were used for two *in vivo* studies: $FeCl_3$ induced-thrombosis in carotid artery and tail bleeding times (BT). In the last procedure, the quantitation of blood loss during bleeding was done by estimating of total hemoglobin content as arbitrary units of absorbance (UA). Moreover, *in vitro* light transmission platelet aggregation analysis induced by collagen, ADP and arachidonic acid were also carried out.
Results: AT+/− mice showed a significantly shorter occlusion time following $FeCl_3$ injury of the carotid artery when compared to WT animals (5.01 ± 1.25 vs. 6.91 ± 2.50 min, respectively; $P = 0.025$). In contrast, both AT+/− and WT mice displayed similar BTs (< 5 min) and total blood loss as assessed by haemoglobin content. Aspirin and clopidogrel treatment inhibited platelet aggregation induced by arachidonic acid and ADP, to a similar extent in WT and AT+/− mice. As expected, aspirin and clopidogrel treatment increased bleeding tendency in WT mice (6/9 with aspirin and 7/9 with clopidogrel had BT > 10 min). Interestingly, among AT+/− mice only two out of 10 aspirin -treated and four out of nine clopidogrel-treated showed BT > 10 min. In agreement, the total haemoglobin content of the blood loosed during the BT procedure was 0.81 ± 0.27 and 1.87 ± 0.62 UA for aspirin and clopidogrel, respectively, in WT mice, compared to 0.11 ± 0.04 and 1.02 ± 0.34 for aspirin and clopidogrel, respectively, in AT+/− mice. We also observed that aspirin efficiently delayed the occlusion time of the carotid flow in the $FeCl_3$ model of-thrombosis on WT mice (no carotid occlusion in 8/9 animals), while this drug has milder effects on AT+/− mice (5/11 animals showed a patent open carotid after $FeCl_3$ injury). In contrast, clopidogrel treatment impaired thrombus formation in this model similarly in both groups.

Conclusions: Our findings in a mouse model support a relevant effect of antithrombin in both arterial thrombosis and in the efficacy of aspirin and clopidogrel. Deficiency of this key anticoagulant might increase thrombin generation under physiological or pathological activation of the clotting cascade, thus resulting in faster clot formation and reduced efficacy of current antiplatelet drugs.

PA 2.17-6

The hypercoagulable profile of stent thrombosis patients

Loeffen R[1], Godschalk TC[2], Van Oerle R[1], Spronk HMH[1], Hackeng CM[2], Ten Cate H[1] and Ten Berg JM[2]

[1]Maastricht University Medical Center, Maastricht; [2]St Antonius Hospital, Nieuwegein, The Netherlands

Background: Stent thrombosis (ST) is a devastating complication after percutaneous coronary interventions (PCI), with major clinical impact due to the high risk of myocardial infarction and death, as well as a high recurrence rate. The incidence of ST is approximately 1–5%, despite long-term dual antiplatelet therapy with aspirin and clopidogrel. The underlying pathophysiological mechanisms of ST are multifactorial. Recent studies showed that a low degree of platelet inhibition, despite antiplatelet therapy, is a risk factor for ST. Whether the coagulation system is also involved in the pathophysiology of ST is unknown.

Aim: In this study we assessed the coagulation profile of ST patients by means of thrombin generation (TG).

Methods: A single-center case-control study was performed, including 63 patients who underwent PCI with stent implantation. All subjects provided written informed consent. Cases ($n = 23$) had a history of an angiographically confirmed ST (Academic Research Consortium criteria) during follow-up. Controls ($n = 40$) had a previously implanted coronary stent but no ST $\geq$ 12 months after the index PCI. The time between the index PCI (controls) or ST PCI (cases) and venous blood collection was $\geq$ 3 months. Subjects using oral anticoagulants at the time of blood collection were excluded. TG in human platelet-poor plasma was measured using the Calibrated Automated Thrombogram (CAT) method with 0, 1, and 5 pM tissue factor (TF) triggers. Active site-inhibited FVII (ASIS) was added to determine the contribution of the contact system, and the protein C pathway was analyzed by addition of recombinant thrombomodulin (TM).

Results: TG was significantly increased in plasma from cases as compared to controls for all TF triggers (0, 1 and 5 pM TF). Results showed a significantly enhanced contact activation in cases compared to controls; peak height: 241 vs. 183 nM, time to peak: 12.1 vs. 16.1 min, velocity index: 98 vs. 63 nM/min, all $P < 0.05$ (0 pM TF trigger with ASIS). These data were confirmed by the 1 pM TF trigger assay and even at the highest TF trigger (5 pM) TG was elevated in cases compared to controls; peak height: 263 vs. 233 nM, time to peak: 5.5 vs. 6.0 min, velocity index: 101 vs. 80 nM/min, all $P < 0.05$. Inhibition of TG by addition of TM reduced the endogenous thrombin potential (ETP) with 22.6% in cases and by 30.6% in controls ($P < 0.05$), suggesting alterations in the protein C pathway for patients with ST.

Conclusions: This is the first study demonstrating the involvement of the coagulation system in ST, as well as an enhanced thrombogenic profile. Patients with a history of ST showed a shift towards a hypercoagulable state, most likely caused by enhanced contact activation and attenuation of anticoagulation by the protein C pathway, as shown by the thrombin generation results. Therefore, oral anticoagulants might be useful in reducing the recurrence rate in ST patients.

Survival effects of inferior vena cava filter in patients with acute symptomatic venous thromboembolism: a subgroup analysis from the RIETE registry

S Jimenez[1], Muriel A[1], Aujesky D[2], Bertoletti L[3], Decousus H[3], Laporte S[3], Mismetti P[3], Yusen R[4] and Monreal M[5]

[1]Ramon y Cajal Hospital, Madrid, Spain; [2]Bern University Hospital, Bern, Switzerland; [3]Hospital of Saint-Etienne, Saint Etienne, France; [4]Washington University School of Medicine, St. Louis, WA, USA; [5]Germans Trias I Pujol Hospital, Badalona, Spain

Background: The effectiveness of inferior vena cava filter use among patients with acute symptomatic venous thromboembolism (VTE) and contraindication to anticoagulation remains unclear.

Methods: In this prospective cohort study of patients with objectively confirmed symptomatic acute VTE and absolute or relative contraindications to anticoagulation, identified from the multicenter, international, prospective, Registro Informatizado de la Enfermedad TromboEmbólica (RIETE registry), we assess the association between filter insertion and all-cause mortality, pulmonary embolism (PE)-related mortality, and recurrent VTE rates through 30 days after initiation of anticoagulant treatment or filter insertion. We used propensity score-matching to adjust for the likelihood of receiving a filter.

Results: A total of 40,142 patients were treated for acute VTE (20,503 with deep vein thrombosis [DVT] and 19,639 with PE). Filter-treated patients ($n = 371$) had significantly greater comorbidity and laboratory abnormalities, with a higher frequency of cancer, immobilization, recent major bleeding, anemia, thrombocytopenia, and renal failure than those not treated with a filter ($n = 39{,}771$). The 344 patients presenting with any acute VTE and treated with a filter (198 also anticoagulated) were matched with 344 patients treated without a filter (328 anticoagulated). Propensity score-matched pairs showed a trend toward lower risk of death for filter insertion compared with no insertion (6.6% vs. 10.2%, $P = 0.12$). The 30-day, risk-adjusted PE-related mortality rate was lower for filter insertion than no insertion (1.7% vs. 4.9%, $P = 0.03$). Risk-adjusted recurrent VTE rates were higher for filter insertion than no insertion (6.1% vs. 0.6%, $P < 0.001$).

Conclusions: In patients presenting with VTE and absolute or relative contraindication to anticoagulation, filter insertion was associated with a lower risk of PE-related death and a trend toward a lower risk of all-cause mortality than no filter insertion. Filter insertion was associated with a higher risk of recurrent VTE.

PA 2.18-2

Improving inferior vena cava (IVC) filter retrieval rates using wristband identification in a tertiary care and trauma centre

Peterson EA, Yenson R, Kritzinger J, Liu D, Chi J and Lee AYY

University of British Columbia, Vancouver, BC, Canada

Background: IVC filter use has been rising dramatically since the introduction of retrievable models but published retrieval rates are suboptimal. We conducted a prospective, quality-improvement study to increase IVC filter retrieval rates in our institution.

Aims: To improve filter retrieval rates at our institution by (i) the application of a labeled wristband to identify patients with filters (ii) educational pamphlets for patients and medical staff and (iii) referral

of patients with filter *in situ* at the time of discharge to our thrombosis clinic for follow-up.

Methods: All consecutive patients who have a filter placed by the Interventional Radiology Department at Vancouver General Hospital from November 2011 to December 2012 were approached for study enrolment within 48 h of filter insertion. Consenting patients were issued a wristband identifying them as IVC filter recipients (intervention cohort). Educational pamphlets regarding retrieval and follow-up were provided to patients and the primary care team. Data on indication for filter insertion, frequency of removal, documentation of a follow-up plan, reasons for non-retrieval, and all-cause mortality were extracted from chart review using standardized forms. Primary outcome of attempted filter retrieval rate is compared with historical data from January 2007 to December 2010 (historical cohort).

Results: During the study period, 50 of 58 patients who had retrievable IVC filters placed were enrolled. Mean age of the intervention cohort was 56 years (range 18–88 years); 57.1% were male and the mean length of hospital stay was 37 days (range 1–879 days). In the historical cohort of 275 patients, mean age was 59 years (range 14–93 years); 55.5% were male with a mean length of hospital stay of 39 days (range 3–166). The most common indications in the intervention cohort and the historical cohort for IVC filter were: a contraindication to anticoagulation (78% vs. 72.4%, respectively), high risk for pulmonary embolism (10% vs. 11.3%, respectively), and primary prophylaxis of pulmonary embolism (12% vs.14.9%, respectively). All baseline patient characteristics (age, sex), length of hospital stay, thrombotic risk factors and indications for IVC filter placement were similar between both cohorts. In our intervention cohort, 78% had a retrieval attempt, with an associated success rate of 94.7%. This was a significant improvement from the attempted retrieval rate of 60% observed in our historical cohort ($P = 0.015$). One patient in the intervention cohort and 28 patients in the historical cohort did not have an attempted retrieval despite no clear reason for the filter to remain permanent (2% vs. 10.2%, respectively, $P = 0.04$). A trend towards increased documentation of a follow-up plan was also noted (86% vs. 73.8%, $P = 0.124$).

Conclusions: In our institution, a simple intervention using a labeled wristband, provision of educational material and referral for outpatient follow-up was associated with a significant improvement in observed IVC filter retrieval rates.

PA 2.18-3

Effect of ethanol locks on occlusion of central venous catheters used for administration of total parenteral nutrition

Berry LR, See R, Clause R-F, Cameron BH, Ratcliffe M and Chan AK

McMaster University, Hamilton, ON, Canada

Background: Central venous catheters (CVCs) are widely used to administer medications and take blood samples. Long term CVC retention in patients gives a risk of catheter-related infections that can evolve serious septic consequences. To prevent infection, some clinics instill 70% ethanol into CVCs during periods between injection of drugs or sampling. Unfortunately, in our pediatric clinic, we have observed blockage in CVCs with an ethanol lock in children receiving total parenteral nutrition (TPN). This has resulted in difficult treatment management for these patients and must be overcome to optimize care.

Aim: To investigate the ability of ethanol to induce aggregation of plasma or blood in catheters used for TPN.

Methods: Initial experiments assessed effects of temperature and increasing ethanol on plasma protein precipitation (measured as loss of 280 nm absorbance in the soluble phase). Next, model CVC catheters were used for incubations in various media and conditions. Citrated blood was obtained from healthy donors with ethical consent and commercial citrated plasma was purchased. CVCs were filled with 70% ethanol and clamped to keep liquid inside. Ethanol-filled CVCs were placed in tubes of plasma and precipitates at the catheter tip collected. Precipitates were resuspended in reducing SDS sample buffer, electrophoresed on polyacrylamide gels and stained for protein. Similar experiments were performed with ethanol-containing catheters in recalcified plasma and blood ± recalcification. Finally, tests were done whereby CVCs were loaded with ethanol containing a small residue of TPN at the catheter tip. Aggregates that were blocking CVC ports in patients were examined to compare with precipitates in the model CVC experiments.

Results: Ethanol-containing CVCs gave plasma protein precipitation that was directly affected by temperature. As expected, increasing ethanol content in plasma gave greater protein precipitation up to a plateau level. In plasma, ethanol-containing CVCs caused slow induction of protein aggregates at the tip. Gel analysis of these precipitates revealed a number of protein bands, including fibrinogen chains. Similar experiments with ethanol-loaded CVC's in citrated blood yielded the same protein bands as with plasma plus some strong low molecular weight species. When calcium was added so plasma or blood samples could clot, only minor differences in bands of proteins precipitated by CVCs with ethanol were observed relative to those of non-recalcified plasma or blood. The presence of TPN residue at the tip of CVCs with ethanol had little additional effect on aggregation and clotting for citrated plasma or blood and recalcified plasma. However, massive clots that strongly adhered to the CVC were induced by TPN with ethanol-loaded catheters in recalcified blood. Comparisons confirmed that banding in gels loaded with samples from patient catheters most closely resembled that from TPN-coated ethanol-containing CVCs in recalcified blood.

Summary/Conclusions: We have shown that the combination of TPN and ethanol induces dense, adhering clots that mimic the occluding aggregates found in catheters of patients receiving TPN that have an ethanol lock. Given the seriousness of CVC function loss, we recommend consideration of a change in protocol for ethanol locks in CVCs delivering TPN.

PA 2.18-4

A multidisciplinary pulmonary embolism response team (PERT). Initial clinical experience at Massachusetts general hospital

Kabrhel C, Jaff M, Channick R, Baker JN, Jama A, Manthripragada GK, Hawkins B, O'Dea J, Weinberg I and Rosenfield K

Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA

Background: The optimal care of patients (pts) with severe pulmonary embolism (PE) involves several specialties. In order to provide timely, organized, evidence-based recommendations and therapy, a multidisciplinary team is required. We established an innovative Pulmonary Embolism Response Team (PERT), with an infrastructure for rapid, multidisciplinary consultation and to facilitate comparative-effectiveness research. Understanding the types of cases seen by our PERT will help other specialists assess the impact of creating similar teams elsewhere.

Methods: The MGH PERT includes specialists in cardiology, emergency medicine, pulmonary/critical care, interventional radiology, vascular medicine and thoracic surgery. We launched the PERT Oct. 22, 2012 and asked clinicians who diagnosed massive or submassive PE to call a 24-h emergency number to activate the PERT. Upon activation, PERT members used commercially available online meeting software (GoToMeeting®) to discuss the case, view data and radiologic images and develop a treatment plan. For each case, prospective clinical data are collected in a research registry. For the current report, we describe our initial 12 week experience with team activation (10/22/12–01/12/13), including demographics, clinical characteristics, treatments and

outcomes. Descriptive statistics (means and proportions) were analyzed using SAS v9.2.

Results: *Activations:* In 12 weeks, there were 30 unique PERT activations, plus two duplicate activations. Twenty seven (90%) occurred during day or evening hours. Most (17, 57%) originated in the emergency department, 7 (23%) in intensive care units and 6 (20%) on hospital floors. Median time from activation to PERT meeting was 54 min.

Patients: Mean age was 57 ± 17 years and 19 (63%) were male. Comorbid illness included: cardiopulmonary disease (n = 10, 33%), recent trauma or surgery (n = 8, 26%); cancer (n = 8, 26%); prior venous thromboembolism (n = 3, 10%). Twelve (40%) patients had a contraindication to thrombolysis or high-risk of bleeding.

PE Severity: Twenty-five (83%) pts had diagnosed PE, 5 (17%) had suspected but unconfirmed PE. Two (6%) were in cardiac arrest. Seven (28%) PE were saddle, 8 (32%) main pulmonary artery, 9 (36%) lobar, and 1 (3%) segmental. Twenty (80%) were bilateral. Sixteen (64%) pts with PE had elevated troponin-t and 13 (52%) had elevated NT-proBNP. Twenty (80%) had right heart strain on echocardiography or computed tomography. Eight (32%) were hypotensive (< 90 mmHg) and 9 (36%) were intubated. Sixteen (64%) had concomitant deep vein thrombosis.

Treatment and Outcomes: After consultation, the PERT considered 5 (20%) PE low risk, 18 (72%) submassive and 2 (8%) massive. Twenty-three (92%) pts received unfractionated heparin, 1 (4%) enoxaparin, and 1 (4%) no anticoagulation. Two (8%) pts had catheter directed thrombolysis and 5 (20%) had a vena cava filter placed. One (4%) pt had hematuria after anticoagulation. Seven (23%) pts overall and 3 (12%) with confirmed PE died prior to hospital discharge.

Discussion: We describe an innovative multidisciplinary Pulmonary Embolism Response Team (PERT). Our initial experience suggests that the PERT was activated frequently and appropriately. Most pts had massive or submassive PE, suggesting clinicians are highly efficient at selecting pts with severe PE. The PERT provided recommendations in < 1 h in most cases.

PA 2.18-5

CHA2DS2-VASc score and risk for reobstruction after endovascular treatment of the superficial femoral artery: differences between balloon angioplasty and stenting

Gary T, Belaj K, Eller PH, Hafner F, Froehlich H, Pilger E and Brodmann M

Medical University Graz, Graz, Austria

Background: The CHA_2DS_2-VASc (congestive heart failure, hypertension, age > 75 years (doubled), type 2 diabetes, previous stroke, transient ischemic attack, or thromboembolism (doubled), vascular disease, age 65–75 years, and sex category) score was published as a predictive scoring model for stroke in atrial fibrillation patients. As multiple vascular risk factors are included in this score we evaluated the occurrence of reobstruction after endovascular treatment (percutaneous transluminal angioplasty (PTA) and stent) of the superficial femoral artery (SFA) in peripheral arterial occlusive disease (PAOD) patients according to their CHA_2DS_2-VASc score independent of a coexisting atrial fibrillation.

Methods: We evaluated 773 PAOD (529 PTA and 244 stent) patients treated at our institution from 2005 to 2010. CHA_2DS_2-VASc score was calculated and the occurrence of a symptomatic reobstruction during a median follow up of 58 months was investigated. Furthermore all constituents of the score were individually investigated concerning their association with reobstruction.

Results: In PTA patients reobstruction rate increased with increasing CHA_2DS_2-VASc Score (P = 0.009). Arterial hypertension was associated with an increased risk for reobstruction (OR 2.4; 95% CI 1.7–3.4), as was type 2 diabetes (OR1.9;95%CI1.5–2.3). In stent patients reobstruction rate was high, but independent of the CHA_2DS_2-VASc Score (P = 0.5). Its constituents were not associated with an increased risk for reobstruction.

Conclusion: A high CHA_2DS_2-VASc score was associated with a high risk for reobstruction after PTA of the SFA. On the other hand the reobstruction risk in stent patients was high but independent of the CHA_2DS_2-VASc score, indicating that the pathophysiology of instent restenoses is different from reobstruction after PTA.

PA 2.18-6

Longitudinal investigation of the effect of centrifugal continuous flow left ventricular assist devices (cfLVADS) on haemostatic parameters

Ly K[1], Muthiah K[1], Connor D[1], Gardiner E[2], Andrews RK[2], Dhital K[1], Jansz P[1], Hayward C[1] and Joseph J[1]

[1]St Vincent's Hospital, Sydney, NSW; [2]Australian Centre for Blood Diseases, Monash University, Melbourne, Vic., Australia

Background: Patients implanted with cfLVADS routinely receive aspirin and/or clopidogrel and anticoagulation. Therapy related bleeding is therefore common, however may also reflect changes secondary to shear forces arising from the implanted device.

Aims: This study aims to assess changes to haemostatic parameters in patients with cfLVADS in order to determine if they can ultimately predict clinical bleeding.

Methods: Twenty-eight patients (24M/4F), implanted with HeartWare cfLVAD were recruited. Baseline blood samples were collected pre-implant and at 1, 7, 30, 90 and 180 days post-implant. Platelet counts were measured by routine methods. Soluble P-selectin (sP-Selectin), soluble GPVI (sGPVI), von Willebrand Factor Antigen (vWF-Ag) and vWF Collagen Binding Activity (vWF-CBA) were measured using ELISA. Microparticle procoagulant phospholipid activity was measured using the Procoag-PL assay. Platelet aggregation was measured using a Multiplate Impedence Aggregometer and platelet function analysis performed using a PFA-100.

Results: Compared to baseline, median platelet counts were significantly lower at day 1 (206 ± 16–159 ± 15, $P < 0.001$), and higher at 30 and 90 days (301 ± 27 × 10^9/L, $P < 0.001$ and 257 ± 16 × 10^9/L, $P < 0.001$ respectively). sP-Selectin levels were significantly elevated at day 1 (29.1 ± 1.9–35.9 ± 2.9 ng/mL) but were not significantly elevated on subsequent days. sGPVI levels were persistently elevated above reference ranges for all timepoints (including baseline). vWF-Ag levels were significantly lower at days 30, 90 and 180 in comparison to baseline (239 ± 18–184 ± 14%, P = 0.024, 165 ± 13%, P = 0.003 and 164 ± 19%, P = 0.001, respectively). vWF-CBA was also significantly decreased at day 1 when compared to baseline (225 ± 18–187 ± 14%, P = 0.003) and remained decreased at all timepoints up to 180 days (99 ± 18%, $P < 0.001$). This corresponded to a decreased vWF ratio (CBA:Ag) for up to 90 days post implant. vWF multimers are pending. Closure times for the PFA-100 were significantly prolonged from day 1 and aggregation to ADP and arachidonic acid was decreased, which was consistent with dual antiplatelet therapy, however further Multiplate testing revealed significantly decreased aggregation to collagen at days 7, 90 and 180 and to ristocetin from day 1 onwards. Microparticle procoagulant activity was significantly increased at day 90.

Summary/Conclusion: Our data shows a persistent elevation in sGPVI levels and decline in vWF-Ag, vWF-CBA and vWF ratio (CBA:Ag) over time in patients supported with HeartWare cfLVAD. Interestingly, levels of sP-selectin are not increased. Platelet aggregation is impaired in addition to that due to the effects of anti-platelet therapy. Overall, these changes may increase the risk of bleeding in these patients and likely reflect the effects of shear forces from the device itself. Microparticle procoagulant activity was increased at only one timepoint – the significance of this finding and its contribution to the overall haemostatic state of these patients remains to be determined.

PA2.19 – Paediatric Thrombosis II

PA 2.19-1

Antiphospholipid antibody syndrome in monozygotic twins

Bruce AK, Sinuff S, Bauman M and Massicotte P
University of Alberta, Edmonton, AB, Canada

Background: Antiphospholipid antibody syndrome (APLAS) is an autoimmune disorder defined by continued presence of antiphospholipid antibodies (aPLa) in association with thrombosis or pregnancy loss. APLAS has a low prevalence in pediatrics. Compared to adults, the condition is unique due to developmental hemostasis, high rates of aPLa related to infections, different laboratory normal values, and prevalence of underlying diseases. In addition, the rarity of teen presentation of thrombosis often leads to delayed diagnosis. APLAS has not been previously described in pediatric monozygotic twins. There is only one reported case in adult monzygotic twins.
Aims: To describe APLAS in pediatric monozygotic twins with similar case presentations.
Methods: Chart reviews were performed to obtain clinical data. A literature review of pediatric APLAS and familial antibody syndrome was performed. Informed consent and ethics review was obtained.
Results: Twin A, 15 year old previously well male presented to multiple healthcare sites with a history of a painful and swollen right arm prior to diagnosis. Family history was significant for a great grandfather with early onset (< 30 years) arthritis. Doppler ultrasound revealed a thrombus in the right subclavian, axillary, and lateral brachial vein. VQ scan demonstrated mismatched perfusion in the right lower lobe. Laboratory Results INR 1.6 (Normal range (NR) 0.8–1.2), PTT 93 s (NR29–43 s) D-Dimer 0.57 mg/L, NR (< 0.5 mg/L), Cardiolipin 74GPL (NR 0–14GPL) at presentation, 85GPL and 83GPL and 3 and 6 months, respectively. Lupus Anticoagulant was positive as per dilute venom viper test on presentation and at 6 months. ANA, anti-centromere antibodies, anti-dsDNA, ENA, ANCA were negative and IgG, IgM, and IgA were normal.
He was commenced on anticoagulation. He had visual disturbances and was diagnosed with transient ischaemic attacks (MRI brain normal) and started on aspirin.
His asymptomatic twin, Twin B, had cardiolipin antibodies of 22GPL and a positive lupus anticoagulant.
Six months later, Twin B presented clinically with a painful, swollen right calf. He was assessed and diagnosed immediately as the presence of aPLa was previously confirmed. Doppler ultrasound demonstrated a right superficial femoral to popliteal vein thrombus. VQ scan revealed bilateral pulmonary emboli. His laboratory investigations demonstrated a D-dimer 3.66 mg/L, APCR 3 (NR ratio > 2.3), Protein C 1.4 U/mL, Protein S 1.02 U/mL, Factor V Leiden and Prothrombin G20210A mutation not detected, Cardiolipin 14GPL, Lupus anticoagulant positive on repeat testing. He was commenced on anticoagulation. Twin B had the similar visual disturbances and was also started on aspirin.
Both patients had no evidence of vasculopathy.
Summary: This is the first case report describing monozygotic pediatric twins with primary APLAS. The first adult case report was recently published. The combination of these 2 reports demonstrates rationale for screening of monozygotic twins if one is diagnosed with APLAS.

PA 2.19-2

In vitro assessment of the effect of dabigatran on thrombosis of adult and neonatal plasma using thromboelastography

Nossair F, Gantioqui J, Chan HH, Stevic I, Atkinson HM, Berry LR and Chan AKC
Thrombosis & Atherosclerosis Research Institute (TaARI), Hamilton, ON, Canada

Background: Thromboelastography (TEG) is a global assay used for evaluating features of clot formation. Although its clinical use is limited, TEG has long been used to assess thrombosis *in vitro*. Dabigatran is an anticoagulant that acts as a reversible direct inhibitor of thrombin. Specific clotting tests have shown a linear relationship between dabigatran plasma concentration and its effects. However, none of these studies used a global assay, such as TEG, to demonstrate this relationship in neonates. Neonatal hemostasis differs from adults. Specifically, most coagulation factors & natural anticoagulants at birth are < 50% of adult levels and there are several structural and functional differences. The effect of varying dabigatran concentrations on characteristics of clotting in neonates compared to adults is unclear.
Aims: To compare the clotting profile of neonatal and adult platelet poor plasma when exposed to different concentrations of dabigatran
Methods: Adult pooled plasma in buffered citrate was purchased from Affinity Biologicals (Ancaster, ON, Canada). Neonatal cord blood was collected from placentas of healthy full term newborns using citrated syringes. The study was IRB approved and informed consent was obtained prior to collection. Platelet-poor plasma was isolated, pooled and frozen. Prior to experiment, plasma was thawed and filtered (using a 0.2 μm filter) to remove microparticles. Optimal tissue factor (TF) levels were predetermined and corn trypsin inhibitor (CTI) was used to inhibit the contact coagulation pathway. Dabigatran was prepared by chemical conversion of the pro-drug. Its structure & activity was verified via standardized testing. Experiments were performed as follows: 30 μL reaction mixture of 0.8 M $CaCl_2$, 30 μg/mL CTI, 2 pM TF and dabigatran (0, 40, 110, 180, 250 and 320 ng/mL) in imidazole buffer (pH = 7.4) was mixed with 330 μL of plasma in a TEG cup. Four fundamental TEG parameters, R, K, α and Maximum Amplitude (MA), were measured for a maximum of 180 min with Haemoscope TEG 5000. Scanning electron microscopy (SEM) was performed to evaluate fibrin clot structure for both neonatal and adult plasma, in the presence and absence of dabigatran.
Results: Without dabigatran, time to clot initiation (R) was similar between neonatal and adult samples. There was a significant delay in clotting of neonatal samples with increasing dabigatran concentrations ($P < 0.05$). Speed of clot strengthening (α) in both samples without dabigatran also showed no difference, whereas neonatal samples with dabigatran were > 4-fold slower in clotting ($P < 0.05$). Additionally, while there were no differences in maximum clot strength (MA) without dabigatran, neonatal samples with dabigatran were weaker ($P < 0.05$), especially at higher dabigatran concentrations. SEM showed minimal differences between neonatal and adult fibrin clot structure in the absence of dabigatran. However, with dabigatran, both neonatal and adult clots contained less small-diameter fibers, thicker large-diameter fibers and greater porosity. Moreover, these dabigatran-induced differences were intensified in neonatal clots.
Conclusions: Neonatal plasma clotting with dabigatran has slower onset, slower speed and weaker clots that are more porous, compared to adult plasma clotting. Thus, neonatal plasma may be more sensitive to dabigatran as assessed by our *in-vitro* TEG study.

PA 2.19-3

A deep look at superficial vein thrombosis in hospitalized children

Rizzi M, Williams S, Connolly B and Brandão LR
The Hospital for Sick Children, Toronto, ON, Canada

Background: Superficial vein thrombosis (SVT) has been studied in adults and there is scarce information about this condition in children.
Aims: To report the spectrum of SVT in hospitalized children.
Methods: Retrospective chart review of children diagnosed with a radiologically-proven SVT between January/2007 and October/2012 at The Hospital for Sick Children, Toronto. Research Ethics Board was obtained. Descriptive and Fisher's exact statistics were utilized.
Results: Eighty-six patients 0–18 years ([median: 12.2 years; IQR: 4.0–15.2]; M/F: 1.2/1]), had 101 SVTs identified. Of 101 SVTs, 54/101 (53%) were exclusive SVT. In those the most common underlying conditions included infection/sepsis [(29%), local infection (n = 5)], cancer (29%), surgery [(29%), post-liver transplant (n = 6)], systemic inflammation (11%) and trauma (11%). The most frequent identified risk factors were catheter-related issues [41/54, 76%: peripherally intravenous inserted central catheters (PICC: 22/41), peripheral intravenous (14/41), catheter insertion attempts (3/41), central venous line (2/41)], and TPN (7/54, 15%). Distribution encompassed upper extremity veins [(46/54, 85%): basilic (33/54), cephalic (11/54), antecubital (2/54)], or lower extremity veins [(8/54, 15%): greater saphenous (5/54), lateral marginal (1/54), other (2/54)]. Initial clinical findings were swelling (72%), tenderness/pain (44%), redness (39%), phlebitis (31%), warmth (20%), and line malfunction (7%). Time between initial clinical findings and imaging was median 0 days [IQR: 0–1].
Treatment modalities included, in isolation or combined, unfractionated heparin (UFH)/low molecular weight heparin (LMWH) (27/54), antibiotics (15/54), catheter-removal (11/54), no therapy (9/54), aspirin/NSAID's (9/54), warfarin (1/54), and mixed (12/54). Radiological follow up was available in 51/54 (94%) (median f 85.5 days [IQR: 20–184]). Radiological resolution rates were: total (35%), partial (13%), unchanged (33.5%), progression (11%), missing (7.5%). SVT progression documented radiologically occurred in six patients, while on no therapy (n = 2), full dose warfarin (n = 1), full dose (n = 1) or prophylaxis (n = 1) UFH/LMWH or antibiotic alone (n = 1); none developed deep vein thrombosis (DVT). There was no significant difference in radiological resolution amongst treatment modality (P = 0.23).
47/101 (47%) SVTs occurred concomitantly with a DVT: 39/47 (83%) were treated with UFH/LMWH (median duration: 109 days [IQR: 89–194]) with complete radiological resolution in 29/39 (74%), partial in 5/39 (13%), unchanged status in 3/39 (8%), and unknown in 2/39 (5%). In the group of SVT without (17/54) and with concomitant DVT (39/47) treated with UFH/LMWH alone, the radiologic resolution rates for the composite total/partial resolution were 6/17 (35%) vs. 34/39 (87%), respectively (P = 0.001). There were two patients with documented radiological SVT progression on: a) prophylaxis UFH (n = 1); and b) full dose LMWH (n = 1).
Summary/Conclusion: Image-proven SVT in hospitalized children is commonly associated with lines, and almost half concurrently with a DVT. Currently, a variety of therapies are used to treat hospital-based SVT in children and a few underlying conditions may particularly predispose patients to those events (i.e. liver transplantation). While progression to DVT may be rare, the role of SVT-related therapy remains to be defined. Further prospective paediatric studies are required to better understand the true impact of this entity in children.

PA 2.19-4

Portal vein thrombosis in neonates: results of an anticoagulation protocol

Williams S, Brandao LR, Labarque V and Williams S
Hospital for Sick Children, Toronto, ON, Canada

Background: Portal vein thrombosis (PVT) is a common thrombotic event in neonates. The majority of patients will have resolution of thrombus with a minority going on to develop complications such as portal hypertension. Due to the scarcity of published studies, the role of anticoagulation (ACT) in neonatal PVT is unclear.
Aims: The aim was to describe the treatment and outcomes following portal vein thrombosis in a neonatal cohort treated according to an institutional anticoagulation protocol.
Methods: The study was approved by the hospital research ethics board and written consent waived. A retrospective chart review of neonates presenting with PVT to the Hospital for Sick Children from January 2008 to September 2010, identified from the clinical thrombosis database, was conducted. All patients were < 30 days at the time of diagnosis and treated according to the institutional protocol for anticoagulation for neonatal portal vein thrombosis. In the protocol, neonates with non-occlusive PVT are not treated with ACT unless thrombotic extension occurs or there is a concomitant other indication for ACT, and neonates with occlusive PVT without contraindication to ACT are treated. Clinical and radiologic data were collected. Poor outcome was defined as portal hypertension, hypersplenism, liver atrophy on follow-up. Descriptive statistics and Fisher exact testing were completed to compare the neonates by presenting features, treatment and outcome.
Results: There were 94 patients identified. The mean age (± SD) was 10 days (± 5). The mean gestational age was 35 weeks (± 5). Fifty-three (56%) patients received ACT and 41 (44%) patients did not receive ACT. Of the patients treated with ACT 6/53 (11%) received standard heparin, 34/53 (64%) received low molecular weight heparin and 13/53 (25%) received both standard and low molecular weight heparin. Follow-up occurred for a mean of 344 days (± 315). ACT was continued for a mean 41 days (± 55). Complete resolution of thrombus occurred in 48/94 (51%), partial resolution in 15/94 (16%) and progression in 25/94 (27%). Progression of PVT was associated with initial non-occlusive thrombus occurring in 15/36 (42%) of patients with non-occlusive thrombus vs. 9/57 (16%) of patients with initial occlusive thrombosis (P = 0.008). Thrombosis involving the inferior vena cava (IVC) was associated with thrombotic progression occurring in 8/12 (67%) of patients with IVC involvement compared to 16/83 (67%) of patients without IVC involvement (P = 0.001). There was no association of anticoagulation with thrombus resolution or decreased rates of poor outcome. Liver atrophy occurred in 25/94 (27%). Portal hypertension or hypersplenism occurred in 6/94 (6%) patients. Major bleeds occurred in 7/53 (13%) of patients who received ACT.
Conclusions: The majority of neonates had a good outcome, and anticoagulation was not associated with decreased rates of poor outcome in this cohort of patients treated according to an institutional protocol for neonatal PVT. Prospective studies may identify a subset of neonates who benefit from anticoagulation.

PA 2.19-5

Clinical presentation and molecular basis of congenital antithrombin deficiency in children: a cohort study

Kumar R[1], Chan AK[2], Castle D[1] and Williams S[1]
[1]*Hospital for Sick Children, Toronto, ON;* [2]*McMaster University, Hamilton, ON, Canada*

Background: Antithrombin (AT) deficiency is a rare autosomal-dominant thrombophilia. The natural history of AT deficiency in children is

poorly understood. Furthermore, the genotype-phenotype correlation in AT deficiency remains debatable.

Aims: To describe the clinical manifestation and molecular basis of congenital AT deficiency in children managed at the Hospital for Sick Children (HSC) over a 13-year period.

Methods: The study was approved by the HSC research ethics board. Pediatric patients (ages 0–18 years) diagnosed with congenital AT deficiency between January 1, 2000 and December 31, 2012 were identified from the thrombosis database at HSC. Clinical and laboratory characteristics were abstracted from the medical records. Identified patients were prospectively solicited for antithrombin (*SERPINC1*) gene sequencing. Written consent was obtained. Genomic DNA was extracted from EDTA-anticoagulated blood. The *SERPINC1* gene was analyzed by PCR followed by sequencing of both DNA strands of the entire coding region and the highly conserved intron-exon splice junctions. Reflex multiplex ligation-dependent probe amplification analysis was done to detect deletions or duplications. Descriptive statistics were used to summarize parameters [Mean (± SD)]. Baseline characteristics were tested for an association with venous thromboembolism (VTE) using t-test and Fisher's exact test.

Result: Twenty five patients (10 females and 15 males) from 16 unrelated pedigrees were identified. Mean age at diagnosis was 9.2 (± 6.2) years. Eight patients were diagnosed after VTE [mean age at diagnosis: 8.7 (± 8.3) years] and 17 patients were diagnosed secondary to a family history of AT deficiency [mean age at diagnosis: 9.4 (± 5.2) years]. Mean duration of follow up for the cohort was 4.7 (± 4.4) years. Of 18 subjects who underwent additional thrombophilia testing, one was found to be heterozygous for prothrombin gene (PG) mutation. Most recent mean AT-activity (n = 25) and AT-antigen (n = 17) were 0.53 (± 0.08) and 0.58 (± 0.12) IU/dL respectively. Of the eight patients with VTE, seven had additional risk factors (three anatomical anomalies, two neonatal age, one oral contraception, one dehydration, one immobilization, one PG mutation). All patients with VTE were treated with anticoagulation and two required supplemental antithrombin-concentrate. Four patients were left on long term anticoagulation (three with anatomical anomalies and one with concurrent PG mutation). No patient has had recurrent VTE with 2.2 (± 2.6) years of follow up. None of the 17 patients diagnosed secondary to a positive family history have had VTE, with 5.8 (± 4.8) years of follow up. Mutation analysis has been completed on 15 subjects from 13 pedigrees. Eight mutations (including four novel mutations) were identified: four on exon 7, three on exon 5 and one on exon 2 of the *SERPINC1* gene. Deletions, frameshift and nonsense mutations had a greater association with VTE as compared to missense mutations (P = 0.007).

Summary/Conclusion: In our institutional cohort of pediatric AT deficient patients, there were often additional risk factors at the time of VTE. Patients with congenital AT deficiency, who developed VTE in the presence of transient-acquired risk factors were taken off anticoagulation after treatment of acute event, with no recurrence. The genotype-phenotype correlation observed in this study needs validation in larger cohorts.

PA 2.19-6

Characteristics and long-term outcome in children with essential thrombocythemia: an analysis of 61 cases from a single Chinese center

Fu R, Zhang L, Xuan M, Lv C, Xue F, Cao Z and Yang R

Chinese Academy of Medical Sciences & Peking Union Medical College, Tianjin, China

Background: Essential thrombocythemia (ET) is a rare thrombotic disorder in pediatric patients, with a risk of progressing to myelofibrosis and leukemia.

Aims: In this retrospective study, we evaluated the clinical and laboratory features and long-term outcome in pediatric patients with ET at our center.

Methods: We reviewed 61 pediatric patients (age ≤ 18 years) who were consecutively diagnosed with ET between July 1983 and October 2012. This study was approved by the hospital based medical ethic committee. Informed consent was obtained from the guardians of the patients.

Results: The median age was 12 years (range 2–18 years), with 41 males and 20 females. Microcirculatory and systemic symptoms occurred in 43 cases (70.5%), of which 3 (4.92%) showed transient syncope. Hepatosplenomegaly was found in 34 patients (55.7%). Minor bleeding occurred in nine cases (14.8%), but none suffered from major bleeding or thrombosis either at diagnosis or during follow-up. JAK2 V617F mutation was analyzed in 41 patients, with nine positive (22.0%) and 32 negative (78.0%). There were no significant differences in white blood cell (P = 0.925), neutrophil (P = 0.969), hemoglobin (P = 0.930), platelet count (P = 0.529), microcirculatory disturbance (P = 0.556), systemic symptoms (P = 0.204) or hepatosplenomegaly (P = 0.402) at diagnosis between JAK2 V617F positive and negative cases. Platelet count was not statistically related to hepatosplenomegaly (P = 0.930) or bleeding (P = 0.222), but positively related to microcirculatory disturbance (P = 0.002). First-line treatment included platelet apheresis (six cases, 9.8%), antiplatelet agents (35 cases, 57.4%), interferon (32 cases, 52.5%) and hydroxyurea (41 cases, 67.2%). Clinical intolerance to hydroxyurea was found in two patients, reversible liver enzymes increased in four cases and skin ulcer in one patient. The median follow-up was 30.5 months (range 1–180 months). None of the patients died. Two patients (3.28%) progressed to overt myelofibrosis, but none developed secondary hematological or non-hematological malignant tumors.

Conclusions: The mutated rate of JAK2 V617F is lower in children than in adults. Most pediatric ET patients have microcirculatory disturbance and the risk is elevated as platelet count increases. Transient syncope is not rare in pediatric patients. The side effects of hydroxyurea should be closely monitored. Major thrombosis and bleeding events are extremely scarce, but some may progress to myelofibrosis. The underlying pathogenesis is to be further studied to develop targeted therapy in the future.

PA 2.20-1

Thromboelastometric parameters heritability and their relation with thromboembolic disease. Results from GAIT-2 project

Carrasco M[1], Martin-Fernandez L[2], Font M[1], Martinez-Perez A[2], Ziyatdinov A[2], Borrell M[1], Fontcuberta J[1], Soria JM[2] and Souto JC[1]

[1]Sant Pau Hospital; [2]IIB-Sant Pau, Barcelona, Spain

Background/Aims: Thromboelastometry (TEM) can provide comprehensive information on the mechanism of clot formation. At present, it is useful for diagnosing hemorrhagic diseases and for the therapeutic use of blood products in transfusion. We investigated the utility of TEM parameters as intermediate phenotypes that might correlate with the risk of thrombosis. With any complex phenotype, usually the first step is to calculate the heritability (estimate of the genetic contribution to the observed variability of the phenotype). The next step is to determine the role of environmental covariates, and the potential relation with thrombophilia.

Methods: The GAIT-2 (Genetic Analysis of Idiopathic Thrombophilia) project included a total of 1113 individuals, belonging to 35 extended pedigrees recruited through a propositus suffering from idiopathic venous thrombosis. A total of 175 subjects suffered from thrombotic disease; 101 of them had venous and 93 arterial thrombosis (19 suffered from both types). The ages ranged from 2 to 101 years old. A TEM test was performed in 935 individuals without adding any exogenous inducer of coagulation (NATEM test). We used the 4-chanels ROTEM^R device (Pentapharma, GmbH, Munich, Germany). We analyzed the following phenotypes: CT (clotting time), CFT (time to a

clot firmness of 20 mm), alpha angle (measured between the midline of the tracing and a line drawn from 1 mm wide point tangential to the curve), MCF (maximum clot-firmness) and MCF-t (time to MCF).
The analyzes used the Sequential Oligogenic Linkage Analysis Routines (SOLAR). This program allows the partitioning of the total variance, into the variance due to genetics (heritability) and the environmental effects. SOLAR also allows the analysis of the correlation with the risk of thrombosis. Age, sex, smoking and oral contraceptives were analyzed as covariates.
Results: The heritability of thromboembolic disease (including venous and arterial thrombosis) was 46% ($P = 0.00009$). Age was the only covariate that significantly influenced the risk of disease. The TEM phenotypes heritabilities were 12%, 13%, 24%, 34% and 37% of the total variance for CFT, alpha angle, MCF, CT and MCF-t, respectively. All of them had statistical significance. Age, sex, contraceptives and smoking influenced on the TEM parameters. In addition, CFT, alpha angle and MCF showed a strong absolute value of genetic correlation [rhoG of 0.88 ($P = 0.006$), 0.89 ($P = 0.012$) and 0.51 ($P = 0.026$), respectively] and environmental correlation [rhoE of 0.44 ($P = 0.0009$), 0.48 ($P = 0.004$) and 0.44 ($P = 0.0008$), respectively] with the risk of disease.
Summary/Conclusions: We detected genetic factors that influence both, the risk of thrombotic disease and the TEM parameters. Also, we determined the influence of environmental effects on the TEM phenotypes. These results confirm the hypothesis that the parameters of the TEM are influenced genetically, and that they can be considered as intermediate phenotypes in the search for genes that influence thrombotic risk

PA 2.20-2
Evaluation of a genetic analysis service for antithrombin deficiency: experience of Sheffield diagnostic genetics service

Beauchamp NJ[1], Makris M[2], Tait C[3] and Goodeve AC[1]
[1]*Sheffield Children's NHS Foundation Trust;* [2]*University of Sheffield, Sheffield;* [3]*Royal Infirmary, Glasgow, UK*

Background: Antithrombin (AT) is a natural anticoagulant that inhibits thrombin and factor Xa (FXa). Inherited autosomal dominant AT deficiency occurs in up to one in six hundred of the population and may increase risk of venous thrombosis by 10–50 fold. The activity of AT as an inhibitor of thrombin and FXa is enhanced over a thousand fold through binding to heparin.
Sheffield Diagnostic Genetics Service (SDGS) has offered a service for the investigation of antithrombin deficiency since 2006 providing both identification of point mutations and large deletions and duplications.
Aims: To evaluate mutation detection rate, mutation spectrum and the profile of mutations in types I and II AT deficiency among index cases (IC) referred to SDGS for confirmation of heritable antithrombin deficiency.
Methods: Genomic DNA was extracted from peripheral blood and individual exons of the *SERPINC1* gene amplified and sequenced. Multiplex ligation-dependent probe amplification (MLPA) was performed, when requested, where point mutations were not identified.
Results: Samples were received over 7 years from 117 families. Of these, point mutations were identified in 77 (66%) of the IC. MLPA was requested in only 10 of the 40 IC where no point mutation was identified and large deletions were identified in two (2% of cohort): a deletion of exons 3–6 and of exons 1–6 (exons numbered sequentially from exon 1), both in patients with type I deficiency.
A wide range of point mutations was identified, both previously reported and novel, with ten mutations identified in more than one IC. Of 79 cases with mutations, 15 (19%) were heterozygous for the p.Ala416Ser mutation (Type II(RS), Cambridge II, legacy numbering A384S), 4 (5%) each for p.Pro73Leu (II(HBS), Basel, P41L), p.Ala414Thr (II(RS), Hamilton, A382T) and p.Asn437Lys (II(PE), La Rochelle, N405K) and 3 (4%) for p.Met283Val (II(RS), M251V). Four further mutations were found in 2 (2.5%) cases each. Two were novel (p.Glu227Lys and c.400delC) and two previously reported (p.Glu227* and c.1154-14G>A). Lastly, two cases of homozygosity for p.Leu131Phe (II(HB), Budapest III, L99F) were identified.
Twenty-five patients had 23 novel mutations including five small deletions, an insertion, acceptor splice site mutation and 14 missense mutations; notable mutations were p.Met1?, affecting the methionine initiation codon, a new heparin binding defect (p.Arg164Leu) and a substitution with pleiotropic effects (p.Val447Asp).
Analysis of AT activity (AT:Ac) and antigen (AT:Ag) levels in IC where levels were supplied by referring clinicians revealed that 33 patients without mutations identified had mean AT:Ac of 68 IU/dL and AT:Ag of 73 IU/dL. This compared with 15 patients with null mutations, mean AT:Ac of 48 IU/dL and AT:Ag of 51 IU/dL and 15 patients with AT Cambridge II, mean AT:Ac of 76 IU/dL and AT:Ag of 103 IU/dL.
Summary/Conclusion: Mutations were identified in 68% of cases referred to SDGS for investigation confirming the cause of their deficiency. The spectrum of mutations included a high proportion of both novel and common mutations. The low rate of follow-up requests for MLPA may result in large deletions or duplications not being identified; such mutations have been reported in up to 10% of patients with antithrombin deficiency.

PA 2.20-3
Who is being screened for hereditary and acquired thrombophilia? A single center experience

Whyman JD[1], Ornstein L[2] and Robert DM[2]
[1]*Dartmouth-Hitchcock Medical Center/Internal Medicine;* [2]*Dartmouth-Hitchcock Medical Center, Lebanon, NH, USA*

Background: Testing for thrombophilia is expensive and time-consuming, and the results have an uncertain role in formulating treatment decisions. Evidence-based and expert opinion criteria for thrombophilia testing are available, but we observe that thrombophilia testing at our institution is frequently performed independent of these guidelines and may not add value to patient care. The aim of our study is to assess the proportion of thrombophilia testing at our institution that is appropriate according to published guidelines and to determine the impact of abnormal test results on medical decision making.
Methods: We reviewed the medical literature for evidence-based and expert opinion guidelines and used these data to synthesize a set of indications for thrombophilia testing. We then retrospectively reviewed all thrombophilia test panels conducted at Dartmouth-Hitchcock Medical Center between January 1 and December 31, 2006, the first year for which complete data are available, to determine if testing was consistent with contemporaneous guidelines. We used our electronic medical record to review patient data to assess testing appropriateness based on these guidelines and to determine what proportion of treatment decisions were altered by abnormal test values. Results are presented descriptively using median values and ranges and percentages where appropriate.
Results: During the study period, 479 patients underwent screening for hereditary and/or acquired thrombophilia. Most were female ($N = 313$; 65%), and the median age was 45 years (range 1 month–87 years). Based on a loose interpretation of guidelines available at the time, we identified 147 patients with a personal history of venous thromboembolism (VTE; 31%), 77 patients with pregnancy complications (16%) and 26 individuals with a family history of VTE or hereditary thrombophilia (5%) in whom we judged testing for thrombophilia to possibly be appropriate. Inappropriate testing was performed in 120 patients with a personal or family history of arterial thrombosis or atherosclerosis (25%) and in 109 (23%) with conditions for which an association with thrombophilia is either unlikely or irrelevant (e.g., confusion, bleeding, seizures, headache) or to determine a pre-test probability of a thrombotic event at the time of presentation with acute symptoms (e.g., rule out pulmonary embolism in a patient with dyspnea). At least

one abnormal test was identified in 176 subjects (37%). Of the abnormal test results, only 9 (5%) were repeated to confirm the abnormality, and four of these were subsequently normal. We identified 16 patients with an abnormal test result whose medical management was then altered, accounting for 3% of the total study population.

Conclusion: Even when applying a flexible interpretation of testing guidelines, we discovered nearly half of all thrombophilia testing at our institution may be inappropriate. Our data suggest that abnormal test results rarely impact treatment decisions for individuals who have undergone testing. Moreover, we identified the potential for misdiagnosis of thrombophilia based on a one-time spurious test value. Our results expose a void and point to a need for increased clinician education regarding indications for and limitations of thrombophilia testing and offer a rationale for placing restrictions on ordering thrombophilia test panels.

PA 2.20-4

Role of ABO blood group and of thrombophilic abnormalities on the presence of residual vein obstruction after deep-vein thrombosis of the lower limbs

Dentali F[1], Di Minno MND[2], Turato S[3], Crestani S[4], Ambrosino P[2], Bonfanti C[4], Di Minno G[2], Franchini M[4] and Ageno W[3]

[1]University of Insubria, Varese; [2]Federico II University, Napoli; [3]Insubria University, Varese; [4]Carlo Poma Hospital, Mantova, Italy

Background: The presence of residual vein obstruction (RVO) has been consistently associated with an increased risk of post-thrombotic syndrome in patients with a previous deep vein thrombosis (DVT) and there is some evidence suggesting an increased risk of DVT recurrence. Only few studies have assessed potential risk factors for RVO.

Aims: In this study, we evaluated whether ABO blood group with or without associated thrombophilic abnormalities is associated with RVO after a standard course of anticoagulation for a first DVT.

Methods: Patients with a first DVT who underwent screening for thrombophilic abnormalities were eligible for this study. Information was collected on ABO blood group and on risk factors for DVT. Each patient underwent compression ultrasonography of lower limbs for the detection of RVO at least after 6 months of a standard course of anticoagulant treatment.

Results: A total of 268 patients (mean age 50.3 years, 120 women) were included. After 8.3 ± 2.9 months of anticoagulant treatment, 126 (47.0%) patients had RVO. At multivariate analysis, active malignancy (Odds Ratios [OR] 5.54, 95% confidence interval [CI] 2.17, 14.13), non-O blood group (OR 3.71, 95% CI 1.61, 8.56), and femoral involvement (OR 3.35, 95% CI 1.94, 5.78) were significantly associated with an increased RVO risk, whereas an unprovoked index event was only marginally significant (OR 1.81, 95% CI 0.98, 3.36 P 0.06) and severe thrombophilia was not associated with RVO (OR 1.32, 95% CI 0.56, 3.11).

Conclusions: After a standard course of anticoagulation for a first DVT, non-O blood group is predictor of RVO.

PA 2.20-5

Genetic determinants of thrombin generation and their relation to thrombosis. Results from GAIT-2 Project

Martin-Fernandez L[1], Carrasco M[2], Ziyatdinov A[1], Martinez-Perez A[1], Borrell M[2], Font M[2], Fontcuberta J[2], Souto JC[2] and Soria JC[1]

[1]IIB-Sant Pau; [2]Unitat d'Hemostàsia i Trombosi, Hospital de Sant Pau, Barcelona, Spain

Background and Aims: There is evidence to support the hypothesis that there is an association between thrombin generation and the risk of thrombosis. From the technology that measures the dynamics of thrombin generation, we studied three distinct quantitative phenotypes that should help identify genes that affect the susceptibility to thrombotic disease.

Methods: We used the families from the Genetic Analysis of Idiopathic Thrombophilia Project (GAIT-2). This sample consisted of 1113 individuals in 35 extended families selected through a proband with idiopathic thrombophilia. The sample had 175 subjects with thromboembolism (101 of them had venous thrombosis, 93 arterial thrombosis and 19 had both venous and arterial events). Of the 1113 subjects, 935 were phenotyped. Thrombin generation was evaluated in plasma according to the method described by Hemker et al. by means of Fluoroskan Ascent (ThermoLab systems, Helsinki, Finland). The quantitative phenotypes were lag time, thrombin peak and endogenous thrombin potential (ETP). The heritabilities, the effects of measured covariates (age, sex, contraceptives and smoking) and the correlations between the risk of thrombosis and the three quantitative phenotypes were estimated by a variance component method, employing the computer package Sequential Oligogenic Linkage Analysis Routines (SOLAR).

Results: Genetic factors accounted for 46% ($P = 9.4 \times 10^{-05}$) of the variation in the risk of thrombosis, with age as its only statistically significant covariate. The heritabilities of lag time, thrombin peak and ETP were 52% ($P = 1.4 \times 10^{-16}$), 48% (1.1×10^{-14}) and 45% (5×10^{-14}), respectively. All the covariates influenced the lag time. The thrombin peak was influenced by age, sex and contraceptives and the ETP was influenced by age, contraceptives and smoking. The ETP was phenotipically ($\rho_p = 0.16$, $P = 0.014$) and genetically ($\rho_g = 0.35$, $P = 0.028$) correlated with the risk of thrombosis. In addition, the thrombin peak showed a weaker genetic correlation ($\rho_g = 0.30$, $P = 0.051$) with risk of thrombosis.

Conclusions: The relatively high heritabilities indicate that genetic factors play a significant role in the risk of thrombosis and thrombin generation. The significant genetic correlations suggest that there are pleiotropic effects of genes. Our studies should help to detect candidate genes responsible for thrombophilia.

PA 2.20-6

Coagulation factor XIII TYR204PHE gene variation and the risk of ischemic stroke

Landau M[1], Campanate G[2], Juliana V[2], Irene B[2], Nelson S[2] and Telma G[2]

[1]Hospital Naval Marcílio Dias; [2]Universidade Federal do Rio de Janeiro – HUCFF/URFJ, Rio de Janeiro, Brazil

Background: The presence of gene variant Tyr204Phe in subunit A1 of the coagulation factor XIII (Tyr204Phe factor XIII) was reported to be strongly associated with ischemic stroke (IS). This risk was further increased in contraceptives users. These findings, however, have never been confirmed in other studies.

Aims: To investigate the Tyr204Phe factor XIII variant as a risk factor in a case-control study of IS Brazilian patients.

Methods: Two hundred and twenty IS patients referred to our service and 220 controls without IS history and not genetically related to the patients were included. Exclusion criteria were transient ischemic attack, cardioembolic events, malignancy or chronic diseases. All cases were tested for Tyr204Phe factor XIII variant by polymerase chain reactions with fluorescent allele-specific oligonucleotide probes. Other IS risk factors, such as hypertension, diabetes mellitus, dyslipidemia, smoking, obesity and estrogen contraceptive use were also recorded.

Results: FXIII Tyr204Phe variant was found in heterozygosis in five patients (2%) and in eight controls (3.6%) with an odds ratio (OR) of 0.6 (95% confidence interval 0.2–1.9), $P = 0.4$. The homozygous form (Phe204Phe) was not found neither in IS patients nor in controls subjects. Also, no evidence for a thrombotic risk related with the presence of the FXIII Tyr204Phe variant was observed in regard to gender, age

(< 50 years), race and estrogen use, when comparing IS patients to controls.
Other risk factors were significantly more prevalent in IS patients than in controls, such as hypertension (OR 4.3), diabetes mellitus (OR 3.4) dyslipidemia (OR 1.7), and smoking (OR 1.9). However, obesity (OR 0.9) and estrogen contraceptive use (OR 1.2) were not associated with a higher risk.
Conclusion: The presence of Tyr204Phe factor XIII variant was not a risk factor for IS in this population. The role of the Tyr204Phe variant as a the risk for IS requires further study.

PA3.01 – Platelet Activation: Receptor Changes – II

PA 3.01-1

Tracking of GPVI-dimer cluster formation at the membrane level with live-cell imaging of platelet binding to various collagenous substrates by TIRF (total internal reflection fluorescence) microscopy

Jung SM[1], Pollitt AY[2], Gardiner E[3], Bihan D[1], Farndale RW[1], Moroi M[1] and Watson SP[2]
[1]University of Cambridge, Cambridge; [2]University of Birmingham, Birmingham, UK; [3]Monash University, Melbourne, Vic., Australia

Background: Dimers of platelet collagen receptor GPVI are the collagen-binding form of this receptor, possessing much higher affinity for collagen than monomers. Quantitation of dimers using dimer-specific antibodies 204-11 Fab and m-Fab-F (Jung et al., *J Biol Chem*, 275: 30000) demonstrated that dimers are constitutively present in resting platelets and increase upon platelet activation by collagen-related-peptide or thrombin. However, although clustering of GPVI-dimers on transfected cells is evident and GPVI-dimer-specific antibodies induce platelet activation, there has been no direct visualization of this in live platelets.
Aims: To determine if clustering of GPVI-dimers occurs on platelets upon interaction with collagenous substrates and whether different collagen substrates support characteristic clustering patterns.
Methods: Platelets labeled with Alexa-488-204-11 Fab (GPVI-dimer-specific) and/or Alexa-588-1G5 Fab (reacts with both GPVI forms) were reacted with collagenous substrate immobilized on glass-bottomed culture dishes (MatTek) and imaged by a Nikon A1R Inverted Confocal/total internal reflection fluorescence (TIRF) microscope. Alternatively, biotinylated $(GPO)_{10}$ or $(GPP)_{10}$ was bound to lipid bilayers on glass coverslips mounted in a flow chamber and fluorescent-antibody-labeled platelets were flowed over this surface and monitored by TIRF microscopy.
Results: Immobilized collagen type III demonstrated two patterns of cluster formation: (i) Cluster formation initiated immediately upon platelet-collagen engagement, with rapid increase in clusters from 0 to 48 s, with well-separated clusters. (ii) Centralized large cluster: initial cluster of GPVI-dimer is formed, which is then enlarged by subsequent recruitment of other GPVI-dimers. Immobilized $(GPP)_{10}$ (inactive peptide): very few platelets adhere and these are still moving, extending filopodia, with few dimer clusters formed. When Collagen Toolkit peptide III-30, a sequence from collagen type III with high affinity for dimer, was immobilized, many platelets adhered with rapid formation of well-separated distinct small clusters. When platelets interacted with $(GPO)_{10}$ attached to a mobile lipid bilayer, freely mobile GPVI-dimer clusters were formed, in some instances coalescing with other clusters to form a larger cluster; this markedly contrasts with the very weak platelet binding on $(GPP)_{10}$.
Conclusions: TIRF microscopy enabled specific observation of interactions of GPVI-dimer or total GPVI with surface-immobilized or lipid-bilayer-bound collagenous substrate. Platelet adhesion to all collagenous surfaces was concomitant with GPVI-dimer-cluster formation. Upon contact with the collagenous surface, platelets form GPVI-dimer clusters, which facilitate adhesion, showing filopodia formation until they are fully activated and spread. Cluster formation patterns were characteristic of the immobilized collagenous substrate. On immobilized collagen type III, 40–60% of platelets showed initial formation of a GPVI-dimer cluster that increased in size without forming other clusters. Other platelets formed numerous independent GPVI-dimer clusters. Platelets formed many small GPVI-dimer clusters on immobilized III-30. Since peptide immobilized at much higher density than collagen, these differences may depend on the density and affinity of GPVI-dimer for the substrates. On lipid-bilayer-bound GPO peptides, the formed GPVI-dimer clusters were mobile. Clustering of GPVI-dimers is an initial and requisite step for platelet adhesion to a collagenous surfaces.
*SMJ and AYP are co-first authors and this work was performed at SPW's lab, with TIRF microscopy performed at the BALM facility, at the University of Birmingham.

PA 3.01-2

Ligand- and force-induced allosteric shift of the platelet integrin aIIbβ3 to a higher affinity state

Litvinov RI[1], Barsegov V[2], Weisel JW[1] and Bennett JS[1]
[1]University of Pennsylvania, Philadelphia, PA; [2]University of Massachusetts, Lowell, MA, USA

Background: The platelet integrin αIIbβ3 and fibrinogen form the receptor-ligand pair essential for platelet aggregation. Previously, we found that αIIbβ3 exists in at least two active forms that we have designated as lower and higher affinity states. These states, in turn, form complexes with fibrinogen that differ in their mechanical stability. Moreover, these states are interconvertible and their relative populations likely determine overall aIIbb3-mediated platelet adhesiveness.
Aims: To elucidate the conditions and mechanisms of the allosteric transition between the lower and higher affinity states of αIIbβ3.
Methods: We studied the nanomechanics of the interactions between fibrinogen and αIIbβ3 using an optical trap to measure the force-free association of individual surface-attached fibrinogen and αIIbβ3 molecules and the forced dissociation of αIIbβ3-fibrinogen complexes and applied a novel approach named Binding-Unbinding Correlation Spectroscopy (BUCS) that combines force-clamp measurements of bond lifetimes with the binding mode to quantify the dependence of the binding probability on the interaction time. Experimental data were modeled using the joint probability distribution $P(T,t)$ for the ligand-receptor bonds formed over time T and that survived until time t, to account for internal dynamics of formation and rupture of a αIIbβ3-fibrinogen complex.
Results: Fibrinogen-reactive αIIbβ3 states differ in their zero-force on-rates ($kon1 = 1.4 \times 10^{-4}$ and $kon2 = 2.3 \times 10^{-4}$ μm^2/s), off-rates ($koff1 = 2.42$ and $koff2 = 0.60$/s),and dissociation constants ($Kd1 = 1.7 \times 10^4$ and $Kd2 = 2.6 \times 10^3$ L/μm^2). The strength of αIIbβ3-fibrinogen interactions was time-dependent due to a progressive increase in the fraction of higher affinity αIIbβ3-fibrinogen complexes that were characterized by a faster on-rate. In other words, the mechanical resistance of the complex increased with the duration of contact between the αIIbβ3- and fibrinogen-coated surfaces, a result of a time-dependent ligand-induced structural rearrangement in the αIIbβ3-fibrinogen complex that favors the formation of a higher affinity state. Unexpectedly, forced off-rates for the higher-affinity form were significantly smaller that their force-free counterpart, implying that application of pulling force also induces a conformational transition from lower to higher affinity αIIbβ3-fibrinogen complexes. We hypothesized that the shift between the active αIIbβ3 conformations from its lower affinity to its higher affinity states resulted from perturbation of sites on αIIbβ3 away from its ligand-binding site. Measurements of the rupture force distribution of αIIbβ3-fibrinogen bonds on ADP-stimulated mouse and human platelets showed that the lower force regime (corresponding to the lower affinity state) was attenuated

and the higher force regime (corresponding to the higher affinity state) was enhanced in mouse platelets. These data support the notion that alterations in the sites of αIIbβ3 responsible for allostery can change the relative distribution of its active affinity states.

Summary/Conclusion: The two-dimensional kinetic rates obtained for the lower and higher affinity αIIbβ3 and fibrinogen interactions at the single-molecule level offer direct evidence for the ligand- and force-dependent shift in αIIbβ3 conformation and activity, underlying the dynamics of fibrinogen-mediated platelet adhesion and aggregation. The identification of allosteric sites that alter the mechanical stability of αIIbβ3-fibrinogen complexes may provide therapeutic targets to alter the distribution of αIIbβ3 activation states.

Disulfide bond exchange is required for integrin activation and post-ligation signaling during fibrin clot retraction

Mor-Cohen R[1], Rosenberg N[1], Averbukh Y[1], Seligsohn U[1] and Lahav J[2]

[1]Tel Hashomer, Ramat Gan; [2]Rabin Medical Center, Belinson Campus, Petah Tiqva, Israel

Background: Integrin αIIbβ3 plays a major role in thrombosis by mediating platelet adhesion, aggregation and fibrin clot retraction. These processes require activation of αIIbβ3 and post-ligation signaling. We previously showed that disruptions of specific disulfide bonds in the β3 subunit activate αIIbβ3 and αvβ3 involving disulfide bond exchange.

Aims: To investigate the role of disulfide bond exchanges in αIIbβ3- and αvβ3-mediated fibrin clot retraction.

Methods: We co-expressed in baby hamster kidney cells human WT-β3 or β3 containing cysteine substitutions that disrupt the C523-C544 bond (C523S, C544S and C523S/C544S) or the C560-C583 bond (C560S) together with human WT-αIIb, giving rise to WT or mutated human αIIbβ3 complexes as well as chimeric complexes between human β3 and the endogenous hamster αv (αvβ3). Activity of αIIbβ3 was determined by measuring the binding of PAC-1 antibody to WT or mutated αIIbβ3 using flow cytometry. The time-course of fibrin clot retraction was recorded in the presence or absence of the thiol blocker dithiobisnitrobenzoic acid (DTNB), the integrin activating antibody anti-LIBS6 and/or an αvβ3 blocker.

Results: All mutants displayed significant PAC-1 binding compared to WT αIIbβ3 that bound PAC-1 only in the presence of anti-LIBS6. Cells expressing WT αIIbβ3 and αvβ3 displayed fibrin clot retraction. Presence of an αvβ3 blocker decreased the rate of retraction, indicating that αvβ3 contributes to clot retraction. The constitutively active mutants and WT cells pre-treated with anti-LIBS6, retracted the clot faster than untreated WT cells. This effect was more pronounced in the presence of an αvβ3 blocker. DTNB significantly inhibited clot retraction by WT cells but had almost no effect on cells expressing the C523S, C544S or C560S mutations; however, cells expressing the double C523S/C544S mutation that has no free thiols were inhibited by DTNB to the same extent as WT cells, either in the presence or absence of αvβ3 blocker. DTNB significantly inhibited anti-LIBS6-enhanced clot retraction of WT cells but only in the presence of αvβ3 blocker. This inhibition was more pronounced when DTNB was added prior to anti-LIBS6 than when it was added after it.

Conclusions: Cells expressing WT αIIbβ3 can retract fibrin clots without prior integrin activation. However, αIIbβ3 activation significantly enhances clot retraction. Both αIIbβ3 activation and post-ligation signaling during clot retraction depend on disulfide bond exchange, suggesting a regulatory role for disulfide bond exchange in this process. In our cell model, αvβ3 significantly contributed to clot retraction in a disulfide bond exchange dependent manner and was not affected by prior activation, suggesting that αvβ3 on platelets and perhaps endothelial cells contribute to clot retraction.

Inhibition of platelet aggregation does not prevent endocytosis of tissue factor-rich microvesicles by platelets: involvement of cytoskeleton, scavenger receptor CD36 and serotonin transporter

Lopez-Vilchez I[1], Diaz-Ricart M[1], Galan AM[1], Roque M[2], Caballo C[3], Molina P[1], White JG[4] and Escolar G[1]

[1]Department Hemotherapy-Hemostasis, Hospital Clinic, CDB, IDIBAPS; [2]Department Cardiology, Hospital Clinic, IDIBAPS; [3]Department Hemotherapy-Hemostasis, Hospital Clinic, CDB, IDIBAPS, Barcelona, Spain; [4]Department Laboratory and Clinical Medicine and Pediatrics, University of Minnesota, MN, USA

Platelets possess innate ability to interact and internalize a wide variety of molecules and circulating particles. We have previously demonstrated that under experimental conditions, platelets internalize and store tissue factor-rich microvesicles from human origin (hTF + MVs) and that this process causes reversible aggregation of platelets, returning to their original resting state. There is limited knowledge on the mechanisms involved in the endocytosis, traffic and redistribution of molecules, particles or microvesicles by platelets.

We have investigated the mechanisms implied in the endocytosis and traffic of hTF+MVs. Implications of membrane receptors GPIIb-IIIa, CD36 and the 5-HT transporter (SERT) were investigated. The involvement of the small GTPase RhoA, PI3K, and modifications of cytoskeletal organization during vesicular trafficking were analyzed.

Isolated platelets were incubated with hTF+MVs for up to 10 min. Inhibitory strategies to the GPIIbIIIa (Abciximab), the scavenger receptor CD36 (anti-CD36), SERT (S-Citalopram, SCit), and PI3-kinase (Wortmannin, Wo) were used. Aggregometry and ultrastructural microscopy were applied to assess platelet activation and vesicle uptake. Cytoskeletal assembly and activation of RhoA and PI3K were analyzed by ELISA and western-blot.

All the inhibitory strategies prevented platelet aggregation induced by hTF+MVs. Ultrastructural studies revealed that endocytosis of hTF+MVs was efficiently prevented by anti-CD36, SCit and Wo, but was minimally affected by blockade of GPIIb-IIIa. Endocytosis caused reversible actin polymerization and association of contractile proteins (alpha-actinin, actin binding protein and myosin) to the cytoskeleton, being maximal at 1 min. Maximal activation of RhoA occurred at 1 min with translocation to the polymerized cytoskeleton, decreasing gradually afterwards, with similar kinetics being observed for activation of PI3K.

We conclude that endocytosis of hTF + MVs by platelets involves reversible cytoskeletal assembly, activation of PI3K and association of the small GTPase RhoA to the cytoskeleton. Mechanisms of endocytosis are not fully prevented by powerful inhibitors of platelet-platelet interactions, such as abciximab, but are effectively interferred by receptorial inhibition of the scavenger receptor (CD36) and the 5HT transporter (SERT). Our results indicate that mechanisms of aggregation and endocytosis by platelets are two independent processes that involve differential receptorial and activating pathways. Further studies should be preformed to assess the involvement of additional endocytosis mechanisms such as Rab GTPases, and toll-like receptors.

First identification and biological characterization of an IgM type platelet cold agglutinin causing temperature-dependent activation, secretion and aggregation of human platelets

Sánchez Guiu I, Martínez Martínez I, Plaza E, Navarro Fernández J, Martínez C, Ferrer F, Vanessa R, Vicente V, Lozano ML and Rivera J

Centro Regional de Hemodonación, Hospital Universitario Morales Meseguer, Murcia, Spain

Background: Platelet cold agglutinins (PCA) are a rare phenomenon mostly recognized by pseudothrombocytopenia (PTCP), or spontaneous *in vitro* platelet clumping, in blood anticoagulated with EDTA (80–90%) or with citrate or other anticoagulants (10–20%). It is considered clinically irrelevant and not associated with specific diseases or drug use. Both immunoglobulin (Ig) IgG and IgM classes can be PCA, but only IgM has been found in few EDTA-independent PTCP. Glycoproteins (GP) IIb, IIb/IIIa, and GP78 were shown as target epitopes of PCA. To the best of our knowledge, no PCA has been reported to induce platelet activation, secretion or aggregation.

Objective: We investigated an atypical IgM PCA type causing activation, secretion and aggregation of both autologous and allogeneic platelets.

Methods and Results: A woman (37 year) with lifelong mild bleeding diathesis and no analytical abnormalities other than chronic moderate thrombocytopenia ($\approx 100 \times 10^9$pl/L), was referred after casual pathological finding in testing with PFA-100 (TO > 300 s, with both col-adp and col-epi cartridges) and Multiplate (null aggregation with all agonist). Blood sampling revealed spontaneous platelet clumping in citrate, ACD-A and heparin, but not in EDTA. Clumping was severe (> 90% platelet drop), rapid (< 15 min), and temperature-dependent (not observed in blood kept at 37 °C). It was prevented by blood collection in the presence of anti-GP IIb/IIIa antibody (LJ-CP8), but not by anti-GP Iba (LJ-Ib1) or anti-vWF (NMC-4). Flow cytometric (FC) analysis of patient's EDTA-platelet rich plasma (PRP), showed an abnormally high degree of basal platelet activation (> 80% CD62+ platelets). While plasma levels of Igs were normal, a FC antiplatelet assay both in plasma and serum distinguished a low titre of antiplatelet IgM. Consecutive blood sampling of the propositus during the last 4 years has consistently demonstrated moderate thrombocytopenia ($\approx 100 \times 10^9$pl/L), maintenance of the atypical pattern of PTCP, high spontaneous platelet activation, and low titre antiplatelet IgM.

In a wide series of experiments incubating patient's plasma or serum with allogeneic platelets (from healthy volunteers, blood-bank leukodepleted platelet concentrates [PCs], or particular patients), we consistently found that: (i) patient's PCA induced temperature-dependent platelet clumping (> 90% drop) in allogeneic citrated blood, platelet-rich plasma or PCs; (ii) it caused no platelet lysis as assessed by LDH measurement; (iii) this PCA promoted full platelet activation as assessed by FC demonstration of surface expression of CD62, ^{14}C-serotonin release (> 50%), TxA_2 production (≥ 100 ng/mL), and thin section electron microscopy and immunofluorescence imaging; (iv) the PCA-induced platelet clumping could be blocked with either EDTA, LJ-CP8 and anti-human IgM antibody, but only anti-human IgM impaired PCA-mediated platelet activation; (v) depletion of IgM from the patient's serum by affinity chromatography removed the PCA activity; (vi) the patient's serum containing PCA, but not fibrinogen, promoted full activation but not clumping of PRP from two different Glanzmann subjects and from one case of afibrinogenemia. All these results demonstrate that the *in vitro* platelet clumping induced by this atypical IgM-PCA represents real platelet aggregation mediated by platelet activation and fibrinogen binding to GP IIb/IIIa.

Summary: This is the first report of an IgM autoantibody causing temperature-dependent platelet activation and aggregation of human platelets.

Phosphospecific flow cytometry enables large-scale signaling profiling and compound screening in human platelets

Naseem KM and Spurgeon B

University of Hull, Hull, UK

Background: Cyclic nucleotide-stimulated signaling cascades represent the most potent endogenous inhibitors of platelet activation and therefore may offer targets for the development of novel antiplatelet agents. Mapping of cyclic nucleotide-dependent phosphorylation events could facilitate the identification of novel compounds that inhibit platelets through these pathways. Identification of phosphorylated proteins by immunoblot techniques are not conducive to large-scale signaling profiling or compound screening. Flow cytometric analyses of protein phosphorylation overcome the limitations of traditional immunologic approaches. Cell-based multiplexing techniques can dramatically increase the throughput of flow cytometric analyses, enabling fast acquisition of large sample sets and rapid screening of entire compound libraries.

Aim: To develop and validate a multiplexed phosphospecific flow cytometry platform for the analysis of cyclic nucleotide signaling events in platelets.

Methods: Flow cytometric analyses of intraplatelet protein phosphorylation were performed using phosphospecific antibodies for VASP. These analyses employed amine-reactive fluorophores to create a multiplexing protocol.

Results: Stimulation of platelets with the nitric oxide donor, S-nitrosoglutathione, or prostaglandin I_2 (PGI_2) led to the concentration-dependent phosphorylation of VASP on serines 157 and 239. Flow cytometric analyses of phosphorylation correlated with Western blotting, with both methods able to discern intermediate levels of phosphorylation. We used a fluorescent cell barcoding protocol to facilitate multiplexing, which enabled large-scale signaling profiling and compound screening through the simultaneous staining and acquisition of 24–72 samples in a single analysis tube. Using this approach to signaling profiling, we were able to demonstrate comprehensive differences in the phosphorylation kinetics of VASP following stimulation with several different cyclic nucleotide-elevating agents including adenosine, forskolin, PGE_1, and PGI_2. Subsequent analyses implicated phosphodiesterases 2, 3, and 5 in the regulation of VASP phosphorylation downstream of different receptor systems. Having established that the method was sufficiently robust to perform simultaneous analyses of single phosphorylation events in multiple samples, we applied the protocol to screen a library of prostaglandin compounds. Initial screening revealed three previously uncharacterized, structurally novel, antiplatelet compounds, which signaled through prostanoid receptors, elevated intraplatelet cAMP, and inhibited collagen-induced platelet aggregation in a concentration-dependent manner.

Conclusions: Phosphospecific flow cytometry is a rapid quantitative method for the measurement of intraplatelet protein phosphorylation, enabling large-scale signaling profiling and compound screening in human platelets. Using this approach, we have identified three potential lead compounds that can modulate platelet activity.

Serotonin contributes to platelet calcium signalling and thrombus formation in flowing blood

Battiston M[1], Cozzi MR[1], Mendolicchio GL[2], Deana R[3], Boz V[1], Ruggeri ZM[4], Mazzucato M[1] and De Marco L[1]

[1]CRO-IRCCS, National Cancer Institute, Aviano, PN; [2]IRCCS, Humanitas Institute, Rozzano, MI; [3]University of Padua, Padova, Italy; [4]Scripps Research Institute, La Jolla, CA, USA

Background: Serotonin (5-hydroxytryptamine, 5-HT) is an important mediator of cell-to-cell signalling both in neuronal and non-neuronal systems. Platelets contain three serotoninergic components – the $5HT_{2A}$ receptor, SERT and VMAT2 – and 5-HT has previously been shown to influence platelet function. Intact platelets take up 5-HT through SERT and store the monoamine in vescicules through VMAT2. After platelet activation, secreted 5-HT binding to $5\text{-}HT_{2A}$ elicits Ca^{2+} signalling through PLCβ activation.
Aim: The aim of this work was to study the role of platelet 5-HT in eliciting intracellular and intercellular Ca^{2+} signalling and regulating platelets thrombus growth under flow.
Methods: Platelet adhesion and activation onto a VWF or collagen type I substrate were monitored under flow at an initial wall shear rate of 1500/s using real-time video microscopy. We analyzed concurrently the instantaneous velocity and intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) in single platelets loaded with FLUO 3-AM and treated with ketanserin or R-96544 (two different $5\text{-}HT_{2A}$ antagonists; 5 μM or 50 nM, respectively), aspirin (1.5 mM) or ADP receptors antagonists (MRS 2179 and ARC-69931 MX). Thrombus formation and volume measurements were obtained by real-time confocal microscopy (UltraVIEW, Perkin Elmer) analyzing series of confocal sections collected at 0.2 μm interval in the *z* axis using Andor™ TECHNOLOGY iQ software.
Results: Platelets adhering to VWF demonstrated $[Ca^{2+}]_i$ elevation and several Ca^{2+} flashes propagating along the flow direction with decreasing intensity as the distance from the origin increased. We identified 5-HT as a key mediator of intercellular calcium communication (ICC) since ketanserin completely abolished its occurrence; similar results were obtained with R96544 and aspirin, while P2Y1 and P2Y12 had apparently no effect. In addition, $5\text{-}HT_{2A}$ blockage was accompanied by decreased initial platelet recruitment and subsequent ratio of thrombus growth. Platelet thrombus volume in the presence of ketanserin significantly decreased from 41.2×10^3 to 28.2×10^3 μm^3 on VWF ($P = 0.012$) and from 83.3×10^3 to 56×10^3 μm^3 on type I collagen ($P = 0.038$).
Conclusion: Our results demonstrate a novel mechanism by which released serotonin, through binding to the $5\text{-}HT_{2A}$ receptor, plays a relevant role in the generation of Ca^{2+} signals that, under high shear stress, contribute to platelet crosstalk through ICC. The resulting amplification and spatio-temporal modification of Ca^{2+} signals can regulate platelet adhesion as well as the rate and extent of thrombus growth.

Advanced multi-parameter assessment of microspot thrombus formation: a systems biology approach

De Witt SM[1], Lamers M[1], Swieringa F[1], Van Kruchten R[1], Mastenbroek TG[1], Coort S[1], Cavill R[1], Pugh N[2], Farndale RW[2], Clemetson KJ[3], Heemskerk JWM[1] and Cosemans JMEM[1]

[1]Maastricht University, Maastricht, The Netherlands; [2]University of Cambridge, Cambridge, UK; [3]University of Bern, Bern, Switzerland

Background: In whole-blood flow assays the roles of glycoprotein (GP)Ib complex, GPVI and integrins α2β1 and αIIbβ3 in thrombus formation on collagen/vWF have been well established. However, platelets can also interact with other components of damaged vessel walls via several adhesive receptors, which can also support the thrombus-forming process. We reasoned that a systematic comparison of thrombus formation at multiple adhesive substrates is needed to fully assess and characterize this process.
Aims: To develop a microspot-based whole-blood perfusion test for assessment of shear-dependent thrombus formation combined with a systematic analysis of a panel of output parameters. To use this test to identify different types of thrombi and to determine how thrombus formation is regulated by different receptor-substrate interactions.
Methods: Arrays of different extracellular matrix proteins and derived peptides were micro-spotted on glass coverslips. In total, 52 (combinations of) substrates were spotted, and their presence was confirmed. Whole blood from healthy controls or patients with a specific platelet function disorder was perfused over the spotted arrays in a new parallel-plate flow device at shear rates of 150–1600/s. Brightfield and multicolor confocal microscopic images of platelets were recorded in real-time and at end-stage, resulting in measurements of parameters reflecting (stable) platelet adhesion, platelet activation, platelet secretion, platelet procoagulant activity, thrombus size, volume and morphology. Values obtained were normalized for comparative analysis, using systems biology techniques. Reproducibility of key parameters was analysed.
Results: The 52 micro-spotted substrates supported thrombus formation at low or high shear rate to a different extent, from weak (adhesion of few discoid platelets) to strong (large, semi-occlusive thrombi with highly activated platelets). Unsupervised hierarchical clustering analysis revealed cohesion of the following outcome parameters: (i) αIIbβ3 activation and α-granule secretion; (ii) thrombus size, morphology and stable adhesion; (iii) thrombus volume and phosphatidylserine exposure. Clustering analysis furthermore indicated three types of thrombus formation, distinguishable in > 6 outcome parameters: type I consisting of adhered single platelets; type II of densely distributed small platelet aggregates; and type III of more disperse distributed large platelet aggregates. Type I thrombi were formed on substrates binding to integrins, GPVI, CLEC-2 or CD36 alone. Type II thrombi were formed on combinations of these substrates with VWF or laminin (binding to GPIb or α6β1, respectively). Type III thrombi were obtained with combined substrates binding to GPIb, α2β1 and GPVI, or binding to GPIb, CLEC-2 ± α2β1 (α6β1). The suitability of this multi-substrate, multi-parameter test to detect platelet functional deficiencies was confirmed with blood from patients with bleeding, i.e. Glanzmann's thrombasthenia and type 2A von Willebrand disease. In these cases, 15–32% of the thrombus scores were reduced.
Conclusions: Advanced multi-parameter detection of microspot-based thrombus formation provides new insight into the combined substrate-receptor interactions that are required for this process. Deficiency in formation of type III thrombi may be a good indicator of major platelet function deficiency, associated with an increased risk of bleeding.

PA 3.02-3

Platelet aggregometry under flow conditions: the rate of change of surface distribution of platelets or thrombi quantifies changes in aIIbβ3 and a2β1 activity in real time

Pugh N, Bihan D and Farndale RW

University of Cambridge, Cambridge, UK

Background: Thrombus formation in flowing blood requires synergy between platelet receptors GpVI, integrin $\alpha_2\beta_1$, GpIb/V/IX and integrin $\alpha_{IIb}\beta_3$. Previously, we used triple-helical collagen-mimetic peptides and confocal microscopy to investigate collagen receptor-mediated platelet thrombus formation under flow conditions *in vitro*. End-point measurements of thrombus formation such as surface coverage and

ZV_{50} were used to quantify platelet adhesion and activation. However, as these parameters do not quantify platelet behaviour in real time, valuable information about dynamic platelet receptor activity is lost.

Aims: To develop image analysis techniques to quantify $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$ activity in flowing human blood, thus providing a dynamic assessment of integrin activity in real time.

Methods: Whole blood was perfused over different thrombogenic substrates at a shear rate of 1000/s during which images of thrombus formation were acquired using confocal microscopy. End-point parameters of thrombus formation were calculated after 5 min. The rate of change of surface distribution of platelets or thrombi (designated platelet mobility, PM) was calculated from image sequences taken at 0.2 Hz. Thrombogenic substrates consisted of collagen, VWF or combinations of collagen-mimetic peptides CRP, GFOGER and VWF-III (ligands for GpVI, $\alpha_2\beta_1$ and VWF respectively). Additionally, the inert peptide GPP_{10} and a panel of $\alpha_2\beta_1$-adhesive peptides of varying affinities were used. GR144053 was used to antagonise $\alpha_{IIb}\beta_3$, thus isolating $\alpha_2\beta_1$-dependent platelet responses. DM-BAPTA-AM was used to block calcium-dependent receptor activation. The role of secondary signalling pathways in thrombus formation was examined using specific antagonists.

Results: PM quantifies the proportion of platelets that have undergone stable adhesion on a thrombogenic surface under flow conditions in real time. On VWF-III or coated VWF, PM was high, indicating continuous platelet rolling. On collagen and CRP/GFOGER/VWF-III, PM decreased exponentially, indicating rapid stable adhesion. Omission of GFOGER from a replete surface abrogated the decline of PM with time, and further treatment with GR144053 abolished stable adhesion. Aspirin, NF449 and MRS2179 had no effect on stable adhesion or thrombus formation. DM-BAPTA-AM, PGE_1 and 2-MeS-AMP abrogated thrombus formation, but had no effect on $\alpha_{IIb}\beta_3$-dependent stable adhesion. PM profiles reflected the affinity of $\alpha_2\beta_1$-adhesive peptides, when coated alongside CRP and VWF-III. DM-BAPTA-AM abrogated PM on low affinity $\alpha_2\beta_1$-adhesive peptides, but not on GFOGER.

Summary/Conclusions: Use of $\alpha_2\beta_1$-adhesive peptides demonstrates that differences in PM profile reflect the activation state of $\alpha_2\beta_1$. $\alpha_2\beta_1$ plays a significant role in platelet adhesion in the early phases of platelet recruitment to thrombogenic collagenous surfaces. On thrombogenic surfaces lacking an $\alpha_2\beta_1$-adhesive ligand, PM quantifies $\alpha_{IIb}\beta_3$ activity in real time and is thus analogous to light transmission platelet aggregometry, albeit under physiologically relevant flow conditions. Stable adhesion and thrombus formation are $\alpha_{IIb}\beta_3$-dependent processes that require engagement of GpVI. However, thrombus formation but not stable adhesion is regulated by $P2Y_{12}$ signalling and is calcium dependent, indicating that these are two functionally distinct processes.

PA 3.02-4

Murine strain differences in platelet adhesion and thrombus formation under flow conditions

Cozzi MR, Boz V and Battiston M

C.R.O. National Cancer Institute, Aviano, Italy

Background: Genetically modified mice have provided significant advances in our knowledge of haemostasis and thrombosis and new targets for anti-thrombotic drugs. However, the use of experimental arterial thrombosis models both *in vivo* and *ex vivo* in several mice strains showed specific differences that reflect differential responses to vascular thrombosis. These could include demonstrated differences in plasmatic proteins (pro-coagulant, anti-coagulant proteins or proteins involved in fibrinolytic system) and in platelet number and/or function (expression of adhesive receptors modulating platelet activation and aggregation). Moreover recent study have reported that platelet adhesion and aggregation in mice still occur in the absence of fibrinogen and VWF, suggesting that other molecules are involved in these processes.

Aim: The aim of our study was to investigate differences among two mouse strains in platelet aggregation and thrombus formation in *ex vivo* experiments and whether these differences can be related to plasmatic and/or platelet features.

Methods: We used confocal videomicroscopy to measure the volume of platelet thrombi forming during blood perfusion over fibrillar collagen type I at wall shear rate of 1500/s in two different mice strains: C57BL/6 (C57) and Balb/C (BalbC). Rate and extent of thrombus growth were calculated in reconstituted blood and in mixed blood by analyzing a series of confocal sections at 0.2 μm intervals in the z axis. Reconstituted blood stands for C57 or BalbC blood with only platelet count normalized ($600 \times 10^3/\mu L$), while mixed blood is constituted by one strain platelets added to the opposite strain plasma: in other words C57 platelets were resuspended in BalbC plasma and viceversa.

Results: In experiments with reconstituted blood the average volume of thrombi was significantly smaller in C57 than in BalbC demonstrating the most thrombotic phenotype of BalbC mice (mean ± CI: 32.125 ± 3277 vs. 135.886 ± 28.784 μm^3). Measurement of total platelet surface coverage in each z-plane of a series of confocal sections demostrated that C57 mixed blood elicits aggregate growth in height and the first layers of platelets contacting collagen were more extended than in C57 reconstituted (mean ± CI: 116.588 ± 46.800 vs. 32.125 ± 3277 μm^3). Otherwise, reconstituted BalbC blood shows thrombi bigger than the ones formed with the same strain type of platelets (BalbC) in C57 plasma (mean ± CI: 135.886 ± 28.784 vs. 92.205 ± 14.182 μm^3).

Conclusions: Measuring platelet thrombus formation in flowing blood we confirm that there are considerable strain differences in thrombosis process: BalbC mice are more thrombotic than C57 mice, as previously evaluated in tail bleeding model as well as in FeCl3-induced model of arterial thrombosis. Platelet and plasmatic features together contribute to the differences observed in our mice strains model of arterial thrombosis. In summary, to fully exploit the opportunities presented by mice models, it becomes important that mice hemostatic system will be defined and standardized in order to have a better comparison with human hemostatic system.

PA 3.02-5

A role of platelet C-type lectin like receptor-2 (CLEC-2) in thrombus formation *in vivo*

Inoue O[1], Hokamura K[2], Umemura K[2], Hatakeyama K[3], Asada Y[3], Ozaki Y[1] and Suzuki-Inoue K[1]

[1]University of Yamanashi, Yamanashi; [2]Hamamatsu University School of Medicine, Hamamatsu; [3]University of Miyazaki, Miyazaki, Japan

Background: C-type lectin like receptor-2 (CLEC-2) induces platelet aggregation by binding to the snake venom rhodocytin or the membrane protein podoplanin. We have reported that CLEC-2 stabilizes thrombi formed on the surface of collagen through homophilic interactions with CLEC-2 under flow conditions. However, an internal ligand of CLEC-2 that induces thrombus formation in the artery is not known.

Aim: To clarify the role of platelet CLEC-2 in thrombus formation at the sites of damaged vessel walls.

Methods: The femoral artery of CLEC-2-chimera (KO) or wild type-chimera (WT) was injured by $FeCl_3$ and the occlusion time was measured. The binding of CLEC-2 rabbit Fc2 fusion protein (hCL2-rFc2) to thin sections of atherosclerotic plaques was detected by immunohistochemical staining. Direct binding of hCL2-rFc2 to coronary artery smooth muscle cells (CASMC) was examined by flowcytometry and immunohistochemistry. Whole blood was flowed over CASMC and platelet adhesion to CASMC was analyzed. Secretion of 5-TH and PDGF from platelets mediated through CLEC-2 by binding to CASMC was examined by ELISA.

Results: The occlusion time of femoral arteries of KO was significantly prolonged compared with that of WT in $FeCl_3$ injury model (979.5 ± 387.2 in WT, 1479.7 ± 549.0 in KO, $P < 0.05$). We hypothesized that there is an unidentified ligand for CLEC-2 in the deep layer of the arterial wall. In the plaque, binding of hCL2-rFc2 was observed along with smooth muscle actin staining. The binding of hCL2-rFc2 to CASMC was observed both flowcytometry and immunohistochemistry. When murine blood was perfused onto CASMC monolayer, platelet aggregate formation was observed under flow conditions and thrombus volume was greatly reduced in the absence of CLEC-2. Granule secretion was observed upon stimulation by CASMC in wild type platelets, however, it was absent in the CLEC-2 deficient platelets.
Conclusion: We propose that CLEC-2 induces thrombus formation at the site of severely damaged vessel walls where smooth muscle cells are exposed to blood flow by binding to unidentified CLEC-2 ligand(s) on the surface of smooth muscle cells. The binding of platelets to CASMC via CLEC-2 may also contribute to the repair of damage and/or facilitate neointimal formation through granule secretion. A ligand for CLEC-2 on CASMC is now under investigation by MS/MS.

Lack of non-neuronal serotonin is associated with reduced ischemia-reperfusion injury in myocardial infarction in mice

Mauler M[1], Koentges C[1], Maier A[2], Bugger H[3], Bode C[3] and Dürschmied D[3]
[1]*Faculty of Biology, University Hospital;* [2]*University Hospital;* [3]*University Heart Center, Freiburg, Germany*

Background: Cardiac tissue serotonin levels are increased during myocardial ischemia, probably with significant contributions from platelet serotonin release. The role of cardiac serotonin in ischemia-reperfusion (I/R) injury is still incompletely understood. Tryptophan hydroxylase-1-deficient mice (Tph1−/−) lack serotonin in platelets and other non-neuronal tissues and were described to develop dilated cardiomyopathy and cardiac dysfunction. We found recently that platelet serotonin promotes inflammatory cell recruitment.
Aims: To study the effect of non-neuronal serotonin on myocardial I/R injury *in vivo* and in an *ex vivo* working heart model.
Methods: Twelve week-old C57Bl/6 (WT) and Tph1−/− mice underwent heart surgery to induce myocardial infarction by ligation of the left anterior descending artery (LAD). After 30 min the ligation was opened to allow reperfusion of the affected myocardium. Hearts were excised 24 h afterwards and infarct size in relation to the area at risk (AAR) was determined by double staining with monolite blue and triphenyl tetrazolium chloride using a Langendorff perfusion system. Hearts of untreated WT and Tph1−/− mice were excised and perfused in working mode using Krebs-Henseleit buffer containing 0.4 mM palmitate and 5 mM glucose. In addition, working hearts were subjected to 20 min of global no-flow ischemia with subsequent reperfusion for 25 min.
Results: Myocardial infarction was reduced in Tph1−/− compared to WT after occlusion and reperfusion of the LAD: Mean infarct size was 53.5 ± 13% AAR in WT and 36.9 ± 10% AAR in Tph1−/− mice ($n = 6$; $P < 0.05$). In isolated working hearts of five WT and Tph1−/− mice cardiac power (30.7 ± 3 vs. 32.9 ± 4 mW/gHW; n.s.) and developed aortic pressure (24.1 ± 3 vs. 23.6 ± 2 mmHg; n.s.) were similar. Isolated working hearts subjected to global no-flow ischemia failed gradually, but recovered similarly in both groups after reperfusion (recovery of cardiac power 63 ± 19% vs. 55 ± 8% and recovery of developed aortic pressure 78 ± 18% vs. 86 ± 30% in WT and Tph1−/−, respectively; $n = 5$; n.s.).
Conclusion: Lack of non-neuronal serotonin decreased tissue damage after myocardial infarction with subsequent reperfusion in an *in vivo* mouse model. Isolated, i.e. denervated working hearts from Tph1−/− mice were equally susceptible to global I/R injury as hearts from WT mice, suggesting that the effect observed *in vivo* depended on circulating blood. In conclusion, blood- and hence most likely platelet-derived serotonin is involved in the regulation of myocardial I/R injury.

Thrombin induces phosphorylation of key components of the mTORC1 pathway via a novel PKC/P2Y12 dependent pathway in human platelets

Hers I, Blair T, Hunter RW and Moore SF
University of Bristol, Bristol, UK

The immunosuppressive and anti-proliferative drug rapamycin (Sirolimus) is currently used in the clinic to prevent transplant rejection, restenosis and as a cancer treatment. It has been suggested that rapamycin has antiplatelet and antithrombotic properties as it can block platelet spreading, clot retraction and thrombus remodelling. However, little is known about how activation of its target the mammalian target of rapamycin complex 1 (mTORC1) is regulated in platelets.
Stimulation of platelets with thrombin, PAR-1, collagen-related peptide or U46619 all induced phosphorylation of the mTORC1 regulator tuberous-sclerosis complex-2 (TSC2) at both S939 and T1462 and the mTORC1 substrate p70S6K at T389. Thrombin induced phosphorylation of TSC2 was rapid and sustained whereas p70S6K phosphorylation was delayed peaking at 15 min. Surprisingly, inhibition of PI3K/Akt with wortmannin/Akti did not block TSC2 phosphorylation and only a small reduction in p70S6K was observed. In contrast, inhibition of PKC resulted in significant loss in both thrombin-mediated TSC2 and p70S6K phosphorylation. One of the mechanisms by which PKC regulates platelet function is by promoting granule secretion and subsequent autocrine activation of P2Y receptors. We observed that antagonism of P2Y12, but not P2Y1, blocked TSC2 and p70S6K phosphorylation. Furthermore, addition of ADP rescued PKC blockade of thrombin-mediated TSC2 and p70S6K phosphorylation. Pretreatment of platelets with the Src inhibitor PP1 strongly reduced both TSC2 and p70S6K phosphorylation, suggesting that the Src family of kinases regulates mTORC1 downstream of P2Y12.
These results demonstrate a significant role for PKC and subsequent autocrine activation of P2Y12 receptors in the activation of the mTORC1 pathway.

Functional responses and molecular mechanisms involved in platelet activation triggered by histones

Carestia A[1], Rivadeneyra L[1], Romaniuk A[1], Fondevila C[2], Negrotto S[1] and Schattner M[1]
[1]*Institute of Experimental Medicine-CONICET;* [2]*Bazterrica Clinic, Buenos Aires, Argentina*

Background: Histones are highly alkaline proteins found in cell nuclei that can be released by dying or inflammatory cells. The recent observation that histones are major components of neutrophil extracellular DNA traps and promote platelet aggregation and platelet-dependent thrombin generation has highlighted these proteins as potent prothrombotic molecules.
Aim: Since the mechanism(s) of platelet activation by histones is not completely elucidated, we explored the ability of individual human recombinant H1, H2A, H3 and H4 to induce platelet activation as well as the molecular mechanisms involved.
Methods: Platelet adhesion and spreading were determined by confocal microscopy. Binding of fibrinogen, expression of P-selectin and forma-

tion of platelet-leukocytes aggregates were evaluated by flow cytometry. The release of von Willebrand factor (vWF) was analyzed by ELISA. Phosphorylation of platelet ERK, AKT, P38 and NFκB was studied by Western blot.

Results: All histones (10–50 μg/mL) were substrates for platelet adhesion and spreading (C:1 ± 1; H1: 1 ± 2; H2A: 2 ± 0.7; H3: 16 ± 3; H4:43 ± 6; number of cells per field, 10 μg/mL, $n = 3$), and triggered fibrinogen binding (C: 12 ± 6; H1: 74 ± 24; H2A: 150 ± 35; H3: 332 ± 50; H4: 510 ± 57, mean fluorescence intensity (MFI), $n = 5$), von Willebrand factor release (C: 17 ± 6; H1: 28.7 ± 1; H2A: 118 ± 33; H3: 144 ± 35; H4: 180 ± 22, ng/mL $n = 3$), P-selectin exposure (C: 9 ± 3; H1: 18 ± 6; H2A: 26 ± 10; H3: 76 ± 24; H4: 123 ± 46 MFI, $n = 5$) and formation of platelet-leukocyte aggregates (C; 17 ± 3; H1: 22 ± 10; H2A: 37 ± 13; H3: 135 ± 69; H4: 215 ± 81, MFI $n = 5$). Histones synergize with thrombin in triggering fibrinogen binding and P-selectin expression. Western blot assays showed that histones induce the phosphorylation of platelet ERK, AKT, P38 and NFκB. Accordingly, platelet activation induced by histones was significantly impaired by pretreatment of platelets with two non-structurally related NFκB inhibitors (BAY 11-7082 and Ro 106-9920), ERK (U0126), PI3K (LY 294002) or P38 (SB 203580) blockers. Pre-incubation of platelets with aspirin or dexamethasone markedly decreased fibrinogen binding and adhesion mediated by histones without modification of P-selectin exposure. Functional platelet responses induced by H3 and H4, but not H1 and H2A, were partially mediated through interaction with Toll like receptors 2 and 4.

Conclusions: Our data identify histones as important triggers of hemostatic and inflammatory-mediated platelet responses, which are partially inhibited by anti-inflammatory drugs.

Regulation of Rap1b activation by cyclic nucleotide-dependent protein kinases in human platelets

Subramanian H[1], Gambaryan S[1], Zahedi R[2], Sickmann A[2] and Walter U[3]

[1]Institute of Clinical Biochemistry and Pathobiochemistry, Wuerzburg; [2]Leibniz-Institut für Analytische Wissenschaften-ISAS-e.V., Dortmund; [3]Center for Thrombosis and Hemostasis (CTH), Johannes Gutenberg University, Mainz, Germany

Introduction: In agonist stimulated platelets, Rap1b is activated by Calcium and Diacylglycerol regulated-Guanine nucleotide Exchange Factor I (CalDAG-GEFI). Rap1b is critical for integrin activation and subsequent platelet aggregation. Cyclic nucleotide-dependent protein kinases were shown to prevent platelet aggregation by inhibiting Rap1b activation. The mechanism of Rap1b inhibition is poorly understood. Though, Rap1b is phosphorylated by both Protein Kinase A (PKA) and Protein Kinase G (PKG), the phosphorylation of Rap1b per se has no effect on its activation.

Aims: The aim of the study is to identify PKA/PKG phosphorylation sites in CalDAG-GEFI and the effect of CalDAG-GEFI phosphorylation on Rap1b activation.

Methods: Phosphorylation site(s) in CalDAG-GEFI was identified by the radio-active phosphate incorporation assay in HEK293 cells transfected with wild-type and phospho-mutant CalDAG-GEFI. The phosphorylation site(s) in platelet CalDAG-GEFI was determined by mass spectrometry. Phospho-antibody (P-CalDAG-GEFI^{S587}) was developed to determine the phosphorylation of CalDAG-GEFI in Western blots. Rap1b activation was detected by pull-down assay using RalGDS coupled sepharose beads. Intracellular calcium measurements were performed with Fura-2/AM loaded platelets in luminescence spectrometer.

Results: Radio-active phosphate incorporation assay and mass spectrometry revealed that S587 is the major PKA phosphorylation site in CalDAG-GEFI. In human platelets, PKA stimulation leads to rapid phosphorylation of S587 and the phosphorylation was 35 fold higher compared to unstimulated control. PKG stimulation also leads to S587 phosphorylation, but to a lesser extent than PKA. PKA pre-activation prevents intracellular calcium increase in thrombin stimulated platelets, which is necessary and sufficient for Rap1b activation and platelet aggregation. Surprisingly, PKA pre-activation prevented Rap1b activation and platelet aggregation also in calcium ionophore stimulated platelets, where PKA did not affect the intracellular calcium increase. This indicated that PKA mediated phosphorylation of CalDAG-GEFI could prevent Rap1b activation. In HEK293 cells transfected with CalDAG-GEFI, calcium ionophore induced Rap1b activation, and PKA pre-activation prevented the Rap1b activation. In phospho-mutant (S587A) transfectants, PKA pre-activation did not inhibit Rap1b activation as wild-type, while the phospho-mimetic (S587D) mutant failed to activate Rap1b following calcium ionophore stimulation. These results confirmed that PKA phosphorylation of S587 in CalDAG-GEFI prevents Rap1b activation.

Conclusion: CalDAG-GEFI is phosphorylated at S587 by both PKA and PKG in human platelets. Using *in vitro* experiments, we demonstrated that CalDAG-GEFI phosphorylation prevents Rap1b activation. We propose that this is one of the important mechanisms of platelet inhibition mediated by cyclic nucleotide signaling.

PA 3.03-4

CGMP signaling pathway regulates platelet shape change through modulation of myosin light chain phosphatase – the role of CPI-17 signalling

Naseem KM and Aburima A

University of Hull, Hull, UK

Background: Platelet shape change requires Rho family GTPase-dependent inhibition of myosin light chain (MLC) phosphatase and MLC phosphorylation. MLCP is a heterotrimer that consists of a 37 kDa catalytic subunit (PP1δ), a 110 kDa regulatory subunit termed myosin phosphatase targeting subunit (MYPT-1) and a 20 kDa protein (M20). Thrombin inhibits MLCP activity through ROCK and protein kinase C (PKC) dependent pathways. Nitric oxide (NO) inhibits shape change through cGMP dependent mechanism although the mechanisms underlying these actions of cGMP are unclear.

Aim: Here we investigated the molecular regulation of MLCP activity by cyclic GMP signaling.

Results: Platelet stimulation with thrombin induced Rho Kinase (ROCK) dependent inhibitory phosphorylation of MTYP1 on threonine^{853}, leading to diminished phosphatase activity and a net increase in phosphoMLC^{Ser19}. RhoA formed a signaling complex with ROCK-II and MYPT-1, which resulted in the disassociation of the catalytic phosphatase unit. Treatment with NO inhibited thrombin induced phosphoMYPT1^{hr853} and increased phosphatase activity to inhibit MLC phosphorylation. The mechanism of action of NO included inhibition of RhoA was through its phosphorylation on Serine^{188} in a cGMP-dependent manner. This phosphorylation event inhibited thrombin induced membrane association and GTP-loading of RhoA preventing its participation in the activation of ROCK.

Interestingly inactivation of MLCP by thrombin was prevented under conditions where PKC was inhibited. Since inhibition of PKC had no effect on thrombin-induced phosphoMTPY-1^{Thr853}, it suggested an alternative mechanism of regulation. Since MLCP activity is also modulated through association of the catalytic subunit PP1δ with the protein CPI-17, a PKC substrate, we examined how these pathways were affected by NO/cGMP signaling. Stimulation of platelets with thrombin led to phosphorylation of CPI-17^{Thr38}, which required PKC but was independent of ROCK activation. The phosphorylation of CPI-17 stimulated its association with PP1δ and loss of phosphatase activity. Pretreatment of platelets with NO blunted thrombin induced CPI-17 phosphorylation, CPI-17/PP1δ complex formation and PP1δ inactivation in a cGMP dependent manner. Importantly, NO/cGMP signalling had no effects on the activation of PKC in response to thrombin.

Conclusion: These data demonstrate that cGMP signaling targets at least two different pathways, ROCK and CPI-17, in platelets to prevent the inhibition of MLCP. The disinhibition of MLCP by NO/cGMP prevents MLC phosphorylation and contributes to the inhibition of shape change. These data demonstrate a completely new mechanism by which cGMP signaling regulates platelets.

PA 3.03-5
Small molecule inhibitors of PDK1 inhibit platelet functional responses

Dangelmaier C, Manne B, Jin J and Kunapuli SP
Sol Sherry Thrombosis Research Center, Philadelphia, PA, USA

Background: PDK1 (3-phosphoinositide-dependent protein kinase 1) has become a valid drug target for anticancer agents to treat tumors that possess elevated PKB/Akt and S6K activity. Many small molecule inhibitors of PDK1 have been described with the ultimate goal of using them in a clinical environment. Their possible influence on platelets and haemostasis has not been addressed.
Objective: The purpose of this study was to investigate the effect of two small molecule inhibitors of PDK1, BX795 and BX912, on platelet functional responses.
Methods: We assessed the agonist-induced phosphorylation state of Akt by Western blotting and measured aggregation, dense granule secretion, thromboxane formation and clot retraction in the presence and absence of BX795. Akt activity was also assessed using an *in vitro* kinase assay.
Results: Both these compounds inhibited agonist-induced phosphorylation of Akt at Thr308 in a concentration-dependent manner. The phosphorylation of two downstream substrates of Akt, GSK3 and PRAS40, was also reduced. However, BX912 also inhibited agonist-induced phosphorylation of Akt at Ser473. BX795 inhibited PAR4-, 2-MeSADP- or collagen-induced aggregation, dense granule secretion, thromboxane formation and clot retraction in a concentration-dependent manner. Using an *in vitro* kinase assay, we demonstrated that Akt activity was completely abolished if Thr308 on Akt was not phosphorylated.
Conclusions: Taken together, this study demonstrates the importance of PDK1 as its inhibition influences platelet physiological responses.

PA 3.03-6
Gas6 regulates thrombin-induced expression of VCAM-1 through a FoxO1 in endothelial cells

Bertin FR, Lemarie CA and Blostein MD
Lady Davis Institute for Medical Research/McGill University, Montreal, QC, Canada

Background: Venous thrombosis is a leading cause of morbidity and mortality in medicine. Increased concentrations of the growth-arrest specific gene 6 (Gas6) in patients suffering from venous thrombosis suggest that Gas6 plays a clinically relevant role in the pathogenesis of this disease. Gas6 is a vitamin K-dependent protein that has been shown to stabilize thrombi, protect endothelial cells from apoptosis and promote endothelial cell activation *in vivo*. In Gas6 deficient (−/−) mice, it has been demonstrated that the expression of VCAM-1 is blunted. The above data suggest that the expression of VCAM-1 induced by Gas6 is critical in the pathogenesis of venous thrombosis; however, the intracellular signaling mechanisms remain largely unknown. We previously demonstrated that the anti-apoptotic effect of Gas6 was mediated partially through Forkhead box O1 (FoxO1). FoxO1 is an effector of the PI3K/Akt signaling pathway and its phosphorylation results in its translocation from the nucleus to the cytoplasm, thereby regulating its transcriptional activity.
Aims: It is hypothesized that Gas6 promotes thrombin-induced VCAM-1 expression through the regulation of FoxO1 in endothelial cells.
Methods: Endothelial cells were isolated from the lungs of wild type (WT) and $Gas6^{-/-}$ mice. Thrombin was used as a pro-thrombotic stimulus. Phosphorylation and cellular localization of FoxO1 was analyzed by western blot analysis. VCAM-1 expression was evaluated by quantitative RT-PCR and western blot analysis in WT and $Gas6^{-/-}$ endothelial cells.
Results: VCAM-1 mRNA expression of was significantly increased after 30 min of stimulation with thrombin in WT cells ($P < 0.05$) but thrombin-mediated induction of VCAM-1 mRNA was blunted in $Gas6^{-/-}$ endothelial cells. At the protein level, thrombin induced a time-dependent expression of VCAM-1 with a maximum at 2 h ($P < 0.05$) in WT but not in $Gas6^{-/-}$ endothelial cells.
In WT endothelial cells, thrombin treatment resulted in maximal phosphorylation of FoxO1 at 30 min ($P < 0.05$) and translocation of FoxO1 from the nucleus into the cytoplasm ($P < 0.05$). None of these effects were observed in $Gas6^{-/-}$ endothelial cells. Finally, FoxO1 siRNA treatment of the endothelium resulted in increased VCAM-1 expression in WT but not $Gas6^{-/-}$ cells.
Summary/Conclusions: Taken together, these data demonstrate that Gas6 promotes VCAM-1 expression through the regulation of FoxO1. This pathway may be involved in the pro-thrombotic role of Gas6. These data also suggest that interfering with Gas6-induced signaling could be exploited clinically to treat thrombotic disease.

Human tears and sweat trigger clotting of blood: the role of tissue factor-exposing vesicles

Böing AN[1], Van Leeuwen J[2], Hau C[1], Tros W[2], Janssen L[2], Rinia H[2], Sturk A[1] and Nieuwland R[1]
[1]Academic Medical Center, Amsterdam; [2]Goois Lyceum, Bussum, The Netherlands

Background: The epithelium provides not only a barrier to microorganisms, but also produces fluids as saliva, tears (lacrima) and sweat to trap, kill and remove microorganisms. Tears contain a thus far unidentified coagulant activity. Recently, we observed high levels of coagulant TF-exposing vesicles in human saliva and urine (Blood 2011;117:3172–80), suggesting that such vesicles may be involved in host defence by supporting clot formation and thus maintenance of the barrier integrity.
Aim: To investigate whether the procoagulant activity of tear fluid and sweat is associated with vesicles.
Methods: We collected tear fluid and sweat from healthy subjects and studied the presence of vesicle associated tissue factor (TF) antigen (flow cytometry and Western Blot) and activity (fibrin generation assay).
Results: Tear fluid from all subjects ($n = 13$) shortened the clotting time of normal pool plasma from ≥ 3600 to $1332\ s \pm 502$ ($P < 0.0001$). This shortening was completely TF-mediated ($P < 0.0001$). TF in tear fluid is exclusively associated with cell-derived vesicles. Sweat contains detectable levels of TF-exposing vesicles ($n = 8$) also, albeit on average 3–4 fold lower than in tear fluid. Sweat from two subjects triggered TF-mediated clotting of plasma.
Conclusions: This study demonstrates for the first time that tears and sweat can trigger the clotting of blood via coagulant TF that is associated with cell-derived vesicles. Thus, clotting of blood can be initiated or facilitated by exposure of blood to sweat or tears.

PA 3.04-2

Characterisation of the procoagulant properties of microparticles derived from different cell types

Alsahli MA[1], Hamali HA[2] and Goodall AH[1]

[1]*University of Leicester, Leicester, UK;* [2]*King Khalid University, Abha, Saudi Arabia*

Background: Microparticles (MPs) are shed by all vascular cells upon activation or apoptosis. They vary in size and inherit antigenic features from their parent cells. Increased numbers of MPs in the circulation carry increased risk of thrombosis. The thrombotic nature of MPs comes from negatively charged phospholipids and tissue factor (TF) on their surface.

Aims: We compared the relative procoagulant activity, in terms of procoagulant phospholipid (PPL) and TF activities, of MPs generated from platelets, endothelial cells and macrophages.

Methods: Washed platelets isolated from five healthy individuals were activated with cross-linked collagen-related peptide to generate Platelet-derived MPs. MPs were generated from the human Eahy926 endothelial cells by stimulation with TNF-α, and from the pro-monocytic THP-1 cell line by LPS (following transformation into macrophages using phorbol-12-myristate-13-acetate) ($n = 3$ for both). MPs were isolated by centrifugation and their PPL and TF activities were measured by Calibrated Automated Thrombogram, using 1 pM TF and 4 μM PL reagents respectively, using peak thrombin (PT) as the measure of PPL and lag time (LT) as the measure of TF activity. The PPL and TF concentrations in the preparations were also measured using the Zymuphen MP-TF and MP-activity ELISAs. The MP count in each sample was measured by nanoparticle tracking analysis (NTA) using the Nanosight NS500 and data was normalized to 10^{12} MP/mL.

Results: Analysis by the CAT assay showed that MPs from all three cell types had significant PPL activity with macrophage-derived MPs > platelet-derived MPs > endothelial cell-derived MPs (PT of 338 ± 63; 297 ± 33 and 200 ± 27 nM respectively). All three types of MPs also showed PPL activity in the ELISA but although macrophage-derived MPs still had the highest activity (36.2 ± 17.9 nM), endothelial cell-derived MPs showed higher levels of PPL activity than platelets in this assay (6.90 ± 1.46 vs. 1.85 ± 0.52 nM respectively). The TF activity of the particles also was different for each cell types. MPs derived from macrophages and endothelial cells showed significant TF activity in both assays (LT of 19 ± 3.1 and 90 ± 8.9 min, and TF concentration of 37.0 ± 3.4 and 3.80 ± 1 pM respectively). In contrast to the two other cell types platelet derived MPs showed no TF activity in the CAT assay and negligible levels of TF by ELISA (0.09 ± 0.08 pM).

Conclusion: These data demonstrate (i) that MPs from different cell types have variable activities of PPLs and TF, (ii) that assays for PPL and TF may vary in their sensitivity and (iii) that platelet-derived MPs do not inherently express TF.

PA 3.04-3

Microparticle-associated tissue factor activity correlates to plasma levels of bacterial lipopolysaccharides in meningococcal sepsis

Hellum M[1], Øvstebø R[2], Brusletto B[2], Berg JP[3], Brandtzaeg P[2] and Henriksson C[2]

[1]*Dep. of Medical Biochemistry, Institute of Clinical Medicine, University of Oslo;* [2]*Oslo University Hospital, Ullevål;* [3]*University of Oslo, Oslo, Norway*

Background: Meningococcal disease, i.e. meningitis and sepsis, is caused by *Neisseria meningitidis (Nm)*, a gram negative bacteria with lipopolysaccharides (LPS) in the outer membrane. The levels of LPS from *Nm* in blood are closely associated with clinical presentation and outcome. Patients with meningitis have undetectable levels of LPS and low grade of coagulation disturbances, whereas patients with sepsis may have very high levels of LPS and often develop systemic septic shock and subsequent disseminated intravascular coagulation (DIC). In meningococcal sepsis, LPS generate tissue factor (TF), the main initiator of coagulation, on circulating monocytes and monocyte-derived microparticles (MPs), which both appear to contribute to the pathogenesis of DIC.

Aims: To measure MP-associated TF activity and relate it to the levels of bacterial LPS in samples from patients with meningococcal disease.

Methods: Citrated plasmas from patients with sepsis or meningitis were centrifuged (2000 *g*, 15 min, room temperature [RT]) and MPs isolated by pelletation (17,000 ***g***, 30 min, RT). MP-associated TF-dependent activity was measured with a plasma-based thrombin-generation assay (CAT) and whole blood rotational thromboelastometry (ROTEM), both assays using contact activation inhibition (corn trypsin inhibitor (CTI), 18.3 μg/mL). LPS levels were measured using a chromogenic Limulus amebocyte lysate assay.

Results: MPs obtained from sepsis patients ($n = 13$) initiated a significantly more efficient thrombin generation in the CAT assay compared to MPs from meningitis patients ($n = 10$), with lagtime = 18 ± 11 vs. 41 ± 9 min, time to peak = 29 ± 17 vs. 64 ± 12 min and peak = 87 ± 66 nM thrombin vs. 21 ± 7 nM thrombin (mean ± SD and $P < 0.05$ for all parameters). In comparison with meningitis patients, clotting time (CT) was reduced from 684 to 382 s. When MPs from sepsis patients were subjected to whole blood rotational thromboelastometry (ROTEM) (mean of two donors in each group). Preincubating the MPs obtained from the sepsis patients with anti-TF antibodies prolonged the lagtime in the CAT assay from 8/6 to 49/52 min ($n = 2$) and clotting time in the ROTEM from 478/286 to 1103/837 s ($n = 2$), indicating a TF-dependent thrombin generation and whole blood clot formation. The levels of plasma LPS in patients with sepsis (range 2–2100 EU/mL) were correlated with all four thrombogram parameters in the CAT assay; lagtime ($r^2 = 0.67$), time to peak ($r^2 = 0.67$), peak ($r^2 = 0.61$) and ETP ($r^2 = 0.50$).

Conclusion: Our results show a close association between bacterial LPS levels and MP-associated TF activity in samples from patients with meningococcal disease.

PA 3.04-4

Thrombin generation in plasma measured with a commercial reagent for the detection of microparticle-derived tissue factor is heavily influenced by contact activation

Boknäs N, Faxälv L, Ramström S and Lindahl T

Linköping University, Linköping, Sweden

Background: Since the discovery of circulating microparticles (MPs) exposing tissue factor (TF), various assays for the detection and characterization of TF-exposing MPs have been established. A commercially available reagent (MP-reagent, Thrombinoscope®,The Netherlands) containing synthetic phospholipids has been developed to allow for quantification of the contribution of TF-exposing MPs to thrombin generation in plasma using the Calibrated Automated Thrombogram (CAT) method. However, it is known that a plethora of materials, including plastics, are capable of activating Factor XII (FXII), and previous work from our group has suggested that synthetic phospholipids might augment the coagulation response to contact activation. Thus, the possibility that contact activation of FXII on synthetic surfaces, assisted by the presence of synthetic phospholipids, and not TF-exposing MPs, could be the main contributor to thrombin generation in the abovementioned assay, deserves investigation.

Aims: To investigate how FXII-dependent and TF-dependent coagulation contributes to thrombin generation using commercially available reagents for microparticle detection.

Methods: Plasma samples were obtained from healthy subjects and treated according to the instructions of the manufacturer. The effects

of increasing concentrations of synthetic phospholipids on FXII-dependent coagulation and thrombin generation were assessed in platelet-free plasma in which the microparticle content had been reduced by filtration (0.2 μm) using the Reorox instrument (Medirox AB, Nyköping, Sweden) and the CAT method, with and without CTI (100 μg/mL). This experiment was conducted either without exogenously added FXII-activator to investigate the effect of contact activation, or in the presence of increasing concentrations of kaolin. The contributions of FXII- and TF-dependent coagulation on thrombin generation using the MP-reagent or the PRP-reagent supplied by the manufacturer were evaluated in the presence of the FXII-inhibitor corn trypsin inhibitor (CTI) or antibodies directed against tissue factor (TF-Ab, shown to block tissue factor-induced coagulation).

Results: It was shown that synthetic phospholipids dramatically enhanced Factor XII-dependent coagulation and thrombin generation in filtrated platelet-free plasma. Even without exogenously added factor XII-activator (kaolin), 0.5–2.0 μM synthetic phospholipids was sufficient to produce robust thrombin generation within 15 min, which was almost completely inhibited by CTI. We then compared CATs from normal plasma samples pre-treated with either CTI or TF-Ab. Using the MP-reagent, thrombin generation was dramatically delayed or completely absent in the presence of 100 μg/mL CTI, while being virtually unaffected by the addition of 100 μg/mL of TF-blocking Ab. When using the PRP-reagent supplied by the same manufacturer, which contains tissue factor but only very small amounts of phospholipids, the reverse held true, i.e. thrombin generation was significantly delayed in the presence of TF-Ab, but unaffected by the presence of CTI.

Conclusions: We conclude that results from thrombin generation experiments conducted with reagents containing synthetic phospholipids are heavily influenced by spontaneous contact activation of FXII. Efforts to investigate the contribution of TF-exposing MPs to thrombin generation using such reagents should be interpreted cautiously, unless being performed in the presence of inhibitors that block the intrinsic coagulation pathway.

PA 3.04-5

Microparticle-associated tissue factor activity in patients with metastatic pancreatic cancer and its effect on fibrin clot formation

Thaler J, Koder S, Kornek G, Pabinger I and Ay C

Medical Univeristy of Vienna, Vienna, Austria

Background: Tissue factor (TF) is a transmembrane receptor and the main initiator of the blood coagulation cascade. Microparticles (MPs) are negatively charged membrane vesicles that are defined by their size (0.1–1 μm) and a procoagulant phosphatidylserine (PS)-rich surface that strongly increases the proteolytic activity of TF. Highly elevated MP-associated TF activity was found in patients with pancreatic cancer, one of the most prothrombotic malignancies.

Aim: To investigate whether MP-TF activity reflects the prothrombotic state in pancreatic cancer patients.

Methods: MP-TF activity was determined with a chromogenic endpoint assay. The TF-dependent and -independent effect of MPs on fibrin clot formation was determined with a plasma clotting assay. Expression of PS on MPs was quantified with a prothrombinase assay. Measurements were performed in patients with metastatic pancreatic cancer, in lipopolysaccharide-stimulated blood (LPS-plasma), which is rich in monocyte-derived TF-bearing MPs, and in healthy individuals. The study was approved by the institutional ethics committee and all participants signed informed consent.

Results: The median MP-TF activity (pg/mL) was 1.06 (range: 0.19–10.34) in 27 pancreatic cancer patients, 0.61 (range: 0.36–0.79) in 10 LPS plasma samples and 0.18 (range: 0.04–0.39) in 10 healthy individuals (each pair-wise comparison: $P < 0.001$).

When MP pellet derived from pancreatic cancer patients was added to normal pooled plasma, the median time to fibrin clot formation was 273.4 s (range: 146.6–354.4), $P < 0.001$). The fibrin clot formation time was significantly shorter when MP pellet from LPS plasma was added to normal pooled plasma (median: 157.4 s, range: 149.5–170.4). The time to fibrin clot formation was longest after the addition of MP pellet from healthy controls (median: 300.6 s [range: 261.1–417.9], each pair-wise comparison: $P < 0.001$). Only in MPs derived from LPS-plasma the fibrin clot formation time strongly depended on TF (median prolongation after TF blockade: 68% in LPS-plasma, 15% in pancreatic cancer patients and 4% in healthy individuals).

The median PS exposure (nM PS equivalent) on MPs was 6.5 (range: 2.5–66.2) in pancreatic cancer patients, 29.7 (range: 28.0–36.4) in LPS-plasma and 17.6 (range: 6.1–49.3) in healthy controls (each pair-wise comparison: $P < 0.05$).

Summary/Conclusions: In the present study we investigated MP-TF activity levels, the procoagulant potential of TF-bearing MPs and PS exposure on MPs. Elevated MP-TF activity levels were found in patients with metastatic pancreatic cancer and in LPS-plasma compared to healthy controls. MPs derived from LPS-plasma but not MPs from patients with metastatic pancreatic cancer had a strong TF-dependent impact on fibrin clot formation. Exposure of PS was high on MPs from LPS-plasma but low on MPs from pancreatic cancer patients, which might explain the different effect on fibrin clot formation.

In conclusion, our results indicate that the prothrombotic potential of TF-bearing MPs is limited in patients with metastatic pancreatic cancer and that elevated MP-TF activity might not be the major trigger for the increased risk of thrombosis in these patients.

PA 3.04-6

Cell-derived microparticles as novel tools for thrombolytic therapy?

Martinez de Lizarrondo S[1], Parcq J[2], Briens A[2], Gauberti M[2] and Vivien D[2]

[1]*Inserm;* [2]*Inserm U919, Caen, France*

Background: Fibrinolysis using recombinant tissue type plasminogen activator (r-tPA) remains the only approved treatment for acute ischemic stroke. The limits of r-tPA treatment include a narrow therapeutic window, a low recanalization rate and direct neurotoxic effects. Therefore, safer and more efficient fibrinolytic therapies are needed. Recent data indicate that besides their procoagulant components, microparticles (MPs) may be a major source of plasminogen activators *in vivo*. Therefore, MPs could be not only clot triggers but also active fibrinolytic agents.

Aims: The purpose of this study was to investigate whether tPA-enriched MPs could trigger efficient fibrinolysis without exerting deleterious effects on neuronal survival.

Methods: tPA-MPs obtained from human HEK293 cells, were isolated by a sequential ultracentrifugation procedure and were finely characterized by high-resolution laser-scanning confocal microscopy. The plasminogen activator activity of these MPs was measured by western blot, fibrin-zymography and tPA-specific chromogenic assay. Their fibrinolytic efficiency was determined by clot lysis assays and on fibrin plaques using a pool of human or murine plasma.

Results: tPA-enriched MPs were able to dissolve fibrin clots and reduced the time for clot lysis as a function of their concentration. The fibrinolytic effect of MPs was two-fold more effective than the corresponding amount of soluble r-tPA. The same results were observed using fibrin plaques. Our results suggest that tPA-MPs may be more resistant to soluble inhibitors than r-tPA. Moreover, unlike r-tPA, tPA-MPs did not exert neurotoxic effects in cultures of murine cortical neurons.

Conclusions: In summary, our results suggest that tPA-enriched MPs develop higher and more efficient fibrinolytic capacity and with fewer sides effects than soluble r-tPA. However *in vivo* studies are required to confirm this potential approach for thrombolytic therapy.

PA 3.05-1

Characterization of the second patient with Hermansky-Pudlak Syndrome type-7 (HPS7), and a novel HPS1 mutation. Value of an autozygosity mapping approach to prioritize mutation screening in HPS

Sánchez Guiu I[1], Lowe GC[2], Velasco F[3], Lordkipanidzé M[2], Dovlatova N[4], Wilde J[2], Watson SP[2], Lozano ML[1], Morgan N[1] and Rivera J[1]

[1]Centro Regional de Hemodonación, Hospital Universitario Morales Meseguer, Murcia, Spain; [2]Birmingham Platelet Group, College of Medical and Dental Sciences, Birmingham, UK; [3]Hospital Reina Sofía, Córdoba, Spain; [4]Thrombosis and Haemostasis Research Group, Queen's Medical Centre, Nottingham, UK

Background: Hermansky-Pudlak syndrome (HPS) is an autosomal recessive disorder characterized by abnormalities of lysosome-related organelles. HPS patients present with variable oculocutaneous hypopigmentation, bleeding diathesis and some with granulomatous colitis and pulmonary fibrosis. Mutations in nine genes (*HPS1-HPS9*) cause HPS in humans. The large number of HPS culprit genes (> 118 exons) and lack of genotype-phenotype correlation, complicate the molecular diagnosis of HPS.

Aims: We aimed to confirm the clinical suspicion of HPS in two unrelated patients, by means of platelet function assessment and identification of alterations in *HPS* genes. The UK patient was recruited to the Genotyping and Platelet Phenotyping (GAPP) study (ISRCTN 77951167).

Methods: Case 1 is a 30 year old Spanish man displaying oculocutaneuos albinism, nygstamus and hemorrhagic history including nose bleeding requiring cauterization, excessive bleeding from small wounds, and abnormal bleeding upon surgery. His parents were related by blood. Case 2 is a 77 year old English woman, with pale skin and hair, reduced visual acuity, nystagmus, as well as menorrhagia from menarche. This led to hysterectomy, prolonged bleeding from minor injuries, long bleeding after dental extractions, and heavy post partum hemorrhage after her three vaginal deliveries, among other lifelong bleeding complications. Her parents were first cousins. None of the two cases had coagulopathy or other recognized cause of bleeding. Platelet function studies included light transmission aggregometry (LTA) with different agonists and ATP secretion by lumiaggregometry (Case 2), ^{14}C-serotonin uptake and whole mount electron microscopy (Case 1). DNA for molecular studies was obtained from both patients. In Case 1, the *HPS1* gene was first chosen for PCR amplification and sequencing, as it is the most frequently mutated in HPS. By contrast, in Case 2 we first performed autozygosity linkage mapping by genotyping microsatellite markers flanking HPS genes, in order to identify a candidate causative gene.

Results: As compared to a parallel control, and to our historical data from healthy subjects, Case 1 platelets displayed impaired aggregation toward ADP (5 mM), epinephrine (5 mM), ristocetin (1.2 mg/mL) and collagen (2 mg/mL) (25%, 85%, 40%, and 95% reduction). Case 2 platelets also showed reduced aggregation with PAR-1 (30 mM) and collagen (1 mg/mL). Deficiency of platelet dense granules was evidenced in Case 1 by 50% reduction of ^{14}C-serotonin uptake and absence of dense bodies in whole mount, and in Case 2 by lack of ATP secretion in lumiaggregometry test with agonists such as PAR-1 (100 mM) and PAR-4 (500 mM). In Case 1 *HPS1* sequencing revealed a novel homozygous nonsense mutation c.844G>T [p.Glu204Stop] in exon 7. In Case 2, only the HPS7 locus displayed autozygosity for an extended genetic distance, prompting us to select *HPS7*/*DTNBP1* as the potential causative gene. Sequencing of *DTNBP1* identified a homozygous mutation c.177 G>A [p.Trp59Stop] in exon 4.

Summary: Here, demonstration of platelet dysfunction, dense granule deficiency, and genetic analysis confirms HPS in two unrelated pedigrees. One is a new variant of HPS type1, while the other represents the second reported variant of HPS7. This work illustrates that autozygosity mapping in consanguineous pedigrees is a useful tool to prioritize mutation screening of HPS genes.

Aberrant mRNA processing in compound heterozygote with glycoprotein IIb gene mutations causing Glanzmann thrombasthenia

Fujita J[1], Murata M[2], Kajiura Y[1], Takagi A[2], Murate T[2], Matsushita T[1], Kunishima S[3] and Kojima T[2]

[1]Nagoya University Hospital; [2]Nagoya University Graduate School of Medicine; [3]National Hospital Organization Nagoya Medical Center, Nagoya, Japan

Background: Glanzmann thrombasthenia (GT) is a rare autosomal recessive bleeding disorder caused by quantitative or qualitative abnormalities of glycoprotein (GP) IIb/IIIa complex in platelet. While many GT mutations acting at the protein level have been investigated, only fewer data on genetic defects affecting GPIIb or GPIIIa mRNA were available.

Aims: The aim of this study was to characterize the molecular mechanism underlying GT in a Japanese patient.

Patients/Methods: The patient was a 8-years old Japanese female who had suffered from hemorrhage and purpura. GPIIb/IIIa expression on the platelet was analysed by flow cytometry analysis. We analyzed the patient by DNA sequencing of all exons and splicing junctions of GPIIb gene (*ITGA2B*) and GPIIIa gene (*ITGB3*). Platelet mRNA was analyzed by quantitative real-time RT-PCR (reverse-transcription polymerase chain reaction) assay.

Results: Flow cytometry analysis revealed undetectable levels of platelet GPIIb/GPIIIa complex. Sequencing of genomic DNA revealed presence of two mutations in the *ITGA2B*, a compound heterozygote for a novel splicing mutation at the acceptor site in intron 5 (c.625-1G>A) and a previously reported nonsense mutation (c.1750C>T, p.Arg584X) in exon 17. RT-PCR assay on the patient's platelet RNA revealed the expression of GPIIb mRNA was about 3% of normal control (N = 6), and some populations in each defect GPIIb mRNA. The former showed the presence of two populations of mRNA, one with the skipping of exon 6 and the first 14-bp of exon 7 (result in deleted 60-bp) and the other with the retention of intron 5 (result in inserted 74-bp). The latter was identified two different mRNA populations, one with the nonsense mutation and the other with lacking of the last 75-bp of exon 17 including the nonsense mutation (resulting in 75-bp deletion).

Conclusions: We supposed that these mRNA populations were caused by splicing error or nonsense-mediated mRNA decay pathway. The elucidation of the genetic basis of GT in the patient suggested that premature terminations seemed to be associated with allele-specific mRNA degradation, and that several aberrant splicing events occurred.

PA 3.05-3

Identification of two novel mutations leading to MYH9-related disease and its correlation of genotype/phenotype

Siqueira LH[1], Duarte VO[2], Medina S[2] and Ozelo MC[2]

[1]State University of Campinas; [2]INCT do Sangue Hemocentro UNICAMP, University of Campinas, Campinas, SP, Brazil

Background: MYH9-related macrothrombocytopenias are among the causes of hereditary thrombocytopenias. They are associated with mutations in the non-muscle myosin gene (MYH9) and are characterized by thrombocytopenia, large platelets and leukocyte inclusions. Depending on the diagnosis, non-hematologic alterations such as cataracts, deafness and renal failure may also be present.

Aims: Evaluate thrombocytopenic patients with large platelets for the diagnosis of MYH9-related macrothrombocytopenia and identify the mutational profile of MYH9 gene.

Patients and Methods: We selected patients with thrombocytopenia and high mean platelet volume (MPV > 10.6 fL). Presence of leukocyte inclusions and large platelets was confirmed by analysis of peripheral blood smear. All cases were assessed for the presence of other non-hematological manifestations such as cataracts, hearing loss, impaired renal function, and also for family history of thrombocytopenia.

Results: Twenty-one patients with a mean age of 31.3 years old (10–57 years old), belonging to 17 families were included in this study. Ten cases (48%) had the previous diagnosis of ITP and had undergone immunosuppressive therapy. Mean platelet count was 50×10^9/L ($11–107 \times 10^9$/L) and MPV was 15.1 fL (8.2–17.7 fL). In morphologic evaluation, it was observed that all patients had large platelets, and in 13 cases more than 20% of the counted platelets were larger than 6 μm. In nine patients (five families) leukocyte inclusions were observed, and in two of them, belonging to the same family (FAM1), renal failure was also present, which features Fechtner syndrome. Another patient presented hearing loss without leukocyte inclusions, rendering the diagnosis of Epstein syndrome probable. Thus, we considered for molecular investigations 10 cases (48%), distributed in six families, in whom the most likely diagnosis was MYH9-related macrothrombocytopenia. The mutation was confirmed in five unrelated families (eight patients). E1841K mutation (exon 38) was found in three families (FAM 1, 4 and 5), and R1933Stop mutation (exon 40) was found in FAM 2. These two mutations had been previously described in several families in Asia, Europe and the USA, and had been associated with May-Hegglin anomaly (consistent with FAM 2, 4 and 5 diagnosis), but not with other macrothrombocytopenias (such as that observed in FAM1). In depth analysis of FAM 1 provided the finding of a novel mutation F636L (exon 15) in MYH9 gene of the two affected subjects (mother and son). Three unaffected daughters were negative for both E1841K and F636L mutations, confirming by segregation that both mutations were present in the same allele and were responsible for the phenotype compatible with Fechtner syndrome. Another not previously described mutation in exon 15 (T664R) was detected in a patient from FAM3. None of these novel mutations was found in a screening of 100 blood donors (200 alleles).

Conclusion: Careful clinical and family history assessments as well as systematic evaluation of peripheral blood smear are key points for correct diagnosis of MYH9-related macrothrombocytopenias. Identification of novel mutations in MYH9 gene can help to gain insights into the pathophysiology of these diseases, since location of molecular alterations reflects in the clinical manifestations.

PA 3.05-4

Variant glanzmann thombasthenia from a newly described Ile282Thr mutation in ITGB3 with functionally defective alpha IIb beta 3 integrin and mild phenotypic presentation

Maier CL and Duncan AS

Emory University School of Medicine, Atlanta, GA, USA

Background: Glanzmann Thrombasthenia is a rare disorder of platelets resulting from defective platelet aggregation and characterized clinically by mucocutaneous bleeding. The mechanism of platelet dysfunction is attributed to defects in the ITGA2B and ITGB3 genes, which encode for the fibrinogen receptor, leading to either quantitative or qualitative deficiencies of the platelet integrin alpha IIb beta 3. Many genetic variants and their clinical significance have been described, although phenotypic heterogeneity exists even among individuals with the same mutation.

Aims: Here we report a novel point mutation in the ITGB3 gene that renders the alpha IIb beta 3 complex unstable.

Case History: The patient had a history of bruising, petechiae, and epistaxis in childhood, which became less pronounced with age. Platelet aggregation studies initially revealed markedly decreased responses to collagen and absent responses to ADP and arachidonic acid. Repeat testing performed in adulthood revealed only mildly decreased responses to ADP and arachidonic acid. Morphologically, the platelets were normal in size and granularity. Flow cytometric analysis showed the presence of alpha IIb beta 3 integrin on platelets and at normal levels.

Results: Sequence analysis of genomic DNA detected heterozygosity for the c.845T>C, p.(Ile282Thr) variant in exon 6 of the ITGB3 gene. No other mutations or unclassified variants were identified, and no mutations were detected in the ITGA2B gene. The possibility of a large deletion or rearrangement was ruled out by the detection of heterozygosity for several polymorphisms. This mutation occurs in an area of beta 3 involved with fibrinogen binding that influences the stability of binding with alpha IIb.

Summary/Conclusion: Despite this mutation and a clinical presentation consistent with variant Glanzmann Thrombasthenia, both the patient's laboratory and clinical findings appeared to demonstrate improvement over time. We conclude that the Ile282Thr mutation in ITGB3 can result in a phenotypically mild form of variant Glanzmann Thrombasthenia.

PA 3.05-5

Identification of three novel mutations in TUBB1 gene in patients with macrotrombocytopenia

Saposnik B[1], Simansour M[1], Latger-Cannard V[2], Nurden P[3], Lecompte TP[4] and Schlegel N[1]

[1]Hôpital Robert Debré APHP, Paris; [2]CHU Nancy, Nancy; [3]CHU Hôpital La Timone, Marseille, France; [4]CHU Genève, Genève, Switzerland

Background: Congenital macrothrombocytopenias represent a genetically heterogeneous group of platelet disorders among which MYH9 and Bernard Soulier syndroms are the most frequent forms. Unfortunately the pathogenesis remains unknown for half of the cases identified.

Beta 1 tubulin is a protein specific of platelets and megakaryocytes. By assembling with alpha tubulin, beta 1 tubulin forms heterodimers and microtubule polymers that are essential during thrombocytopoiesis. A recent study revealed for the first time a mutation, p.R318W, in *TUBB1* gene resulting in macrothrombocytopenia (Kunishima *et al.* 2009; Blood, 113, 458–461).

Aim: To screen *TUBB1* gene in our french cohort of patients with congenital macrothrombocytopenia of unknown etiology after having

excluded MYH9, Bernard Soulier, gray platelet and platelet von Willebrand syndroms.
Methods: In 73 propositi with macrothrombocytopenia, we amplified the entire coding sequence of exons and exons-introns boundaries of *TUBB1* gene, and sequenced the PCR products.
Results: An alteration of *TUBB1* gene was identified in three propositi. The platelet count (G/L) was 77, 83 and 96 and the mean platelet volume (MPV) was not given by the analyzer for the first patient and 15.8 and 14.5 fl for the two last patients respectively. Platelet size was larger than normal on May Grünwald Giemsa stained blood smears in the three cases. The platelet agregation was normal in the three cases. Electron microscopy for the patient bearing the mutation p.F260S in *TUBB1* gene (hereafter) revealed the presence of round platelets with an enlarged size.
We identified three different missense mutations in *TUBB1* gene, one in exon 3, c.185 G>A predicting the substitution of arginine for a glutamine p.R62Q, and two in exon 4 c.779 T>C and c.1041 C>G predicting the substitution of a phenylalanine for a serine p.F260S and an asparagine for a lysine p.N347K, respectively. The patients were heterozygous for the mutations. These mutations were not found in 100 healthy controls and in the NCBI SNP database. In addition, these mutations are different from the first one published.
Conclusion: The beta 1 tubulin residues affected were highly conserved among species indicating their functional impact on the protein. These new results highlighted the role of an alteration of beta tubulin 1 in the mechanism of macrothrombocytopenia.

PA 3.05-6
Exome sequencing for causal gene discovery in three patients with primary platelet secretion defect

Lotta LA[1], Tuana G[2], Maino A[1], Rossio R[2], Artoni A[2] and Peyvandi F[2]
[1]*Angelo Bianchi Bonomi Hemophilia and Thrombosis Center;* [2]*Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico, Milan, Italy*

Background: Platelet secretion defects (PSD) are heterogeneous platelet functional defects characterized by reduced granule secretion upon stimulation by different platelet aggregation agonists. Autosomal dominant inheritance has been described in PSD, making it a phenotype amenable to genetic mapping by exome sequencing (i.e. sequencing of protein-coding areas of the genome). However, the clinical and laboratory heterogeneity of PSD warrants a tailored approach.
Aims: To undertake a pilot study in order to develop analysis pipelines for gene discovery and compile a list of candidate causal genes for PSD.
Patients/Methods: We sequenced the exome of three unrelated Italian patients with PSD and seven controls. Sequencing was carried out by Illumina HiSeq after DNA target capture by NimbleGen SeqCap EZ Exome Libraries v2.0. SOAPaligner, SOAPsnp and BWA were the software of choice for read alignment and mapping onto the reference genome sequence and for single nucleotide variant and indel calls. Annotation on databases of common (and likely neutral) genetic variation and exclusion of variants found in healthy controls were used as criteria to identify potentially disease-related genes. Databases included dbSNP132, 1000Genomes Project and exome variant server repositories.
Results: Sequencing was successful with > 95% of the 44-megabase target DNA being covered by at least 10 sequence reads. On average, approximately 25,000 single nucleotide variants and 450 indels were found in the 10 sequenced exomes. After removal of variants found in dbSNP, 1000Genomes databases or seven control exomes, 608, 635 and 592 genes had at least one nonsynonymous or splice-site SNV or coding indel in the three PSD patients. Intersection of the three gene-lists yielded eight candidate genes. After exclusion of large, highly-variable genes and genes with little or no gene-expression in platelets, *ANKRD36* and *NPRL3* were the strongest candidate genes.
Conclusions: This study illustrates the power of exome sequencing for the identification of genes underlying PSD and identifies candidate causal genes for this condition.

PA3.06 – Fibrinolytic System: Clinical – III

PA 3.06-1
The effect of factor XIII and other regulators of fibrinolysis on the outcome of thrombolysis in ischemic stroke patients

Bagoly Z[1], Székely E[1], Kovács KR[2], Mezei ZA[1], Katona E[1], Kappelmayer J[3], Csiba L[2], Muszbek L[1] and Bagoly Z[1]
[1]*Clinical Research Center, University of Debrecen, MHSC;* [2]*Department of Neurology, University of Debrecen, MHSC;* [3]*Department of Laboratory Medicine, University of Debrecen, MHSC, Debrecen, Hungary*

Background: Thrombolysis by recombinant tissue plasminogen activator (rtPA) is among the most effective pharmacological strategies in acute ischemic stroke (IS). Little is known why in some patients thrombolytic therapy is less efficient and which are the factors promoting intracranial hemorrhage in others. In most cases, these complications cannot be foreseen at the initiation of therapy and their occurrence remains unexplained. Effectiveness as well as adverse effects of the thrombolytic agent are likely to depend on factors influencing fibrinolysis and clot structure.
Aims: To investigate whether levels of factor XIII (FXIII) and of other major regulators of fibrinolysis affect the outcome of thrombolysis (the opening of the closed vessel) and the risk of hemorrhagic complications. To find out whether known polymorphisms of FXIII and of fibrinolytic proteins have an effect on the outcome of thrombolytic therapy in IS patients.
Methods: The study population included 100 IS patients, who underwent thrombolytic therapy within 3 h of the onset of clinical symptoms. Blood samples were taken at admission, 1 and 24 h after the initiation of rtPA infusion. FXIII activity and antigen levels, α_2-plasmin inhibitor (α_2PI) activity and antigen levels and thrombin activatable fibinolysis inhibitor (TAFI) antigen were measured from all blood samples. FXIII-A Val34Leu and Tyr204Phe, FXIII-B His95Arg and intron K (IVS11 + 144) polymorphisms as well as α_2PI Arg6Trp and TAFI Thr325Ile polymorphisms were genotyped. Clinical data of patients using the National Institutes of Health Stroke Scale (NIHSS) score and results of imaging tests were registered at admission and on day 1 and 7 after therapy. Unfavorable short-term outcome was defined as an increase in NIHSS score by at least four points on day 7. Long term functional outcome was assessed at 3 months after the event by the modified Rankin scale. The study was approved by the Regional Ethics Committee and informed consent was obtained in all cases.
Results: FXIII levels were significantly lower after thrombolytic therapy. The decrease was more pronounced in the case of severe IS (NIHSS > 5), but the levels did not correlate with the outcome of thrombolysis. α_2PI levels at admission were significantly lower in patients with severe IS but were not associated with the outcome. The decrease in FXIII and α_2PI levels after therapy were more pronounced in atherothrombotic than in cardioembolic stroke. FXIII-B intron K and α_2PI Arg6Trp polymorphisms showed protective effect against the development of an ischemic lesion, other FXIII polymorphisms were without effect. TAFI levels significantly decreased after thrombolytic therapy but were not associated with stroke severity or with thrombolysis outcome. Thr325Ile polymorphism increased stroke severity (OR:2.6; 95% CI:1.1–6.6), but did not influence the outcome.

Conclusions: FXIII, α_2PI and TAFI levels decreased after thrombolytic therapy but did not influence the outcome of thrombolysis. Decreased levels of α_2PI before the initiation of rtPA infusion, which might be due to increased α_2PI consumption, predict more severe stroke. For the first time we have shown that the outcome of thrombolysis is influenced by FXIII-B intron K and α_2PI Arg6Trp polymorphisms.

PA 3.06-2

Quality of life outcomes in a randomized trial of tenecteplase versus placebo for submassive pulmonary embolism

Kline JA[1], Kabrhel C[2], Courtney MD[3], Diercks DB[4], Jones AE[5], Nordenholz KN[6], Rondina MT[7], Klinger J[8] and Hernandez J[9]

[1]Indiana University, Indianapolis; [2]Harvard School of Medicine, Boston; [3]Northwestern University, Chicago; [4]University of California, Davis, Sacramento; [5]University of Mississippi, Jackson; [6]University of Colorado, Denver, Aurora; [7]University of Utah, Salt Lake City; [8]Brown University, Providence; [9]Carolinas Medical Center, Charlotte, USA

Background: Acute submassive pulmonary embolism (PE) can cause persistent symptoms that degrade quality of life (QOL). Possible causes of poor QOL include persistent right ventricular (RV) dysfunction and complications from deep venous thrombosis (DVT). This study was designed to test the hypothesis that intravenous tenecteplase would improve measurements of QOL 3 months after submassive PE.

Methods: Multicenter randomized double-blind, placebo controlled trial. Eligible patients were ambulatory at baseline, had image-proven acute PE, SBP >90 mm Hg and evidence of RV dysfunction (hypokinesis on echocardiography (echo), elevated serum troponin or brain natriuretic peptide). Patients received anticoagulation with low molecular weight heparin (LMWH) and either tiered-dose tenecteplase or saline, followed by anticoagulation with oral warfarin sodium. Patients were assessed 3 months later as follows: 1. RV function on resting echocardiography, 2. exercise capacity with the 6 min walk distance (6MWD), 3. dyspnea severity with a validated instrument to estimate NYHA functional class, 4. self-perception of wellness, assessed by the Physical Component Summary [PCS] and Mental Component Summary [MCS] scores from the SF-16®, and 5. For PTS symptoms with the VEINES-QOL. Unfavorable indexes of QOL were predefined as poor functional capacity (RV dysfunction and NYHA score >2 or 6MWD < 330 m), and SF16 or VEINES-QOL scores <2SD below the mean for this population.

Results: 83 patients with PE were enrolled with mean age 55 ± 14 years, including 38 with concomitant DVT; 43 were randomized to placebo and 40 to tenecteplase. In hospital, one patient treated with placebo died from PE and one patient treated with tenecteplase died of intracranial hemorrhage. No other patient had a significant hemorrhagic adverse event and the frequency of minor bleeding was not different between groups. Within 5 days, two patients, both treated with placebo, had circulatory deterioration, both requiring rescue thrombectomy. Within 3 months, five (11%) placebo patients had recurrent VTE vs. one (3%) treated with tenecteplase. The mean values (±SD) for the 76 patients with complete follow up for the 6MWD, SF36® PCS and SF36® MCS scores and VEINES-QOL scores were 405 ± 105 m, 44 ± 12, 53 ± 10 and 91 ± 15, respectively. The 6MWD values correlated significantly with PCS scores ($r^2 = 0.35$, $P < 0.001$) but not with MCS scores ($r^2 = 0.04$, $P = 0.1$). RV dysfunction (dilation or hypokinesis) was present in 27/76 (36%) and no QOL scores were significantly different between patients with and without RV dysfunction. Comparison of patients treated with placebo vs. tenecteplase at 3 month follow-up revealed poor functional capacity in 8/39 vs. 4/37 ($P = 0.23$). On the SF36®, a higher proportion of placebo patients had poor PCS scores (12/39 vs. 4/37, $P = 0.03$) but not MCS scores (3/39 vs. 2/37, $P = 1$). Among the 37 patients with DVT, the VEINES-QOL scores were poor in 2/19 placebo patients vs 0/18 tenecteplase patients ($P = 0.25$).

Conclusions: In this randomized, double-blinded study, the primary benefit of fibrinolytic treatment for submassive PE to patients was a significantly improved self-perception of their quality of physical health, which was correlated with exercise capacity.

PA 3.06-3

Fibrinolysis impairment in obstructive sleep apnoea syndrome is driven by increased PAI-1 and TAFI activity

Undas A[1], Borratynska A[2], Stopyra-Pach K[2] and Fil K[2]

[1]Jagiellonian University Medical College; [2]John Paul II Hospital, Krakow, Poland

Background: Obstructive sleep apnoea syndrome (OSAS) is a common disorder associated with a hypercoagulable state. Prothrombotic alterations have been suggested to explain in part increased cardiovascular risk, including risk of myocardial infarction and stroke, in OSAS patients. Little is known about fibrinolysis in OSAS.

Aim: We sought to investigate fibrinolysis and coagulation parameters in OSAS.

Methods: One hundred and sixty-seven consecutive subjects with suspected OSAS underwent a polysomnography. There were 35 subjects with severe OSAS (apnoea/hypopnoea index (AHI) > 30 events/h), 26 with moderate OSAS (AHI = 15–30 events/h), and 49 with mild OSAS (AHI = 5–15 events/h). Fifty-seven individuals in whom OSAS was ruled out (AHI < 5 events) served as a reference group. Prior to polysomnography, fasting blood samples were obtained from all subjects to determine clot lysis time (CLT), plasminogen activator inhibitor (PAI)-1 antigen, activated thrombin-activatable fibrinolysis inhibitor (TAFIa), plasmin and antiplasmin.

Results: OSAS patients and the reference group had similar clinical characteristics, including the prevalence of smoking habit, chronic obstructive pulmonary disease, asthma, hypertension, coronary artery disease, history of myocardial infarction or stroke. Both groups differed with regard to age (OSAS vs. reference group: 59 [49.0–64.0] vs. 49 [42.0–58.0] years), BMI (31.6 [28.1–37.4] vs. 28.3 [26.3–30.6] kg/m^2), diagnosed diabetes (23.6% vs. 7.0%), total cholesterol (5.1 [4.4–5.8] vs. 5.4 [4.6–6.3] mM), C-reactive protein (2.3 [1.1–3.9] vs. 1.2 [0.8–2.6] mg/L), and fasting glucose (5.4 [5.0–5.9] vs. 5.2 [4.9–5.5] mM; all $P < 0.05$). Both groups had similar plasma fibrinogen. OSAS patients compared with the reference group had higher plasma levels of PAI-1 antigen (31.8 [23.0–36.6] vs. 21.4 [19.3–24.6] ng/mL; $P < 0.000001$), TAFIa (28.4 [22.8–33.9] vs. 24.0 [20.0–30.7] ug/mL; $P = 0.002$), and prolonged CLT (98 [84–111] vs. 76 [70–80] min; $P < 0.000001$). All these parameters increased with the severity of OSAS (from mild through moderate to severe OSAS: PAI-1, 26.4 ± 6.0 vs. 30.4 ± 6.8 vs. 39.3 ± 8.5 ng/mL; $P < 0.000001$; TAFIa – 27.2 (IQR, 21.9–32.5) vs. 28.1 (20.8–32.9) vs. 32.5 (25.8–40.1) ug/mL; $P = 0.04$; CLT, 88.0 (79.0–98.0) vs. 98.0 (88.0–106.0) vs. 111.0 (101.0–128.0) min; $P < 0.0001$). There were no differences in plasmin and antiplasmin activity between OSAS subjects and reference group. There were positive correlations in OSAS patients between PAI-1, TAFIa, CLT and polysomnographic parameters such as AHI ($R = 0.66$, $P < 0.001$; $R = 0.29$, $P = 0.002$; $R = 0.55$, $P = 0.001$, respectively), apnoea index ($R = 0.55$, $P < 0.001$; $R = 0.28$, $P = 0.004$; $R = 0.42$, $P < 0.001$), hypopnoea index (HI) ($R = 0.54$, $P < 0.001$; $R = 0.20$, $P = 0.038$; $R = 0.49$, $P < 0.001$), desaturation index ($R = 0.66$, $P < 0.001$; $R = 0.32$, $P = 0.001$; $R = 0.56$, $P < 0.001$), time of snoring ($R = 0.34$, $P < 0.001$; $R = 0.28$, $P = 0.003$; $R = 0.33$, $P < 0.001$), and inverse correlations with blood oxygen saturation ($R = -0.36$, $P < 0.001$; $R = -0.24$, $P = 0.012$; $R = -0.40$, $P < 0.001$). Antiplasmin activity showed inverse correlations only with HI ($R = -0.21$, $P = 0.031$) and time of snoring ($R = -0.23$, $P = 0.016$). No correlation was observed between plasmin activity and polysomnography parameters.

Conclusions: OSAS is associated with impaired fibrinolytic capacity which is largely driven by increased plasma PAI-1 antigen and TAFIa. A novel observation is that prolonged fibrin clot lysis along with PAI-1 and TAFIa increase with the progression of OSAS, which could contribute to increased rate of thromboembolic cardiovascular events among severe OSAS patients.

PA 3.06-4

Type 1 plasminogen activator inhibitor (PAI-1) and risk of acute coronary syndrome in the european prospective investigation into cancer (EPIC)-Italy cohort

Iacoviello L[1], Agnoli C[2], De Curtis A[1], Cutrone A[1], Krogh V[2], Mattiello A[3], Matullo G[4], Panico S[3], Sacerdote C[5], Tumino R[6], Vineis P[7] and De Gaetano G[1]

[1]Catholic University, Campobasso; [2]National Cancer Institute, Milano; [3]Federico II University of Naples, Napoli; [4]Human Genetic Foundation HuGef, Torino; [5]Cancer Prevention Centre (CPO) Piemonte, Torino; [6]Cancer Registry ASP, Ragusa, Italy; [7]Imperial College, London, UK

Background: PAI-1 levels were associated with arterial disease in multiple studies. However, whether high PAI-1 levels independently increase the risk remains to be elucidated.

We evaluated the association between PAI-1 and risk of acute coronary syndrome (ACS) in four out of five centers of the European Prospective Investigation into Cancer (EPIC)-Italystudy.

Materials and Method: We conducted a case-cohort study on 1454 (702 men; 752 women) volunteers of the EPIC-Italy cohort, by comparing subjects who developed ACS (MI fatal or nonfatal, coronary revascularization, sudden death) in a mean follow-up of 11.93 years.

Using a nested case-cohort design in the EPIC-Italy study (n = 34,148), we identified a random subcohort (n = 820) and incident acute coronary syndrome cases (n = 634 plus 13 cases originated from the random subcohort) occurring between baseline (1993–1997) and end of 2006 (Varese and Naples), of 2007 (Ragusa) or 2008 (Turin); PAI-1 levels were measured in citrated plasma collected at recruitment by ELISA (Hyphen Zymutest PAI-1, IL, Milano). The relative risk (RR) and 95% confidence interval (CI), adjusted by relevant confounders and stratified by center, were estimated by aCoxregression model using Prentice method.

Results: Individuals in the highest compared with the lowest quartile of PAI-1 had significantly increased risks of ACS (RR: 4.11; 95% CI: 2.90–5.82; P for trend < 0.001) in univariate analysis, after adjustment for sex, age and recruitment center the risk decreased to 2.67 (1.82–3.92). Additional adjustment for education, smoking habit, BMI, total physical activity, hypertension, diabetes and hyperlipidemia treatment, further decreased the risk to 1.97 (1.28–3.03) (P for trend < 0.001). The risk of ACS increased by 34% for each increase in 1 standard deviation of PAI-1 levels.

Conclusions: Our data provide the first evidence for a link between high PAI-1 levels and an increased risk of ACS in the population.

PA 3.06-5

N-terminal heterogeneity of alpha-2-antiplasmin is associated with plasma clot lysis time and risk of arterial thrombosis

Uitte de Willige S, Malfliet JMC, Deckers JW, Dippel DW, Leebeek FWG and Rijken DC

Erasmus University Medical Center Rotterdam, Rotterdam, The Netherlands

Background: A reduced fibrinolytic potential is associated with risk of arterial thrombosis, although the exact mechanism underlying this association is yet unknown. The main function of alpha-2-antiplasmin (a2AP), the inhibition of plasmin, is influenced by the proteolytic modifications the protein undergoes in the circulation. Approximately 70% of circulating a2AP is N-terminally cleaved between residues Pro12 and Asn13, turning the native Met-a2AP into Asn-a2AP. Additionally, approximately 35% of circulating a2AP is cleaved at its C-terminus, resulting in a form of a2AP that has lost most of its activity by losing its ability to bind to plasmin(ogen). Non-plasminogen binding a2AP can still inhibit plasmin, but kinetically very slow.

Aims: We investigated the association of N-terminal heterogeneity of a2AP and the risk of arterial thrombosis. Additionally, with a2AP being a fibrinolysis inhibitor, we investigated the association of N-terminal heterogeneity of a2AP and the lysis times of plasma clots.

Methods: We focused on the active plasminogen-binding form of a2AP, PB-a2AP, and on individuals homozygous for the common R-allele of polymorphism Arg6Trp, as this polymorphism strongly influences N-terminal cleavage of a2AP. New ELISA assays were set up to measure the antigen levels of both total PB-a2AP and N-terminally intact Met-PB-a2AP. With these data we calculated the percentage Met-PB-a2AP, reflecting N-terminal heterogeneity. a2AP antigen levels were measured in the plasma samples of 404 patients with arterial thrombosis (myocardial infarction, ischemic stroke or peripheral artery disease) and 318 healthy control individuals from the ATTAC study. Informed consent was obtained and the study was approved by a recognised medical ethics committee. Risk estimates were determined by using the 75th percentile (P75) as calculated in control individuals and were adjusted for age and sex. Plasma clot lysis times (PCLT) were measured previously.

Results: Total-PB-a2AP levels (mean ± SD) did not differ between patients and control individuals, 47.3 ± 11.1 vs. 46.7 ± 11.9 μg/mL respectively, P = 0.416. Although individuals with Total-PB-a2AP levels above P75 had a slight increase in arterial thrombotic risk (OR:1.19, 95% CI: 0.83–1.71), this did not reach statistical significance. We did find that patients had significantly higher Met-PB-a2AP levels compared to the Met-PB-a2AP levels in control individuals, 14.8 ± 5.2 vs. 13.4 ± 4.8 μg/mL respectively, P < 0.001. Individuals with Met-PB-a2AP levels above P75 had a 1.76-fold increased risk of arterial thrombosis (95% CI: 1.25–2.49). This was also observed in the percentage Met-PB-a2AP, which was increased in patients (31.7 ± 10.0%) compared to the percentage Met-PB-a2AP in control individuals (29.3 ± 9.8%, P = 0.002), with a 1.56-fold increase in risk for individuals with a percentage Met-PB-a2AP above P75 (95%CI: 1.10–2.21). Furthermore, PCLT is known to be increased in patients with arterial thrombosis compared to the PCLT in control individuals (99.7 ± 30.4 vs. 92.6 ± 20.9 min, P = 0.005 in our study). We additionally found a positive correlation (Spearman's rho) of the percentage Met-PB-a2AP with plasma PCLT in the control individuals (0.172, P = 0.020).

Conclusions: We found that an increase in Met-PB-a2AP, i.e. a decrease in N-terminal cleavage of a2AP, is associated with an increase in PCLT and an increased risk of arterial thrombosis.

Polymorphisms of matrix metalloproteinase gene and adiposity indices in European children: results of the IDEFICS study

Iacoviello L[1], Cugino D[1], Gianfagna F[1], Ahrens W[2], De Henauw S[3], Marild S[4], Molnar D[5], Moreno L[6], Pitsiladis Y[7], Siani A[8], Tornaritis M[9] and Veidebaum T[10]

[1]Catholic University, Campobasso, Italy; [2]Bremen Institute for Prevention Research and Social Medicine, University Bremen, Bremen, Germany; [3]Department of Public Health, Ghent University, Ghent, Belgium; [4]University of Gothenburg, Gothemburg, Sweden; [5]University of Pecs, Pecs, Hungary; [6]University of Zaragoza, Zaragoza, Spain; [7]University of Glasgow, Glasgow, UK; [8]Consiglio Nazionale delle Ricerche, Avellino, Italy; [9]Research and Education Institute of Child Health, Strovolos, Cyprus; [10]National Institute for Health Development, Tallin, Estonia

Objective: We investigated the relationship between matrix metalloproteinase 3 (*MMP3*) polymorphisms and adiposity indices in European children of the IDEFICS (Identification and Prevention of Dietary- and Lifestyle-Induced Health Effects in Children and Infants) project.

Subjects: Sixteen thousand two hundred and twenty-four Caucasian children (2 ± 9 years) were recruited into a population-based survey from eight European countries. Four thousand five hundred and forty children were randomly selected for genetic studies (T0); 3238 children were re-examined 2 years later (T1). Anthropometric measures were collected by standardized protocols at T0 and T1.

Results: Six variants of *MMP3* gene were genotyped. Homozygotes for the variant A allele of rs646910 and for the H3 haplotype had higher hip circumference ($P = 0.002$ and 0.001; age, sex and country adjusted) at T0. The association remained significant after false discovery rate (FDR) correction. At T1, subjects carrying rs646910 A/A genotype or H3/H3 diplotype showed significantly higher values of BMI, waist and hip circumference and sum of tricipital and subscapular skinfolds, all associations remaining significant after FDR correction ($P = 0.020$–0.048).

Conclusions: We showed for the first time an association between the *MMP3* rs646910 variant and indices of adiposity in European children, highlighting the involvement of metalloproteinase genes in adipose tissue remodeling and growth.

PA 3.07-1

Concomitant low doses of activated prothrombin complex concentrate (APCC) and recombinant activated factor VII are efficacious in hemophilic mice and exhibit additive joint action *in vitro*

Dockal M, Knappe S, Leidenmüller P, Palige R, Resch M, Tippl S, Verdino D, Bauer KA, Höllriegl W and Scheiflinger F

Baxter Innovations GmbH, Vienna, Austria

Background: Treatment of hemophilia A is complicated by development of FVIII neutralizing antibodies, occurring in approximately 30% of patients with severe hemophilia A. In these cases, acute bleeds are often treated with bypassing agents, APCC or recombinant factor VIIa (rFVIIa), which act independently of FVIII to achieve hemostasis. However, in 10–20% of bleeding events, patients are refractory or non-responsive to monotherapy. Sequential combined bypass therapy (SCBT) or concomitant combined bypass therapy (CCBT) of APCC and rFVIIa are one of the last resorts to arrest bleeding.

Aim: We developed a translational *in vitro*-to-*in vivo* approach to study the combined effect of APCC and rFVIIa (BAX817) in human global hemostasis assays, and the efficacy of CCBT in a hemophilia A mouse model.

Methods: The activity of APCC and rFVIIa was assessed in a calibrated automated thrombograph (CAT) assay in FVIII-inhibited normal human plasma at high phospholipids and without tissue factor. We tested clinically relevant plasma concentrations of APCC (20–1000 mU/mL) and rFVIIa (0.11–5.25 μg/mL), alone and in combination, to select a ratio that normalized thrombin generation. For the efficacy study, FVIII knockout mice ($n = 16$ per group) received a single intravenous injection of 200–2700 μg/kg rFVIIa, 60–250 U/kg APCC, concomitantly administered combinations of 60 U/kg APCC + 200–2000 μg/kg rFVIIa, or buffer. Tail clips were performed and blood loss measured over 60 min.

Results: APCC and rFVIIa, alone and in combination, showed a concentration-dependent response under the given CAT conditions. The total effect of the combination on thrombin generation was consistenty lower or equal to the sum of the individual effects, suggesting an additive effect of the joint action of rFVIIa and APCC. Several combinations reached activity equivalent to 1000 mU/mL APCC; we selected 200 mU/mL APCC + 0.88 μg/mL rFVIIa as the starting point for the efficacy study. Based on previous efficacy data from rFVIIa and APCC monotherapy studies, we translated these *in vitro* plasma concentrations into doses for the mouse tail clip model. Statistical analysis of blood loss showed that the minimally effective doses were 2000 μg/kg rFVIIa, 250 U/kg APCC, and for the combination therapy, 1200 μg/kg rFVIIa + 60 U/kg APCC. Importantly, the effectiveness of 1200 μg/kg rFVIIa and 60 U/kg APCC alone was not significantly different from that of buffer. Thus, we demonstrate that suboptimal doses of rFVIIa and APCC when administered alone, correct a bleeding phenotype in combination.

Summary/Conclusions: To our knowledge, this is the first efficacy study evaluating CCBT with low doses of rFVIIa and APCC in a hemophilia animal model. We show that combined doses of rFVIIa and APCC – inefficacious on their own – reduce blood loss in FVIII knockout mice after tail clipping. Interestingly, the minimally effective combination dose in mice translates into human doses of 40 μg/kg rFVIIa + 20 U/kg APCC, which fall into the dose ranges of CCBT as applied in the clinic. We further provide new *in vitro* evidence that the joint action of rFVIIa and APCC is additive rather than synergistic.

PA 3.07-2

A single residue in tissue factor pathway inhibitor (TFPI) determines the specificity of an inhibitory peptide to TFPI and guides selection of preclinical models

Dockal M[1], Hartmann R[1], Pachlinger R[1], Brandstetter H[2], Höllriegl W[1], Polakowski T[3] and Scheiflinger F[1]

[1]Baxter Innovations GmbH, Vienna; [2]University of Salzburg, Salzburg, Austria; [3]3B Pharmaceuticals, Berlin, Germany

Background: TFPI is a potent inhibitor of the extrinsic factor X activation complex and efficiently regulates coagulation initiation. We developed *de novo* peptide inhibitors of TFPI that enhance coagulation in hemophilia models. Direct inhibition of TFPI in hemophilia models alleviates bleeding complications and may become an important approach in hemophilia treatment. TFPI inhibitors are currently under investigation for inhibitory antibodies and aptamers. Recently, we demonstrated that an optimized linear peptide JBT-A7 bound to the Kunitz-1 (K1) domain of human (h)TFPI with a Kd < 1 nM and efficiently inhibited TFPI in human test systems.

Aims: We characterized target cross-reactivity of TFPI inhibitors including a fusion peptide of a linear (JBT-A7) and a cyclic (JBT-B5) peptide, to efficiently select animal species for preclinical studies.

Methods: We co-crystallized JBT-A7 with human K1 and JBT-B5 with K1-K2 produced by *E. coli*. Critical residues for JBT-A7 binding to K1 were identified from the structure and compared to animal TFPI by

sequence alignment. Species selective TFPI inhibitory activity of peptides was tested in TF-triggered thrombin generation in mouse, rat, rabbit, dog, minipig, macaque and marmoset plasma, which was supplemented with anti-FVIII inhibitors to mimic hemophilia A conditions and to be more sensitive to TFPI inhibition. Recombinant TFPI1-160 from several animal species was used to show direct inhibition of TFPI by peptides in a FXa inhibition model assay. The interaction of JBT-A7 with recombinant TFPI1-160 was studied using Biacore.

Results: Crystallographic measurements showed that the specificity of JBT-A7 to K1 is determined by electrostatic interactions at distinct charged hot spots, e.g. Lys29 and Asp32 interact with an Asp and Arg-Lys, respectively, in JBT-A7. Extended steric surface complementarities of the binding partners explain both the high affinity and specificity. JBT-B5 interacts with K1, K2 and the linker region between these Kunitz domains. Activity screening in plasma indicated cross-reactivity of JBT-A7 to mouse and marmoset TFPI only. Macaque TFPI did not react with JBT-A7 despite a sequence identity of 92.5% to human TFPI1-160. Sequence alignment revealed a single mutation A30P, impacting the binding site and resulting in a complete loss of cross-reactivity. Reduced binding to macaque TFPI was confirmed by Biacore studies. Although marmoset TFPI is less related to human TFPI than macaque TFPI is, it did not show the A30P exchange. JBT-A7 blocked marmoset TFPI with activity similar to human TFPI. The cyclic JBT-B5 does not cross-react to any animal TFPI tested. Nevertheless, fusion of both peptides results in TFPI inhibitory activity in marmoset plasma similar to that in human plasma.

Summary/Conclusions: The data show that detailed knowledge of a compound guides the selection of an appropriate animal species, and that a change of only one critical residue within the protein target may determine species specificity for preclinical studies. This structure-guided *in vitro* approach aids in reducing the number of animal experiments.

PA 3.07-3

Regulation of plasminogen activator inhibitor-1 promotes immune tolerance to factor VIII in murine hemophilia A

Madoiwa S

Jichi Medical University, Shimotsuke, Japan

The development of inhibitory antibodies against factor VIII (FVIII) is the enormous impact on hemophilia A patients, who are treated with FVIII products. Plasminogen activator-plasmin system is associated with not only thrombolysis but also various reactions including inflammation. However, little is known about how fibrinolytic components coordinate immune response. Here we show that plasminogen activator inhibitor-1 (PAI-1), a regulator of fibrinolytic system, is a key player in controlling immune response in a mouse model of hemophilia A. Genetic deletion of PAI-1 prevented FVIII deficient mice from development of inhibitor formation after repeated loading of FVIII. PAI-1 depletion was associated with decreased major histocompatibility complex class II expression by bone marrow F4/80 positive cells and reduced T cell proliferation. Transplantation of mouse bone marrow cells transduced with a short hairpin RNA sequence targeting PAI-1 as well as administration of synthetic PAI-1 inhibitor caused a significant reduction of anti-FVIII antibody titer in FVIII deficient mice. These results suggest that PAI-1 regulation before FVIII exposure may represent a novel therapeutic option for preventing the development of FVIII inhibitors in hemophilia A patients.

The effect of FVIII deficiency on the dynamics of thrombin and fibrin generation under flow on tissue factor-rich surfaces

Onasoga A[1], Leiderman K[2], Fogelson AL[3], Manco-Johnson M[4], Di Paola JA[4] and Neeves KB[1]

[1]Colorado School of Mines, Golden, CO; [2]University of California, Merced, Merced, CA; [3]University of Utah, Salt Lake City, UT; [4]University of Colorado, Denver, Denver, CO, USA

Background: Blood flow affects coagulation by determining the rate of zymogen delivery to, and enzyme transport away from a growing thrombus. While it is known that FVIII deficiencies diminish the rate of thrombin generation under static conditions, there is little known about how this deficiency influences thrombus formation under flow on well-defined TF-rich surfaces.

Aims: The objective of this study was to measure the effect of FVIII deficiencies on fibrin formation and thrombin generation under flow in a whole blood system, using a microfluidic flow assay (MFA). We compared how the MFA compared to static assays in terms of their sensitivity to FVIII levels. Finally, we used the MFA to measure the response to replacement therapies and bypassing agents.

Methods: Whole blood from individuals with severe ($n = 7$), moderate ($n = 8$), mild ($n = 5$) hemophilia or healthy controls ($n = 8$) was perfused over a collagen-tissue factor surface at a shear rate of 100/s for 5 min. Transient fibrin and platelet accumulation were measured by fluorescence microscopy. Thrombus morphology was measured by scanning electron microscopy. To aid in the interpretation of the experiments, thrombin generation as a function of FVIII levels was simulated using computational models of thrombus formation. Pre- and post-treatment assays were run on samples from individuals receiving recombinant FVIII replacement therapies or FVIIa bypassing agents. Results from the MFA were compared to turbidity and thrombin generation (TG) assays to gauge the relative sensitivity of a flow based approach to FVIII deficiency.

Results: The rate of fibrin formation and final fibrin accumulation was a strongly correlation to FVIII plasma levels. ($r = 0.81$, $P < 0.001$). The FVIII levels also influenced the magnitude and the distribution of thrombin generation as predicted by computational models. The average thrombin concentration in the thrombus was 50 nM at 100% FVIII, 5 nM for 10% FVIII and 1 nM for 1% FVIII. Integrated fibrin density in the MFA was able to discriminate between healthy controls (39.03 ± 6.1 RFU), mild (22.34 ± 2.86 RFU) and severe (11.4 ± 1.5 RFU) hemophilia. The MFA was equally or more sensitive to FVIII levels compared to maximum absorption in a turbidity assay ($r = 0.69$, $P < 0.004$) and TG assay ($r = -0.18$, $P = 0.50$). Fibrin accumulation following replacement and bypass therapy showed a marked increase in fibrin density before (10.0 ± 0.7 RFU) and 1 h after treatment (52.8 ± 2.3 RFU).

Conclusions: These results show that a collagen-TF based microfluidic flow assay is sensitive to FVIII levels. This assay could also potentially be used to predict bleeding severity, as well as for preventive dosing and response to new coagulation products.

PA 3.07-5

Characterization of large deletions in the F8 gene using multiple competitive amplification and genome walking technique

You G

Shanghai Institute of Hematology, Shanghai, China

Background: Large deletions in the F8 gene are responsible for approximately 3% of severe hemophilia A (HA) cases. However, only a few breakpoints in large deletions have been characterized.

Aims: To identify large deletions in the F8 gene and to characterize the molecular mechanisms leading to these deletions.

Methods: We used the AccuCopy technology, a copy number variation (CNV) genotyping method based on multiplex competitive amplification, to confirm deletions in index patients and to screen potential female carriers in 10 HA families. Also, breakpoints of these large deletions were characterized by a primer walking strategy and genome walking technique.
Results: Ten large deletions and four female carriers were identified by AccuCopy. The extents of deleted regions ranged from 1.3 to 68.5 kb. Exact breakpoints of these deletions were successfully characterized. Eight of them presented microhomologies at breakpoint junctions and several recombination-associated elements (repetitive elements, non-B conformation forming motifs and recombination-associated sequence motifs) were also observed in close proximity to the junctions.
Conclusions: The AccuCopy technology is a reliable and efficient tool for detecting large deletions in the F8 gene and for identifying HA female carriers. Genome walking technique is a highly specific, efficient and versatile method for characterizing the deletion breakpoints. Molecular characterization of deletion breakpoints revealed that non-homologous end joining and microhomology-mediated replication-dependent recombination were the major causative mechanisms of the ten large deletions in the F8 gene.

Role of mannose-ending glycanes in the immunogenicity of FVIII in FVIII-deficient mice

Delignat S[1], Rayès J[1], Dasgupta S[1], Peyron I[1], Martinez-Pomares L[2], Chtourou S[3], Plantier J-L[3], Kaveri SV[1] and Lacroix-Desmazes S[1]

[1]Inserm, Paris, France; [2]Queens Medical Center University, Nottingham, UK; [3]LFB, Les Ulis, France

Background: Ten to thirty percent of patients with hemophilia A develop anti-factor VIII (FVIII) inhibitory antibodies after FVIII replacement therapy. The reasons for the elevated immunogenicity of FVIII are still poorly understood. A mandatory step for developing an anti-FVIII immune response is the endocytosis of the exogenously administered FVIII by antigen presenting cells (APCs), such as dendritic cells or macrophages, and the presentation of FVIII-derived peptides by APCs to CD4+ T lymphocytes. Previously, using human monocyte-derived dendritic cells (Mo-DCs) as a model of APCs, we have demonstrated that endocytosis of human recombinant FVIII by Mo-DCs leads to presentation of FVIII peptides to T cells *in vitro*, and that endocytosis is mediated at least in part through the macrophage mannose-receptor (CD206). However, we also showed that the latter mannose-sensitive pathway is not involved in the uptake of FVIII by murine bone marrow-derived dendritic cells (BM-DCs).
Aim: The aim of this study was to evaluate the importance of mannose-sensitive pathway in the immunogenicity of FVIII *in vivo* using FVIII-deficient (FVIII°) mice.
Methods: To investigate the importance of mannose-ending glycans in the immunogenicity of FVIII, we used different strategies. (i) We produced a demannosylated (DM-FVIII) human B domain-deleted FVIII lacking oligomannose carbohydrates at Asn239 and Asn2118, and a wild-type B domain-deleted FVIII (WT-FVIII, Δ2FVIII, LFB, Les Ulys) by transducing CHO-S cells with lentiviral vectors. To evaluate FVIII immunogenicity, FVIII° mice were injected intravenously with 1 UI of WT-FVIII or DM-FVIII 4 times at weekly interval. (ii) We saturated mannose-sensitive receptors in FVIII° mice with mannan, or mannose-ending glycans of FVIII with soluble CD206 (sCD206), prior to FVIII injection. (iii) We also compared the immunogenicity of FVIII in wild-type (WT) mice and CD206-deficient (CD206°) mice. In all cases, the anti-FVIII immune response was evaluated by measuring anti-FVIII IgG titers by ELISA and FVIII inhibitory titers by chromogenic assay.
Results: Purified WT-FVIII and DM-FVIII had similar specific activities (2007 and 2783 IU/mg, respectively) and presented the same capacity to bind VWF and activated platelets. Surprisingly, we observed a significantly increased immune response in FVIII° mice treated with DM-FVIII as compared to mice treated with the WT-FVIII: anti-FVIII IgG titers of 21,732 ± 12,349 and 2546 ± 1219 μg/mL, respectively ($P = 0.015$); FVIII inhibitory titers of 685 ± 335 and 84 ± 26 BU/mL, respectively ($P = 0.004$). Saturation of mannose-sensitive receptors *in vivo* or *ex vivo* quenching of mannose-ending sugars on FVIII using sCD206, prior to injection to FVIII° mice, both showed the same tendency. Likewise, CD206° mice developed a significantly higher anti-FVIII immune response than wild-type mice.
Conclusion: In contrast to our hypothesis based on results generated using human cells *in vitro*, blocking the interaction between FVIII and mannose-sensitive receptors in FVIII° mice increases FVIII immunogenicity. Whether this is due to intrinsic differences in CD206 expression in mice as compared to human, or to the fact that Mo-DCs are not an appropriate surrogate to mimic mannose-dependent antigen endocytosis *in vivo* is being investigated.

Background: Life-threatening HIT is treated with the non-heparin anticoagulants argatroban (A), lepirudin (L), or danaparoid (D). Frequently, fondaparinux (F) is used off-label.
Aims: The aim was to obtain data on therapy efficacy and safety of the different anticoagulants.
Methods: In a national multi-centre registry study, patients diagnosed with HIT between 01/2005 and 10/2009 were included when the retrospectively determined 4T's scores were ≥ 4 points (intermediate or high clinical risk for HIT), and when they were treated with at least one dose of A, L, D, or F. Outcome measures were: incidences of thromboembolic complications, amputations, skin lesions, thrombocytopenia, skin lesions, platelet recovery, bleeding and fatal complications.
Results: Ninety-six (49.2%) of 195 patients had an intermediate, and 94 (48.2%) patients had a high 4T's score (median: five points; six points in the F therapy group). Immunogenic and functional heparin-induced activation assays were positive in 54.6% and 32.8%, respectively. Of the patients, 57 (24.2%) were exposed to A, 9 (3.8%) to L, 70 (29.7%) to D, and 98 (41.5%) to F. The composite endpoint (thrombosis, amputation, skin necrosis) occurred with A in 8.8%, with L in 11.1%, with D in 12.9%, and with F in 0.0% of patients. Platelet counts recovered in all but 9 (4.6%) patients within 9.0 days (median). Of these, only one patient, who was also refractory to A/D, did not respond to F. All cause in-hospital mortality rates were 10.5% for A, 22.2% for L, 17.1% for D, and 0.0% for F. Bleeding complications occurred with A in 8.8%, with L in 22.2%, with D in 5.7%, and with F in 4.1%.

Summary/Conclusion: Fondaparinux seems to be an effective and safe alternative therapy option in suspected acute HIT although currently not licensed; no HIT-specific complications occurred even in patients with a high clinical probability for HIT. Further data are needed urgently because Lepirudin has been retrieved off the market, Danaparoid access has been limited due to manufacturing problems, and argatroban is contraindicated in patients with impaired hepatic function.
The Ethics Committee of the State Chambers of Physicians (Landesaerztekammer), Bavaria, confirmed that ethics approval was not required due to the complete anonymisation of the retrospective data that were acquired from the patients' individual medical records. The provision of study information to the patients and an informed consent form were not required. The study was registered at ClinicalTrials.gov (NCT01304238).

Laboratory testing for heparin induced thrombocytopaenia (HIT); current practice amongst UK NEQAS and ECAT participants

Jennings I[1], Meijer P[2], Horner K[3], Kitchen S[1], Kitchen D[1], Woods T[1] and Walker I[1]

[1]UK NEQAS (Blood Coagulation), Sheffield, UK; [2]ECAT Foundation, Leiden, The Netherlands; [3]Sheffield Haemophilia and Thrombosis Centre, Sheffield, UK

Background: Diagnosis of Heparin Induced Thrombocytopaenia (HIT) is based on a combination of clinical assessment, usually employing a 4T's score or similar, and laboratory testing. Therefore to ensure an accurate diagnosis, sensitive and specific laboratory assays are required.
Method: UKNEQAS initiated proficiency testing surveys for Heparin-Induced Thrombocytopenia (HIT) screening in 2008, to explore diagnostic accuracy amongst laboratories and to support improved laboratory performance of HIT screening. In the most recent exercise carried out in July and August 2012, three lyophilised citrated plasma samples were sent to 90 centres, of which approximately half were UK-based. One sample was a pooled normal plasma (coded HIT 12:02 below), one was a sample from a patient with positive results in several laboratory tests for HIT (Coded HIT 12:03), the third sample (HIT 12:01) was a dilution of the same positive sample constructed using normal plasma.
Results: A number of trends in relation to laboratory testing have occurred in the period between 2008 and 2012. Platelet aggregation tests are less frequently used and none of the four centres currently using conventional aggregometry reported use of washed platelets recommended in guidelines based on improved sensitivity relative to unwashed platelets. Amongst users of ELISA techniques an increasing proportion utilise assays detecting only IgG antibodies as recommended in UK Guidelines. For sample HIT12:03 (undiluted positive) all centres using either IgG or IgG, A & M-based assays reported an abnormal result. For sample HIT12:02 (normal plasma) all ELISA user reported a negative result. For sample HIT12:01 (diluted positive sample) there was a lack of concordance in interpretations – 4/16 (25%) of centres using a IgG/A/M ELISA reported a positive screen, and 6/16 reported an equiviocal result, whilst 12/14 centres using IgG-only ELISAs reported a negative screen, with the remaining two centres reporting equivocal results. For HIT12:02 (normal plasma) false-positive results were reported by five of 21 users of the Diamed technique with five more considering results to be equivocal or weakly positive. This technique recommends the use of fresh serum, and the effect of using lyophilised citrated plasma as a quality control material is being investigated. One of 12 IL HIT latex assay users reported an equivocal result on this sample, with the remainder reporting negative results, as did all users of ELISA, Stago STIC lateral flow assay, platelet aggregation assays and two Multiplate users. Samples HIT12:01 and HIT12:02 were also distributed to participants in the ECAT quality assurance programme. Two hundred and nine centres reported results; in general, ECAT results were comparable to those of NEQAS. Amongst ECAT participants, 49% of centres employing the Diamed method reported a positive screen on sample HIT12:02 (normal plasma) whilst all those using an ELISA-based method reported a negative result. For sample HIT12:01, a split of interpretations was observed amongst centres employing the same methods.
Conclusion: These survey data indicate that variability in laboratory test results is sufficient to influence patient management decisions, and confirms the continued need for proficiency testing in this area to help improve laboratory testing in the investigation of possible HIT.

Detection and measurement of anti-IL8 IgG antibodies in cardiac surgery patients and heparin-induced thrombocytopenia using a multiplexed fluorimetric assay

Pouplard C[1], Abraham JD[2], Leroux D[1], Lapalud P[2], Pfieffer C[2], Galea P[2], Laune D[2], Molina F[2] and Gruel Y[1]

[1]University Hospital of Tours, Tours; [2]Sysdiag UMR3145 CNRS, Montpellier, France

Background: Antibodies (Abs) to interleukin-8 (IL8) have been detected alone or in combination with Abs to PF4/heparin (H) complexes in few patients with heparin-induced thrombocytopenia (HIT). However, their pathogenicity remains uncertain such antibodies to IL8 have also been detected in healthy subjects. Cardiac surgery (CS) is a clinical situation associated with a high risk of Abs to PF4/H and HIT. In addition, CS induces a systemic inflammatory response with strong release of IL8.
Aims: To develop a sensitive and specific method for investigating whether Abs to IL8 may exist after cardiac surgery and in HIT patients, or not.
Methods: We developed a cytometry-based immunoassay using color-coded paramagnetic beads (Bio-plex Protm Magnetic COOH Beads) on which a murine monoclonal antibody to human CXCL8/IL8 was covalently coupled. Beads were then incubated without (w/o) or with recombinant human IL8 (rhIL8) and after washings, 'test beads' (i.e. with rhIL8) or 'control beads' (i.e. w/o rhIL8) were incubated with diluted plasma samples. After washings, a conjugated anti-human IgG was incubated with 'test beads' and 'control beads'. Beads were then washed and analyzed with a Bioplex100tm. Mean fluorescence intensity (MFI) was measured and results were expressed as 'MFI ratio' (=MFI with 'test beads' divided by MFI with 'control beads') and as 'Differential MFI' (=MFI with 'test beads' minus MFI with 'control beads'). To define the cut-off values, experiments were done with plasma samples from 54 healthy subjects. The cut-off values of 'MFI ratio' and 'differential MFI' were defined as > the 90th percentile and three of the 54 controls (5.5%) were identified as having significant levels of Abs to IL8. The presence of Abs to IL8 was then studied in 196 consecutive CS patients treated by heparin post-operatively and in 52 patients having definite HIT.
Results: Significant levels of Abs to IL8 were measured in 15 CS patients (7.6%) on day 7 postoperatively and in six HIT patients (11.6%). Results obtained were highly specific since in every case no significant fluorescence signal could be recorded when an excess of free IL8 was added in diluted plasma before incubation with 'test beads'. Abs to PF4/heparin complexes were also detected in 15 of the 21 plasma samples containing anti-IL8 Abs (six from HIT and nine from CS patients). No inhibition of anti-IL8 Abs binding to 'test beads' was obtained after spiking diluted plasma samples with purified PF4. Interestingly, anti-IL8 Abs were also detected preoperatively in every positive CS patients, with similar levels compared to those measured postoperatively. In addition, SRA performed with CS plasma samples and variable concentrations of rhIL8 and unfractionated heparin was consistently negative.

Summary/Conclusion: IgG Abs to IL8 may be detected by a specific assay in few patients with HIT and after cardiac surgery, but with an incidence that is not significantly higher than in healthy subjects. Moreover, our data obtained with pre-operative samples and with SRA do not support a role of heparin treatment in the synthesis of Abs to IL8 and their pathogenicity that remains to be demonstrated.

PA 3.08-4

Prospective evaluation of a rapid and IgG specific nanoparticle-based lateral flow immunoassay (Stic Expert HIT®) for the diagnosis of heparin-induced thrombocytopenia

Leroux D, Pouplard C, Gruel Y and Working Group*
University Hospital of Tours, Tours

Background: The diagnosis of Heparin Induced Thrombocytopenia (HIT) is based on clinical suspicion and biological assays detecting antibodies to PF4/H but many require some delay before obtaining a result. Recently, a rapid and IgG-specific lateral flow immunoassay (LFIA) using PF4/polyanion complexes linked to biotin as antigens and gold nanoparticles coated with antibodies specific to biotin has been developed (Stic Expert HIT®, Stago).
Aims: To evaluate the performances of this assay in a prospective cohort of patients with suspected HIT.
We also compared the results obtained with serum and plasma and evaluated the inter-reader reproducibility of the assay.
In addition, results obtained with the Stic expert HIT® were compared to those collected in five centers with the rapid particle gel immunoassay (H/PF4-PaGIA®, Bio-rad).
Methods: Three hundred and thirty-seven consecutive patients were enrolled from February to October 2012 in 10 French centers. The pre-test probability of HIT was evaluated using the 4T's score. The LFIA was performed in each center on plasma and serum. IgG specific ELISA (Asserachrom HPIA IgG®, Stago) and serotonin release assay (SRA) were performed in our lab. PaGIA was performed in five centers in 124 patients.
Results: Definite HIT was diagnosed in 42 patients with positive ELISA and SRA (12.5%). The 4T's concluded to a low risk (LowR), intermediate risk (IR) and high risk (HR) of HIT in 28.8%, 61.4% and 9.8% of patients, respectively.
The interpretation of LFIA results is visual but the inter reader reproducibility was excellent with both plasma and serum (kappa ratio values higher than 0.9).
The negative predictive value (NPV) of LFIA performed on plasma was 99.6% with a negative likelihood ratio (LR) of 0.03. The LFIA was positive in 88 patients including 41 with definite HIT. Therefore, the PPV and positive LR of the Stic Expert were 46.6% and 6.06, respectively. Results obtained with serum were comparable.
According to the Bayes' equation, the post-test probability of HIT was 0.4% when the Stic Expert was negative in IR patients (pre-test probability = 11.6%), and equalled 43.3% when the test was positive.
The agreement between results obtained with the LFIA and PaGIA was not good, with 37.1% of discrepant results (kappa ratio < 0.4).
The NPV of PaGIA was 100% with a negative LR < 0.001 but PPV and positive LR were 22.2% and 2.24, respectively. Therefore, the post-test probability was < 0.1% when PaGIA was negative in IR patients, but it increased from 11.6% to 22.7% only, when the result was positive.
Summary/Conclusions: The LFIA Stic Expert HIT® is a rapid assay, which reliably allows to exclude HIT in < 40 min when used in combination with the 4T's score. This test can be performed on both serum and plasma and is particularly useful in LowR or IR patients for whom heparin treatment can be continued safely if the result is negative.

The clincal impact of anti-protamine/heparin antibodies in patients undergoing cardiac surgery

Bakchoul T[1], Zöllner H[1], Amiral J[2], Delcea M[1], Panzer S[3], Warkentin T[4], Sachs UJ[5] and Greinacher A[1]
[1]Ernst-Moritz-Arndt University Greifswald, Greifswald, Germany; [2]Hyphen BioMed, Neuville sur Oise, France; [3]Medical University Vienna, Vienna, Austria; [4]McMaster University, Hamilton, ON, Canada; [5]Institute for Clinical Immunology and Transfusion Medicine, Justus-Liebig Univ, Giessen, Germany

Background: Protamine, routinely used post-cardiac surgery to reverse the anticoagulant effects of heparin, is immunogenic and a cause of anaphylaxis. We observed an otherwise unexplained rapid platelet count decrease directly after protamine adminstartion post cardiac-surgery.
Aim: To determine the incidence and clinical relevance of protamine-reactive antibodies in cardiac-surgery patients.
Methods: We tested 591 cardiopulmonary-bypass surgery patients for anti-protamine and anti-protamine-heparin IgG antibodies by enzyme-immunoassay (days 0, 6, 10, > 120) and by a functional assay to identify platelet-activating antibodies. We compared platelet counts and thromboembolic events for patients with platelet-activating anti-protamine-heparin antibodies against patients with and without non-platelet-activating antibodies. An animal model was used to assess antibody pathogenicity *in vivo*.
Results: Of 591 cardiopulmonary-bypass surgery patients, 57 (9.6%) patients tested positive for anti-protamine-heparin antibodies at baseline and 154 (26.6%) tested positive at day 10. Diabetes was identified as a risk factor for the development of anti-protamine-heparin antibodies. Fifty-two (8.8%) and 64 (10.8%) patients seroconverted until day 6 and 10 post CPB surgery, respectively, of which only 13/52 (25.0%) and 12/64 (18.8%) developed IgM antibodies. In the majority of patients these antibodies were transient and titers decreased substantially after 4 months ($P < 0.001$).
In vitro studies showed that these antibodies activate platelets in the presence of heparin and protamine in a FcgRIIa dependent fashion. Seven patients had platelet-activating, anti-protamine-heparin antibodies at baseline. They showed a greater and more prolonged decline in platelet counts compared to antibody-negative patients ($P = 0.003$), in addition, two of those patients developed early arterial thromboembolic complications vs. 9/584 controls (multivariate analysis: odds ratio 21.58; 95% confidence interval 2.90–160.89, $P = 0.003$). Using a NOD/SCID mouse model anti-protamine/heparin antibodies activated human platelets via FcgRIIa and induced thrombocytopenia only when protamine and heparin were present but not with protamine alone.
Summary/Conclusion: Our studies identify a novel post-protamine prothrombocytopenic disorder in post-cardiac surgery patients associated with platelet-activating anti-protamine-heparin antibodies, characterized by increased risk for early arterial occlusions.

PA 3.08-6

Impact of heparin-induced thrombocytopenia on acute coronary artery thrombosis in patients undergoing percutaneous coronary intervention

Maeda T[1], Noguchi T[1], Saito S[2], Yoshioka R[3], Horibe E[4] and Miyata S[1]
[1]National Cerebral and Cardiovascular Center, Suita Osaka; [2]Hirosaki University School of Medicine and Hospital, Hirosaki, Aomori; [3]Medical Care Education Research Fundation Yanagawa Hospital, Yanagawa, Fukuoka; [4]Takayama Red Cross Hospital, Takayama, Gifu, Japan

Background: Percutaneous coronary intervention (PCI) has drastically reduced mortality in patients with acute coronary syndrome.

Anticoagulation with heparin during the procedure and concomitant (and subsequent) intensive antiplatelet therapy help to greatly reduce the recurrence of coronary artery thrombosis (CAT). Nonetheless, acute CAT remains associated with high mortality rates in patients who undergo PCI, despite receiving such intensive antithrombotic treatment. One possible cause is heparin-induced thrombocytopenia (HIT), a severe thrombotic side effect of heparin, because heparin is frequently administered to treat acute coronary syndrome in addition to anticoagulation during PCI. However, there are very few comprehensive reports on HIT-associated CAT during or soon after PCI, although some case reports have described HIT-associated CAT in PCI patients. Extensive analysis to elucidate the impact of HIT on acute CAT can potentially provide insights into how to decrease mortality in PCI patients.

Aims and Methods: To clarify the characteristics of HIT-associated CAT, we retrospectively investigated 21 patients who suffered from acute CAT during or soon after PCI and were clinically suspected of having HIT at 20 hospitals between August 2008 and January 2012. HIT was ultimately diagnosed by the detection of anti-platelet factor 4 (PF4)/heparin IgG with platelet-activating properties (HIT antibodies) at a therapeutic heparin concentration, but not at a high heparin concentration or with anti-FcγRIIa antibodies. The assay was performed using washed platelets prepared from whole blood of HIT antibody-sensitive healthy volunteers. The HIT and non-HIT groups were compared to identify characteristics associated with HIT.

Results: Of the 21 patients, five were diagnosed with HIT (23.8%). Optical density values of anti-PF4/heparin antibodies detected by ELISA were significantly higher in HIT patients than in non-HIT patients (2.88 ± 0.71 vs. 0.22 ± 0.51 in ELISA for IgG/A/M, $P < 0.01$; 2.02 ± 0.77 vs. 0.11 ± 0.012 in ELISA for IgG, $P < 0.01$). The decrease in platelet count was significantly greater in the HIT group ($74.9 \pm 14.3\%$ vs. $35.6 \pm 21.1\%$; $P < 0.001$). All the patients in the HIT group underwent PCI using unfractionated heparin within the past month (but not in the last 10 days) ($P = 0.014$), which led to the presence of HIT antibodies when the next PCI was performed. Within 90 min of heparin administration for PCI, acute CAT occurred concomitantly with a precipitous (> 50%) fall in platelet count, a clinical picture consistent with rapid-onset HIT. Among the five HIT patients, two had other thrombotic complications (stroke or pulmonary embolism), and one died even with immediate cessation of heparin and administration of a nonheparin anticoagulant. There were no significant differences between the groups in terms of sex ($P = 0.517$), age ($P = 0.734$), hyperlipidemia ($P = 0.34$), body mass index ($P = 0.972$), current tobacco use ($P = 0.469$), and renal dysfunction ($P = 0.554$).

Conclusions: Our results suggest that the contribution of HIT to acute CAT should be considered in patients who will undergo PCI if they underwent interventions involving heparin such as PCI within the past month (but not in the last 10 days). In such high-risk patients, routine screening for HIT antibodies before PCI or use of a nonheparin anticoagulant for PCI may be effective for reducing the incidence of acute CAT.

PA3.09 – Von Willebrand Factor: Clinical – II

PA 3.09-1

Re-evaluation of sequence variation in type 1 von Willebrand disease in the MCMDM-1VWD cohort

Goodeve AC[1], Hampshire D[1], Batlle J[2], Budde U[3], Castaman G[4], Eikenboom HCJ[5], Federici AB[6], Schneppenheim R[7] and Peake IR[1]

[1]University of Sheffield, Sheffield, UK; [2]Hospital Teresa Herrera, La Coruna, Spain; [3]Asklepios Klinik Altona, Hamburg, Germany; [4]San Bortolo Hospital, Vicenza, Italy; [5]Leiden University Medical Center, Leiden, The Netherlands; [6]Universita' degli Studi di Milano, Milano, Italy; [7]University Medical Centre Hamburg-Eppendorf, Hamburg, Germany

Background: The MCMDM-1VWD study investigated involvement of the von Willebrand factor (*VWF*) gene in the pathogenesis of type 1 von Willebrand disease (VWD1). Previously published mutation analysis on index cases (IC) (Goodeve et al, Blood 2007;109:112) identified 124 candidate mutations in 105 IC (70%), with 87 IC having one mutation, 17 having two and one having three mutations.

Aims: (i) To use current technology to seek further candidate mutations in IC. (ii) To re-evaluate the cohort in light of current knowledge of *VWF* sequence variation.

Methods: Samples from 150 IC with a historic VWD1 diagnosis along with their affected and unaffected family members were available. *VWF* PCR primers were redesigned where necessary to eliminate single nucleotide polymorphisms within their sequence. Twenty-eight IC in whom candidate point mutation(s) had potentially been missed in previous analysis were PCR amplified and sequenced. Exon deletions/duplication were sought in 104 IC using multiplex-ligation dependent probe amplification. One thousand genomes and African-American/white American VWF sequence variant data was compared with candidate mutations (Wang et al JTH 2012 doi: 10.1111/jth.12093; Bellissimo et al Blood 2012;119:2135). Data was available on bleeding score (BS), linkage analysis and multimeric profile along with several phenotypic parameters.

Results: Among 150 IC, an additional 11 candidate mutations were identified; five through sequence analysis (two splice, two missense, one silent) plus six large deletions (exons 3, 33–34, 32–34; 1 IC each and exons 4–5; 3 IC). Comparison of candidate mutations in IC with published sequence variant data plus pedigree inheritance suggested that candidate mutations in 7 IC; p.M740I, p.P2063S, p.P2145S, p.R2313H and p.R2663P were likely polymorphic. Previously identified variants in the *VWF* promoter were also discounted ($n = 8$). Following re-evaluation, 119 candidate mutations were present in 106 IC (71%), with 93 IC having one mutation and 13 having two mutations (10 compound heterozygotes, three allelic mutations). Previous multimer analysis identified slight multimer abnormalities (AbM) in57 IC. Mutations were identified between exons 24–45 in all these 57 IC and 34 mutations (60%) were fully penetrant. IC were divided into four groups based on 20 IU/dL VWF:RCo increments. Among 48 IC with ≤ 20 IU/dL VWF:RCo, 98% had a mutation identified and 88% had AbM; 63% families had fully penetrant mutations. Figures decreased to 81% with mutation(s) and 29% AbM among those with > 20–≤ 40 IU/dL VWF:RCo, 45% with mutation(s) and 2% AbM with > 40–≤ 60 IU/dL VWF:RCo, and 35% with mutation(s), 10% AbM with > 60 IU/dL VWF:RCo. Only 18% of IC with VWF:RCo > 40 IU/dL had fully penetrant mutations. Forty-four IC (29%) had no mutation identified. Among these, 30 IC were unlikely to have VWD1 as no *VWF* mutation was identified and linkage analysis did not support *VWF* gene involvement. Twenty-one of these IC had BS 3–19; VWF:Ag and VWF:RCo were both ≥ 40 IU/dL.

Conclusions: Further analysis of *VWF* sequence variation has enhanced understanding of VWD pathogenesis in the MCMDM-1VWD cohort. Patients diagnosed with VWD1, no *VWF* mutation but

high BS are likely misdiagnosed and further defects in for example, platelet function may be responsible and should be investigated.

PA 3.09-2

NHLBI guidelines and the percentile 2.5th of plasma VWF for the diagnosis of type 1 VWD. Comparison in 4517 referred patients and 280 selected patients with conclusive bleeding history

Quiroga T, Goycoolea M, Zuñiga P, Belmont S, Panes O, Pereira J and Mezzano D

Pontificia Universidad Catolica, Santiago, Chile

Background: Global consensus regarding laboratory criteria for diagnosing type 1 VWD are still lacking. The overlapping of lower cut-off values of plasma VWF between non-bleeder population and patients with pathologic bleeding, as well as the relative high frequency of bleeding symptoms in otherwise healthy individuals constitute major diagnostic difficulties. To transitorily circumvent this problem, the 2008 NHLBI Guidelines recommended diagnosing definitive VWD in patients with plasma VWF < 30 IU/dL and those patients with VWF levels between 30–50 IU/dL would be labeled as 'possible VWD' or 'low-VWF'. A recent survey found that only 27% of North American Laboratories followed the NHBLI guidelines. An alternative criterion is to use the 2.5th percentile of plasma VWF as cut-off value for the diagnosis of VWD, also including the VWF:CBA.

Aims: To analyze and compare the yield of both approaches to diagnose VWD.

Methods: We diagnose type 1 VWD when VWF is < 2.5th percentile in at least two of these three measurements: VWF:Ag, VWF:RCo and VWF:CBA, using cut-off values of < 42, < 37 and < 39 IU/dL, respectively, obtained from 299 non-bleeders healthy controls. Types 2 are diagnosed as usual (discrepant VWF antigen and function, RIPA, multimers..). We reviewed retrospectively 4517 patients tested in our Lab for diagnosis of VWD in a five-year period (2008–2012). They were referred by their physicians and we had no access to the bleeding history of most of them. Also, we compared these approaches in a different group of 280 selected patients interviewed by one of us (TQ) and judged as pathological bleeders, matched for age, gender and ABO blood type with the controls (Haematologica 2007;92:357)

Results: Applying NHLBI guidelines, a total of 158/4517 patients were diagnosed as VWD (3.5 ± 0.4% per year) and 802/4517 (17.9 ± 1.9% per year) were classified as Possible VWD, whereas using the percentile 2.5th criterion we diagnosed VWD in 312/4517 (6.9 ± 0.27% per year). In the selected 280 patients the NHLBI criterion diagnosed 39 (13.9%) and 67 (23.9%) of the patients as VWD and Possible VWD, respectively, whereas the percentile 2.5th criterion diagnosed VWD in 50 (17.9%) patients. Among the 299 Controls, 46 (15.4%) would have been considered as Possible VWD with NHLBI recommendations.

Conclusions: (i) Independent of the criterion, a very small proportion of the patients referred end up with VWD diagnosis. (ii) As expected, stringent clinical criteria to select patients for study increase the proportion of diagnosed patients. (iii) Patients considered Possible VWD are 5-fold more than those with Definitive VWD (NHLBI), and most of them have VWF in the range of 42–50 IU/dL, which is higher than the percentile 2.5th. This is why more than 15% of the non-bleeder Controls qualify as 'laboratory' Possible VWD. (iv) NHLBI Guidelines appear too restrictive and might miss the diagnosis of VWD in a significant proportion of patients. (v) Patients with type 1 VWD do not differ clinically from those with other Mild Bleeding Disorders; specific treatment for each disorder demands further refinement and universal consensus on the laboratory criteria for VWD diagnosis. (FONDECYT 1130853).

PA 3.09-3

Comparison of pediatric bleeding questionnaire (PBQ) and ISTH/SSC bleeding assesment tool (BAT) scores in pediatric patients referred with mucocutaneous bleeding

Labarque V[1], Blanchette VS[2], Clark DS[2], James PD[3] and Rand ML[2]

[1]UZ Leuven, Leuven, Belgium; [2]Hospital for Sick Children, Toronto, ON; [3]Queen's University, Kingston, ON, Canada

Background: The accurate assessment of hemorrhagic symptoms in pediatric subjects referred with mucocutaneous bleeding to determine the presence of an underlying bleeding disorder is essential, but can be difficult; epistaxis and bruising are common in childhood, and major hemostatic challenges may not yet have occurred. The PBQ, based on the MCMDM-1VWD Bleeding Questionnaire, incorporates pediatric-specific bleeding symptoms to quantify bleeding severity in children, scoring symptoms in a −1 to +4 range. An abnormal score has been determined to be ≥ 2 (Bowman et al, JTH 2009;7:1418). The ISTH/SSC BAT, in which bleeding symptoms are scored in a 0 to +4 range, has been developed to standardize reporting of bleeding symptoms in adults and children (Rodeghiero et al, JTH 2010;8:2063). Criteria for scoring each symptom are similar between the questionnaires, but differences exist.

Aim: To perform a detailed comparison between PBQ and ISTH/SSC BAT scores in a prospective study of children < 18 years of age referred to our tertiary-care Bleeding Disorders Clinic with mucocutaneous bleeding and/or a family history of von Willebrand disease or a platelet function disorder.

Methods: Bleeding scores were determined by face-to-face interview of 100 subjects/parents.

Results: The mean age of the study population was 9.7 years (range: 0.5–17.8 years), and 58% were female.

The median PBQ and ISTH/SSC BAT scores were 3, with ranges of 0–12 and 0–13, respectively. The two scores were identical in 52% of children. In the 25% of children with a lower ISTH/SSC BAT score, it was lower by 1 (in 92%) or 2 (in 8%), mainly due to a lower score for cutaneous bleeding symptoms. In the 23% of children with a higher ISTH/SSC BAT score, it was higher by 1 (70%), 2 (26%) or 3 (4%), mainly due to the lack of a −1 score for a child who did not bleed with at least two tooth extractions or surgeries and/or a higher score for menorrhagia.

Fifteen percent of children received scores for pediatric-specific symptoms, specifically macroscopic hematuria, post-circumcision bleeding, cephalohematoma, umbilical stump bleeding, post-venipuncture bleeding, or conjunctival hemorrhage. A normal PBQ score (i.e., 0 or 1) was observed in 11% of children. In these subjects, the ISTH/SSC BAT ranged from 0 to 3, with 5 children scoring 2 or 3.

Summary/Conclusions: In this population of children referred with mucocutaneous bleeding symptoms and/or a family history of a mucocutaneous bleeding disorder, PBQ and ISTH/SSC BAT scores were similar, but not identical. Although pediatric-bleeding symptoms have not been observed by others using the PBQ and/or ISTH/SSC BAT (Bowman et al. JTH 2009;7:1418; Bidlingmaier et al, JTH 2012;10:1335), they were reported in the present study, indicating that inclusion of these symptoms in the standardized questionnaires is important. Since many children with a normal PBQ score had an ISTH/SSC BAT score higher than the PBQ cut-off, it will be essential to determine the cut-off for a normal ISTH/SSC BAT bleeding score in pediatric subjects if it is to be adopted for general use in evaluating whether a child has an underlying bleeding disorder.

PA 3.09-4

Previously missed mutations in the MCMDM-1VWD type 1 von Willebrand disease study

Alyami NH[1], Hampshire D[1], Goudemand J[2], Castaman G[3], Federici AB[4], Cartwright A[1], Peake IR[1] and Goodeve AC[1]

[1]University of Sheffield, Sheffield, UK; [2]University of Lille, Lille, France; [3]San Bortolo Hospital, Vicenza; [4]Regina Elena and University of Milano, Milan, Italy

Introduction: Three studies conducted in Europe, the UK and Canada provided details about the molecular genetic basis of type 1 von Willebrand disease (VWD1), but failed to detect mutations involved in 30–40% of cases. Reasons for this failure may include SNP within primer annealing sites leading to lack of mutant allele amplification or insensitivity of mutation analysis methods. The EU study MCMDM-1VWD undertook mutation scanning and DNA sequencing of the von Willebrand factor (*VWF*) gene in 154 index cases (IC) with a historic diagnosis of VWD1 but failed to detect mutations in 30%.

Aim: (i) To reanalyse *VWF* in IC where phenotype suggested that mutations may have been missed. (ii) To determine mechanisms by which mutations identified affect VWF synthesis and secretion.

Methods: *In silico* analysis was performed to screen previously used MCMDM-1VWD PCR primers for presence of SNP within primer binding sites and when necessary new primers were designed. The 52 *VWF* exons and flanking regions were amplified and sequenced. Eighteen IC (four where a previously identified heterozygous mutation did not fully explain phenotype and 14 with no mutation identified) having low VWF levels and significant bleeding were investigated. Site-directed mutagenesis was used to create recombinant mutant cDNA expression vector, then transiently transfected into HEK293T cells. Media and cell lysates were analysed after 48 h for VWF:Ag by ELISA.

Result: Heterozygous mutations were identified in four families comprising missense mutations p.W2271G (in compound heterozygosity with p.R854Q) and p.C1157R (in compound heterozygosity with p.S539Lfs*38; IC subsequently classified as VWD3) silent mutation p.L1382 = and splice mutation c.1432+1G>T (in compound heterozygosity with p.R816W). p.W2271G and p.C1157R, predicted to be damaging by *in silico* analysis, affect fully conserved residues. Unlike p.R854Q and p.R816W, p.W2271G and c.1432+1G>T segregated with disease phenotype and their presence alone or in compound heterozygosity with p.R854Q (VWF:Ag 37–38 IU/dL, VWF:RCo 32–43 IU/dL, FVIII:C (p.[W2271G;R854Q]) 28–34 IU/dL, FVIII:C (p.W2271G) 85 IU/dL) and p.R816W (VWF:Ag 47–49 IU/dL, VWF:RCo 52–67 IU/dL, FVIII:C (c.1432+1G>T;p.R816W) 14 IU/dL, FVIII:C (c.1432+1G>T) 113 IU/dL) explain phenotype differences in the affected families. Expression studies of recombinant mutant VWF (rVWF_G2271 and rVWF_R1157) showed reduced secretion levels in the homozygous state ($P < 0.0001$) by 96.7% and 98.2% respectively compared to rVWF_wt with significantly increased intracellular retention (30%; $P = 0.03$ and 90%; $P < 0.0001$ respectively). In the heterozygous state, both also resulted in significantly reduced secretion ($P < 0.05$) by 77% and 55% respectively while intracellular retention was observed only in rVWF_R1157 by 47% ($P = 0.001$).

Conclusion: *In vitro* expression data indicates that mutations located within D3 and D4 domain can lead to intracellular retention. Mutations were missed due to insensitivity of mutation analysis method (p.W2271G) and SNP within primer annealing sites (p.C1157R and c.1432+1G>T). For the remaining IC, no mutations were found but presence of other genetic defects in deep intronic/regulatory *VWF* regions, intronic or non-coding copy number variation or mutation within other genes may influence disease phenotype.

PA 3.09-5

Molecular characterization of 14 italian patients with type 3 von Willebrand disease

Castaman G[1], Giacomelli S[1], Messina M[2], Rodorigo G[3], Rossetti G[4] and Linari S[5]

[1]San Bortolo Hospital, Vicenza; [2]Sant'Anna Hospital, Torino; [3]Sant'Orsola Hospital, Bologna; [4]Trento Hospital, Trento; [5]Careggi Hospital, Firenze, Italy

Background: Type 3 von Willebrand disease (VWD) is a rare autosomal recessive bleeding disorder characterized by a quantitative defect of the von Willebrand factor (VWF).The genetic analysis of type 3 is required to identify patients at possible risk of inhibitor occurrence in presence of homozygous partial or complete gene deletions.

Aim of the Study: We investigated the molecular basis of VWD in 14 patients affected by type 3 VWD, after carrying out the complete sequence of the VWF gene coding region.

Results: A causative mutation as identified in 27/28 disease-associated alleles. Six novel mutations and 10 already described were found. Six homozygous null mutations were found in eight patients: a splicing mutation in intron 13 (c.1534-3C>A); a novel insertion in exon 11 (c.1209insA, Y403 fs); a novel small deletion in exon 36 (c.6187DelC, P2063 fs); two nonsense mutations (Cys2533X and Gln2544X); finally a novel splicing mutation in intron 21 (c.2820+5G>C) that by *in vitro* analysis seems to reduce significantly the donor splice site score. One patient shows a novel homozygous missense variation (Cys2325Ser). Three other patients were compound heterozygous. One has two null mutations, Arg1659X and a novel small deletion in exon 28 (c.4470delC), which forms a premature stop codon 97 codons downstream. The second patient presents a c.4944delT and a splicing mutation in intron 18 (c.2443-1G>C). Finally one patient shows the Gln2544X mutation (already found in homozygosis) and a splicing variation in intron 15 (c.1946-4C>T). One patient shows three mutations: a deletion in exon 18 (c.2435DelC) in one allele, and the missense variation Ser85Pro together with a potential splice variation c.5170+10C>T in the other allele. Only in a single patient a single heterozygous mutation was found, a novel small deletion in exon 24 (c.3179delG) with creation of a premature stop codon 58 amino acids downstream; no other variations were found after complete sequencing of entire VWF coding region.

Conclusions: The molecular bases of type 3 VWD in Italy show a wide heterogeneity, at variance with what is observed in Great Britain or in North Europe where homozygous partial or complete gene deletions are rather common. mRNA studies are ongoing to verify the pathophysiological mechanisms associated with splicing mutations and to study the nonsense mediated mRNA Decay (NMD) process possibly associated with null mutations.

PA 3.09-6

Orthopaedic surgery in patients affected by von Willebrand disease and rare bleeding disorders

Siboni SM[1], Biguzzi E[2], Pasta G[3], Mistretta C[2], Solimeno LP[3] and Peyvandi F[4]

[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, University of Milan; [2]A Bianchi Bonomi, Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico; [3]Ortho-Trauma Unit, Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico; [4]Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, University of Milan, Milan, Italy

Background: Patients affected by VWD and severe RBDs may suffer from disabling chronic arthropathy as a consequence of recurrent intra-articular bleeding or may require orthopaedic surgery independently of their coagulation disorder. Orthopaedic surgery in patients with clotting disorders represents a surgical challenge and information

regarding the management of orthopaedic surgery in such patients are limited.

Aim: Description of orthopaedic surgery management in patients affected by VWD or RBDs.

Methods: Retrospective data collection regarding orthopaedic surgery between January 1981 and November 2012. Seventy-one procedures were made in 48 patients affected by VWD (25 patients) or RBDs (23 patients). In RBDs patients, the classification in severe, moderate or mild factor deficiency was defined on the basis of RBDs project [JTH 2012].

Results: Of the 71 orthopaedic procedures, 12 were minor surgery (seven hand surgery, five others) and 59 were major surgeries (19 arthroprosthesis, 19 arthroscopic procedures, 21 others procedures). The median age of the patients at surgery was 47 years (range: 10–78) and the median follow-up time was 37 months (range: 1–384). The most frequent RBDs were FVII (11/22) and FXI (7/22) deficiency. Sixty procedures were performed using replacement therapy (RBDs: 16 severe, two moderate, three mild; VWD: eight type 1, eight type 2, seven type 3, two AWVS), replacement therapy and desmopressin (three severe RBDs, one AVWS), desmopressin (VWD: five type 1 and two type 2), tranexamic acid (RBDs: three mild and 1 severe). Eight procedures (seven mild RBDs, one VWD type 1) were performed without prophylaxis, with a bleeding complication reported in one case of mild FVII deficiency that required treatment with replacement therapy after surgery. Bleeding complications occurred in five more procedures (overall 8%): three patients affected by VWD (one type 1, one type 2 and one AVWS), one patient affected by severe FVII deficiency and one patient affected by moderate FXI deficiency. In two cases (VWD type 1 and AVWS) the bleeding complication was associated with low molecular weight heparin (LMWH), started 12 h after surgery. In one patient affected by type 3 VWD, the presence of anti-VWF inhibitor was diagnosed after surgery (ankle arthroscopy). This patient was treated with high dosage and frequent administration of FVIII/VWF concentrate (70–90 U/kg every 6–8 h), with no bleeding complications. Post-operative rehabilitation was started immediately after surgery, when indicated, with anti-haemorrhagic prophylactic treatment in patients affected by severe/moderate deficiencies. No late bleeding problems were recorded. Only three patients received prophylaxis with LMWH.

Conclusion: Good control of haemostasis can be achieved with an appropriate substitutive therapy in severe bleeding disorders. In mild deficiency replacement therapy can be avoided before surgery in some cases, but needs to be available and used in case of excessive bleeding. The control of the bleeding disorder combined with the surgical technique is the reason for a high success rate. Post-operative rehabilitation begins immediately after surgery under treatment coverage when indicated. In conclusion, orthopaedic surgery performed in a specialised haemophiliac centre by a highly experienced surgeon is a safe procedure.

DATA III survey. Ten-year follow-up on Dutch orthopedic thromboprophylaxis

Struijk-Mulder MC[1], Ettema HB[1], Büller HR[2] and Verheyen CPM[1]
[1]*Isala Clinics, Zwolle;* [2]*Academic Medical Centre, Amsterdam, The Netherlands*

Background: Our two previous surveys in the Netherlands have revealed that guidelines regarding orthopedic thromboprophylaxis were not followed and that a wide variation in protocols exists.

Aims: The DATA III survey (Dutch Antithrombotic Treatment for Arthroplasties) was performed to assess the current use of thromboprophylactic modalities and to compare it with the results of two previous surveys and with national guidelines.

Methods: All departments of orthopedic surgery in the Netherlands were sent a follow-up survey on venous thromboprophylaxis, and the data obtained were compared to the results of two surveys performed 5 and 10 years earlier.

Results: The response rate was 94 out of 108 departments (87%). All used pharmacological thromboprophylaxis following arthroplasties of the hip and knee. Low molecular weight heparin (LMWH) was used most frequently (77% of the departments), followed by rivaroxaban (15%), fondaparinux (6%), Vitamin K Antagonists (VKA) (6%), the combined use of VKA and LMWH (5%) and dabigatran (3%). Ten years earlier, VKA treatment was the predominant prophylaxis (79%). All departments prescribed pharmacological prophylaxis after femoral and tibia fractures during admission. Ninety percent of the departments used LMWH. Prophylaxis was continued for 6 weeks in 78% of cases. Only two departments did not use extended prophylaxis after hip fracture surgery and in one department, no extended prophylaxis after proximal knee fracture surgery was given. After hip and knee arthroplasty, LMWH treatment was initiated on the day before surgery in 21% of cases (compared to 65% 10 years ago), perioperatively in 57%, and in the evening following surgery in 22%.

In general, for daycare surgery and arthroscopies either no prophylaxis was given (68% and 56% respectively) or a single shot of LMWH. After anterior cruciate ligament reconstruction, 89% of the departments used prophylaxis. Twenty-nine percent administered prophylaxis once or during admission, whereas 71% used extended prophylaxis, varying from 10 until 42 days.

During plaster cast immobilization, more departments used thromboprophylaxis nowadays. Patients treated with a below knee plaster cast, received thromboprophylaxis in 88% of the departments (compared to 50% 10 years ago). Thirty-three percent of the departments only used thromboprophylaxis when the patient is not allowed to bear weight on the below knee plaster cast. Patient with a plaster cast above the knee were given thromboprophylaxis in 96% of cases. Prophylaxis was most frequently given by means of LMWH. VKA are not used nowadays, in contrast to 2002, when 68% of the departments used VKA for this indication.

Summary/Conclusions: The use of pharmacological prophylaxis after arthroplasty of the hip and knee and also after fracture surgery around the hip and knee is common practice in the Netherlands. Five years ago, the widely used VKA had been largely replaced with LMWH. In 2012 low molecular weight heparin remains the most commonly used thromboprophylactic agent. The new oral anticoagulant rivaroxaban is used more frequently than fondaparinux after hip and knee arthroplasty. There is a significant increase in the use of thromboprophylaxis during below knee plaster cast immobilization. In general, national guidelines are properly adhered to.

PA 3.10-2

First year experience with the German external quality assessment scheme for the new oral anticoagulants (INSTAND e.V.)

Peetz D[1], Dick A[2], Lodemann P[1] and Spannagl M[2]
[1]*Helios Klinikum Berlin-Buch, Berlin;* [2]*INSTAND e.V., Düsseldorf, Germany*

Background: The new oral anticoagulants (NOAC) dabigatran and rivaroxaban are assigned for use without laboratory monitoring. However, in clinical situations as (major) bleeding events or renal failure drug monitoring might be required. Especially for dabigatran, the manufacturer recommends specific drug level monitoring in situations with an assumed bleeding risk.

Aims: An external quality assessment scheme (EQAS) of the German proficiency testing organization INSTAND e.V. was established in 2012 to investigate the suitability of different monitoring methods for dabigatran and rivaroxaban.

Methods: In two trials in May and October 2012 lyophilized and stabilized plasma samples containing two concentration levels of dabigatran and rivaroxaban, respectively, were sent to the participants.

Overall 38 laboratories participated with eight different methods for dabigatran monitoring and 34 laboratories with seven different methods for rivaroxaban monitoring. Target levels were 0.12 and 0.30 mg/L for the dabigatran samples and 0.05 and 0.25 mg/L for the rivaroxaban samples, respectively.

Results: The same samples were used for the two trials to test reproducibility. Results are shown as: (all samples/results of first trial/results of second trial).

Dabigatran level 1 samples showed the following results mean ± SD (0.12 ± 0.026/0.12 ± 0.019/0.12 ± 0.032), coefficient of variation, CV (22.1%/15.9%/27.1%), median (0.11/0.11/0.11), interquartile range, IQR (0.10–0.12/0.11–0.12/0.10–0.13), min-max (0.08–0.23/0.08–0.18/0.08–0.23) and level 2 samples: mean ± SD (0.31 ± 0.041/0.32 ± 0.040/0.30 ± 0.042), CV (13.3%/12.6%/13.9%), median (0.31/0.31/0.30), IQR (0.28–0.33/0.30–0.33/0.28–0.33), and min-max (0.23–0.45/0.25–0.45/0.23–0.43).

Rivaroxaban level 1 samples: mean ± SD (0.10 ± 0.014/0.10 ± 0.016/0.10 ± 0.013), CV (14.4%/16.3%/13.2%), median (0.10/0.09/0.10), IQR (0.09–0.10/0.09–0.10/0.09–0.10), min-max (0.06–0.14/0.06–0.14/0.06–0.14), and level 2 samples: mean ± SD (0.28 ± 0.035/0.28 ± 0.048/0.29 ± 0.022), CV (12.4%/17.2%/7.6%), median (0.29/0.29/0.29), interquartil rage (0.27–0.30/0.27–0.31/0.27–0.30), and min-max (0.14–0.34/0.14–0.34/0.25–0.34).

Summary: Accuracy, precision and reproducibility in this first German NOAC EQAS were better than expected as most of the participants just established their assays and several different (new) methods were used. Calibration of the dabigatran methods seems to be slightly better than calibration of the rivaroxaban methods as target values were very good reproduced in both sample levels with the dabigatran methods. Overall, available methods for measurement of plasma concentrations of the new oral anticoagulants are suitable for drug monitoring purposes.

PA 3.10-3

Case fatality of antithrombotic therapy associated major bleeding or major trauma

Coppens M[1], Douketis JD[2], Mathew J[2], Da Fonte D[2], Hanif H[2], Heddle N[2] and Eikelboom JW[2]

[1]Academic Medical Center, Amsterdam, The Netherlands; [2]McMaster University, Hamilton, ON, Canada

Background: Antithrombotic therapy (antiplatelet drugs [AP] and oral anticoagulants[OAC]) is associated with an increased incidence of haemorrhagic complications. The outcome of bleeding complications is equally important as the incidence itself. With the introduction of new oral anticoagulants the outcome may become even more important as these new drugs do not have a specific agent that can restore normal haemostasis in case of life-threatening bleeding. Most available data on the impact of bleeding is derived from large randomized trials. It is uncertain to what extent these data apply to real-world patients who generally have more pre-existent comorbidities than a standard trial population.

Aims: To compare the outcome of bleeding complications in real-world patients treated with oral anticoagulants, antiplatelet drugs or both.

Methods: The medical records of all patients admitted to three academic hospitals in Ontario, Canada with major bleeding (selected with ICD-10 codes) or major trauma (injury severity score of 12 or higher) between October 2010 and March 2012 were reviewed. Transfers from community hospitals were excluded. Patients were divided into groups according to pre-admission antithrombotic therapy: OAC only, AP only, and combined OAC and AP therapy. Primary outcome was in-hospital mortality for all patients and for subgroups of type of admission (intracranial haemorrhage [ICH], gastro-intestinal [GI] bleeding, or major trauma). Secondary outcomes were length of hospital stay and transfusion requirements.

Results: Of 1834 screened patients, 289 were eligible and included in the analysis (mean age 76 years, mean duration of admission 12 days, SD 21 days): 74 were treated with OAC only (group 1; 70 patients used vitamin K antagonists [VKA], three used dabigatran etexilate), 180 were treated with AP only (group 2), and 35 received combined OAC and AP therapy (group 3; 34 VKA, 1 dabigatran etexilate). The proportions of patients admitted with spontaneous ICH, GI bleeding and major trauma were 18%, 41% and 27% in group 1, 11%, 57% and 32% in group 2, and 14%, 60% and 26% in group 3. The case-fatality rate for groups 1, 2, and 3 respectively were 28%, 8% and 17% for all patients combined ($P < 0.001$), 69%, 30% and 40% for spontaneous ICH ($P = 0.08$), 3%, 2% and 10% for GI bleeds ($P = 0.21$), and 41%, 10% and 22% for patients with major trauma ($P = 0.005$). None of the patients treated with dabigatran etexilate died. There were no differences in the duration of admission between groups. Erythrocyte transfusion was given in 47%, 57% and 69% of patients in groups 1, 2 and 3 respectively ($P = 0.02$). In patients treated with VKA, 41% of patients received prothrombin complex concentrate (PCC) and 59% of patients received either PCC or fresh frozen plasma.

Conclusions: The case-fatality rate of haemorrhagic complications associated with oral anticoagulants seems higher for real-world patients treated with oral anticoagulants than for patients treated with antiplatelet therapy only. The number of patients treated with dabigatran etexilate was too small to draw any conclusions.

PA 3.10-4

Tissue factor-induced hypercoagulability in rats is increased by low doses of the direct thrombin inhibitor dabigatran but decreased by the factor Xa inhibitor rivaroxaban

Perzborn E[1], Heitmeier S[2], Buetehorn U[3] and Volker L[2]

[1]Formerly Global Drug Discovery, Bayer Pharma AG; [2]Global Drug Discovery Bayer Pharma AG; [3]Bioanalytics, Bayer Pharma AG, Wuppertal, Germany

Background: Hypercoagulability has been reported with low doses of the direct thrombin inhibitor melagatran in preclinical studies. Melagatran increased thrombin generation in human plasma *in vitro* and aggravated disseminated intravascular coagulation at low plasma concentrations *in vivo* in rats. This phenomenon was not observed with the direct Factor Xa inhibitors DX-9065a or edoxaban.

Aims: The purpose of this study was to compare the effects of rivaroxaban – a direct Factor Xa inhibitor, with those of dabigatran – a direct thrombin inhibitor, in a rat model of tissue factor (TF)-induced hypercoagulability by measuring thrombin-antithrombin (TAT) and fibrinogen levels.

Methods: Fasted male Wistar rats were anaesthetized and received intravenous rivaroxaban (0.0009–0.9 mg/kg) or dabigatran (0.001–1.0 mg/kg), or the appropriate vehicle. Disseminated intravascular coagulation was induced by TF. TF (RecombiPlasTin, Instrumentation Laboratory; 8 mg/kg) or vehicle was given at 0.3 mL/min as an intravenous bolus 5 min later; a control sham group received appropriate vehicle only. Blood was withdrawn 10 min later by puncture of the abdominal aorta for the measurement of TAT and fibrinogen levels using ELISA kits (Enzygnost, Dade Behring, and Rat Fibrinogen Elisa, Immunology Consultants Laboratory, respectively), and the plasma levels of rivaroxaban and dabigatran were determined by liquid chromatography-tandem mass spectrometry.

Results: Rivaroxaban dose-dependently inhibited TF-induced TAT generation over the dose range of 0.009–0.9 mg/kg (corresponding to plasma levels of 24–1952 μg/L) compared with the TF-control group. Rivaroxaban normalized TAT generation completely at a dose of 0.27 mg/kg (481 ± 21 μg/L) from 133 ± 6 to 21 ± 1 μg/mL ($P < 0.001$) but did not affect TAT generation at lower doses (0.0009–0.0027 mg/kg; 4–14 μg/L). Rivaroxaban had no effect on plasma

fibrinogen levels at any dose tested. At a dabigatran dose of 0.3 mg/kg (390 ± 23 μg/L), TF-induced TAT generation was completely normalized to 31 ± 2 μg/L ($P < 0.001$). In contrast, dabigatran potentiated TF-induced TAT generation at low doses. TAT increased to 144 ± 12 μg/L at a dabigatran dose of 0.01 mg/kg (< 25 μg/L) and to 133 ± 10 μg/L at 0.03 mg/kg (40 ± 3 μg/L), compared with 105 ± 7 μg/L in the TF-control group ($P < 0.01$, $P > 0.05$, respectively). Similarly, plasma fibrinogen levels were significantly reduced by 0.01 and 0.03 mg/kg dabigatran from 2.4 ± 0.1 to 1.9 ± 0.1 g/L ($P < 0.05$).

Conclusions: Both rivaroxaban and dabigatran potently reduced TF-induced hypercoagulation in this rat model. However, direct thrombin inhibition with dabigatran increased hypercoagulability at low plasma concentrations (which was not seen with rivaroxaban). These results are consistent with the findings in previous studies comparing the direct thrombin inhibitor melagatran and the direct Factor Xa inhibitors DX-9065a and edoxaban.

PA 3.10-5

Relative lack of effect of steady-state erythromycin on the pharmacokinetics and pharmacodynamics of a single dose of rivaroxaban in subjects with renal impairment or with normal renal function

Moore T[1], Vaidyanathan S[2], Natarajan J[1], Ariyawansa J[1], Turner KC[1] and Haskell L[1]

[1]Janssen Pharmaceutical Research & Development LLC; [2]Janssen Research and Development LLC, Raritan, NJ, USA

Background: Rivaroxaban is eliminated through renal excretion and drug metabolism, with cytochrome P450 (CYP) 3A4 enzymes and P-glycoprotein (P-gp) transporters both playing significant roles. Separate assessments of renal impairment (RI) and concomitant administration of erythromycin (a moderate inhibitor of CYP 3A4 and P-gp) have shown that each, individually, can result in increases in rivaroxaban exposure. Although these individual increases were not considered clinically relevant, the previous studies did not discount the potential for a complex drug-drug and disease interaction that, in theory, may lead to a synergistic increase in exposure to rivaroxaban as suggested previously in a physiologically-based pharmacokinetic (PK) model from the FDA.

Aims: The aim of this study was to investigate the PK and pharmacodynamics (PD) of rivaroxaban when co-administered with steady-state (SS) erythromycin in subjects with mild/moderate RI relative to subjects with normal renal function (NRF).

Methods: The PK and PD of rivaroxaban were assessed in subjects with NRF ($n = 8$), mild RI ($n = 8$) or moderate RI ($n = 8$) who were otherwise healthy, after a single 10 mg dose of rivaroxaban either alone or with SS erythromycin (i.e. after 5 days of a 500 mg three-times-daily regimen).

Results: Rivaroxaban t_{max} and $t_{½}$ were similar between renal function groups and treatments; C_{max} was reached 2–4 h post-administration, and elimination half-lives ranged between 7.4 and 10 h in all groups. When assessing the effects of RI, administration of rivaroxaban 10 mg to subjects with mild/moderate RI increased rivaroxaban C_{max} by 23% and 36%, and AUC_{∞} by 15% and 17%, respectively, relative to subjects with NRF. When assessing the effects of erythromycin, co-administration of rivaroxaban 10 mg with SS erythromycin to subjects with NRF increased rivaroxaban C_{max} by 40% and AUC_{∞} by 39%. When assessing the effects of RI plus erythromycin, co-administration of rivaroxaban 10 mg with SS erythromycin in subjects with mild/moderate RI increased rivaroxaban C_{max} by 56% and 64%, and AUC_{∞} by 76% and 99%, respectively, relative to subjects with NRF. Changes in PD parameters displayed similar trends to those seen for PK. RI and concomitant erythromycin use had generally similar independent effects on Factor Xa inhibition and prothrombin time prolongation. When RI and erythromycin use were combined, the effects on Factor Xa inhibition and prothrombin time prolongation were approximately additive in most cases. No serious adverse events occurred during the study and no subjects reported persistent adverse events at the end of the study or at the time of the last follow-up visit.

Summary/Conclusions: Considered separately, RI and erythromycin co-administration each increased rivaroxaban PK and PD as expected. When the effects of RI and erythromycin were combined, approximately additive effects on PK and PD were observed, in contrast to the synergistic effect predicted in the previous model. These data suggest that clinically relevant interactions of rivaroxaban with erythromycin in patients with mild to moderate RI are unlikely. All treatments in all renal function groups examined were well tolerated, and no new safety concerns were identified.

PA 3.10-6

Effects of rivaroxaban and dabigatran on hemostasis and reversion of their antithrombotic effects by different coagulation factors: evidence raised from a clinical study in healthy volunteers

Galan AM[1], Arellano-Rodrigo E[1], Sanz V[1], Molina P[1], Reverter JC[1], Villalta J[2], Carne X[2], Diaz-Ricart M[1] and Escolar G[1]

[1]Hospital Clinic, IDIBAPS; [2]Hospital Clinic, Barcelona, Spain

Background: There is a lack of information on therapies that could reverse the effects of new oral anticoagulants in patients that require an urgent restoration of their impaired hemostatic mechanisms.

Aims: (i) To assess the effects of new oral anticoagulants rivaroxaban and dabigatran on hemostasis, and (ii) To evaluate the effects of different coagulation factor concentrates (prothrombin complex concentrates (PCCs), activated PCCs (aPCCs) and rFVIIa) to reverse the alterations of hemostasis induced by these new anticoagulants.

Methods: The study was approved by our institutional medical ethics committee (Eudra CT2010-022985-29; ClinicalTrials.gov Identifier: NCT01478282). Studies were performed using blood samples from 10 healthy individuals subjected to 5 days of treatments with 20 mg/day for rivaroxaban and 150 mg/12 h for dabigatran doses separated by a washout period of 14 days. Blood samples were spiked *in vitro* with: a) PCCs (50 IU/kg); b) aPCCs at 75 IU/kg, or c) rFVIIa at 270 μg/kg. Several laboratory approaches were applied to explore modifications on overall hemostasis including: (i) thrombin generation (TG), (ii) thromboelastometry parameters (TEM), (iii) standard coagulation parameters, and (iv) studies under flow conditions to evaluate modifications on platelets and fibrin deposition on damaged subendothelial surfaces.

Results: Rivaroxaban and dabigatran treatments resulted in alterations of the different laboratory tests related to their recognized anticoagulant action. Standard coagulation parameters (PT, INR and APTT) were variably affected by rivaroxaban and dabigatran. aPCCs and rFVIIa totally reversed the effects of rivaroxaban on these routine tests, whereas only aPCC were capable to reverse partially the effects of dabigatran on APTT. Rivaroxaban and dabigatran caused alterations of TG with delayed time to peak, reduced maximum thrombin peak and decreased velocity index ($P < 0.05$), though alterations in TG were clearly dependent on the reagents used for activation. Modifications in TG caused by rivaroxaban were corrected by the different coagulation factors with efficacies following this order aPCC>rFVIIa = PCC. Reversion of alterations in TG after dabigatran were accomplished according to the following order of efficacy aPCC = PCC>rFVIIa. Clot viscoelastic parameters (TEM) were significantly altered by rivaroxaban or dabigatran treatments. While all concentrates (rFVIIa, aPCC and PCC) were able to reverse the effects of rivaroxaban ($P < 0.05$) on this test, only aPCCs seemed effective at reversing alterations induced by dabigatran ($P < 0.05$). Treatment with rivaroxaban or dabigatran did not cause marked alterations on platelet reactivity towards damaged vascular surfaces, but both anticoagulants demonstrated a consistent effect decreasing fibrin formation

on the subendothelium ($P < 0.01$). Reductions in fibrin formation observed after rivaroxaban were significantly improved ($P < 0.01$) by rFVIIa and aPCC, whereas alterations in fibrin formation following dabigatran treatment were only reversed by aPCCs ($P < 0.05$).
Conclusions: Reversal strategies may differ depending on the new anticoagulant agent and its specific mechanism of action. Our results indicate that while alterations in hemostasis induced by rivaroxaban were reversed to a variable extent by all the concentrates tested, reversion of dabigatran actions were predominantly achieved with aPCCs. Finally, TEM technologies may be useful as a point of care for a rapid evaluation of effects of new anticoagulants.

Capillary electrophoresis improves the selection of DNA-aptamers against activated coagulation factors

Müller J[1], Krammer R[1], Shahidi N[1], Blümke F[1], Rudan O[1], Oldenburg J[1], Mayer G[2] and Pötzsch B[1]
[1]University of Bonn Medical Center; [2]University of Bonn, Bonn, Germany

Background: The development of enzyme-capture assays for direct measurement of activated coagulation factors in plasma samples requires enzyme-specific ligands that bind their targets with high affinity even in complex matrices. Due to their high affinity and specificity, DNA-aptamers, proved to be valuable tools for the development of such assays (Angew Chem Int Ed Engl. 2011; 50: 6075–8; J Thromb Haemost. 2012; 10: 390–8).
Aims: The aim of this study was to establish a highly efficient method based on capillary electrophoresis (CE) for the separation of unbound ssDNA from protein targets to expedite the selection of DNA-aptamers against activated coagulation factors.
Methods: A PA800 CE-System and silica-fused capillaries (Beckman Coulter) were used for all experiments. The system was run in normal polarity under electroosmotic flow (EOF). The used ssDNA-pool comprised a randomized region of 40 nucleotides at a total length of 81 nucleotides. For initial assay optimization, activated protein C (APC) and activated factor XIIIA (FXIIIAa) were chosen as targets. Binding affinities of selected aptamers were assessed by filter retention analysis.
Results: After optimization of system settings and buffer conditions, the retention time of the random library was found to be at least two times longer than that of the target proteins. Thus, the protein fraction, also containing bound aptamers, could be collected separately. In total, six selection cycles, including (i) incubation of ssDNA with target, (ii) CE for separation, (iii) amplification of selected sequences, (iv) single-strand separation for next round, were performed for both targets. In both cases, highest binding affinity of enriched pools was found after only five rounds of selection (Kd: APC: approximately 10 nM; FXIIIAa: approximately 30 nM).
Summary/Conclusions: The use of CE for the selection of DNA-aptamers targeting activated coagulation factors was successfully established. In comparison to previously applied methods for aptamer-selection, the CE-based method described here proved to be more efficient, resulting in a decrease of needed selection cycles by a factor of 2. The future goal is to apply this method for the identification of a variety of ligands against activated coagulation factors.

PA 3.11-2

Endogenous thrombin potential measured in the presence of thrombomodulin as a tool in prediction of thombotic events

Shmeleva V, Namestnikov Y, Matvienko O, Saltikova N, Soldatenkov V and Papayan L
Russian Research Institute of Hematology and Transfusion, St-Petersburg, Russian Federation

The Calibrated Automated Thrombogram (CAT) could be more effective in assessing thrombotic risk than standard coagulation tests, but clinical experience in this field is insufficient and association between the endogenous thrombin potential (ETP) and phenotype remains to be established. Predictive values of ETP obtained in the presence and in the absence of thrombomodulin (TM) may differ. Aim of our study was to assess the relationship between venous thromboembolism (VTE) recurrence and ETP measured by CAT with and without adding TM. The study involved 48 VTE patients on VKA in the extended-treatment phase (M/F 24/24, mean age 54.6 VTE ± 15.8 years, duration of VKA 1.5–4 years), among them 19 patients at low intensity treatment i.e. international normalized ratio (INR) 1.5–1.9; 15 patients with therapeutic INR range of 2.0–3.0 and 14 patients on gradual discontinuation of VKA therapy with INR 0.9–1.4. The last subgroup was followed up for 18 months. Control group ($n = 28$) was age matched. ETP was measured according to Hemker et al., 5 pmol concentration of tissue factor was used. STATISTICA 6.1 was used, data are given as mean ± SD. In controls ETP was 1731.4 ± 253.7 nM/min without added TM and 932.8 ± 272.6 nM/min with TM. Two-fold significant ($P < 0.001$) decrease of ETP compared to controls was measured even in patients with INR 1.5–1.9: 642.8 ± 129.7 nM/min in the absence of TM and 481.2 ± 106.8 nM/min in the presence of TM. In patients with INR 2.0–3.0 the corresponding parameters were 358.1 ± 210.4 nM/min and 293.2 ± 167.4 nM/min respectively. ETP in patients with INR 0.9–1.4 was much less decreased compared to the above mentioned subgroups of patients, and significantly differed from controls only when measured without TM (1487.4 ± 425.3 vs. 1731.4 ± 253.7 nM/min, $P = 0.02$). In the presence of TM ETP was 896.9 ± 296.0 vs. 932.8 ± 272.6 nM/min in controls, $P = 0.6$. Increased ETP was defined as > 2114 nM/min without TM and > 1433 nM/min with TM (i.e. above 95th percentile in controls). Two patients from the subroup with INR 0.9–1.4 had abnormal values of ETP. In one case increased ETP in the absence of TM (2257 nM/min) was accompanied by normal result (1210 nM/min) in the presence of TM, so VKA's therapy was discontinuated and during the following 18 months of observation patient had not recurrent thrombosis. In the other patient with ETP 2343 nM/min in the absence of TM and importantly 1603 nM/min in the presence of TM (i.e. both above 95th percentile measured in controls) thrombosis took place 12 months later in spite of prolonged VKA therapy. We conclude that though ETP determined without TM demonstrate strong positive correlation with the ETP obtained with adding of TM ($R = 0.93$, $P < 0.001$), the last one seems to be more sensible in detecting a degree of hypercoagulobility that predicts thombotic event. Our data suggest that CAT may allow individualized treatment based on global haemostatic response in patients on VKA, but predicting clinical events with the help of ETP needs further elucidation.

PA 3.11-3

Evaluation of the performance characteristics of a diluted thrombin time assay for dabigatran determination using a new thrombin time liquid reagent

Camacho E, Bono M and Martorell D
Diagnostic Grifols, Parets del Vallés, Spain

Background: DG-TT L Human is a new ready-to-use liquid reagent developed by Grifols, consisting of human thrombin for thrombin time (TT) determination in citrated human plasma samples. Additionally, the reagent DG-TT L Human may be used in a quantitative assay for dabigatran determination in samples from patients treated with the new oral anticoagulant dabigatran etexilate. This assay consists in the addition of the thrombin reagent to a plasma sample that has been previously diluted in a buffer and supplemented with normal lyophilized plasma (DG-Ref, Grifols) to normalize fibrinogen. Results are not interfered by the presence of heparins in plasma samples. Calibrator plasmas with known dabigatran concentrations are used to construct a four point calibration curve that allows the calculation of the dabigatran concentration present in a sample.
Aims: The aim of this study is to evaluate the performance of a procedure for dabigatran quantification with a new thrombin time liquid reagent.
Methods: Tests were performed in the optical coagulometer Q Hemostasis Analyzer (Grifols). A precision study was performed over 10 days using plasma containing two different levels of dabigatran (110 and 310 ng/mL). Linearity and limits of detection and quantification of the assay were determined using dabigatran calibrator and control plasmas from Hyphen Biomed. Accuracy was estimated at two different concentrations of dabigatran (130 and 320 ng/mL). The performance of the assay was tested using samples from patients treated with dabigatran ($n = 60$, collected at different time points of treatment). Results with the new assay were compared with the data obtained with the commercially available kit Hemoclot Thrombin Inhibitors (Hyphen).
Results: Precision results showed appropriate coefficients of variation (CV) of 9.34% and 4.70%, for dabigatran concentrations of 110 and 310 ng/mL respectively. The accuracy was satisfactory at the dabigatran concentrations tested (130 and 320 ng/mL, maximum bias of minus 2.6%). The assay measurement range obtained was from 30 to 760 ng/mL of dabigatran (usual plasma concentrations range between 20 and 400 ng/mL). In the method comparison study, the measurement limit of the new assay was taken into consideration and samples containing dabigatran concentrations lower than 30 ng/mL were not used for calculations. Good correlation of the new assay and the results obtained with the Hemoclot kit (30–328 ng/mL) was observed in this subset of samples ($y = 0.96x + 0.00$; $r = 0.90$) and no significant differences were observed in a Passing Bablok fit and a difference plot ($n = 26$; allowable bias of 20%). Comparison between methods in samples with dabigatran from 0 to 30 ng/mL ($n = 34$) showed a significant difference, as expected in samples with dabigatran levels under the measurement range of both assays.
Conclusion: The new DG-TT L Human is a reagent that allows both, thrombin time determination and dabigatran quantification when using a calibration curve with plasma containing dabitragan. This assay shows an adequate range of measurement and performance features comparable to the specific kit for dabigatran determination currently available in the market.

PA 3.11-4

A simplified assay for quantification of circulating activated protein C levels

Medina P, Navarro S, Bonet E, Martos L, Mira Y, Vayá A, Ferrando F, Aznar JA, Estellés A and España F
Hospital Universitario y Politécnico La Fe, Valencia, Spain

Background: The protein C pathway plays a crucial role in the regulation of blood coagulation, as it controls the generation of thrombin. Protein C circulates in plasma as an inactive zymogen and is activated on the vascular endothelial cell membrane by the thrombin-thrombomodulin complex, a process further enhanced when protein C binds to its membrane receptor, the endothelial-cell protein C receptor. Activated protein C (APC) is an enzyme with anticoagulant and cytoprotective functions. Accumulative data suggest that the number of situations in which *in vivo* circulating APC will need to be measured will increase over the next few years. Therefore, the availability of a rapid, sensitive and simple assay for quantifying circulating APC is crucial. Available assays are difficult to apply in routine laboratory. Our previously reported assay required an excessive pre-analytical handling: drawing of blood into two citrate tubes; immediate addition of a fresh APC inhibitor to one tube in order to block complexation of circulating APC to protein C inhibitor (PCI) (tube 1), and of heparin to the other tube to force all circulating APC to bind to PCI (tube 2), measurement of APC:PCI complexes in both tubes by ELISA, and subtraction of APC:PCI complexes (tube 2−tube 1) (method A).
Aims: To set up a simplified method based on the measurement of APC:PCI in a unique blood tube anticoagulated with heparin (method B).
Methods: We measured APC levels, with both methods, in 187 plasma samples, 117 from patients with venous thrombosis (VT) and 70 from healthy controls. Informed consent was obtained from all subjects of the study and it was approved by the medical ethics committee of our Institution.
Results: The mean APC level in the 125 samples was 1.09 ± 0.40 ng/mL (method A) and 2.07 ± 0.71 ng/mL (method B). The coefficient of correlation between both methods was $r = 0.789$ ($P < 0.001$). The mean APC level in the 117 VT patients was 0.95 ± 0.36 (method A) and 1.73 ± 0.55 (method B), significantly lower (as previously reported) than those in the 70 controls, 1.33 ± 0.36 and 2.64 ± 0.74, respectively, ($P < 0.001$). In both groups there was a significant correlation between the levels obtained by the two methods (VT, $r = 0.730$; controls, $r = 0.731$) ($P < 0.001$). Both Passing & Bablock regression and Bland & Altman plot analyses showed that both assays are equivalent.
Conclusions: These results confirm that the APC level is lower in VT patients than in healthy individuals. As both assays are equivalent, the new simplified assay, which measures the sum of circulating free APC and APC complexed to PCI, may be used to estimate the level of circulating APC, and will allow its use in routine laboratories.

PA 3.11-5

The use of the new Siemens Innovance VWF activity assay in monitoring treatment for von Willebrand disease

Bowyer AE, Shepherd M, Leeson K, Lowe A, Kitchen S and Makris M
Sheffield Teaching Hospitals, Sheffield, UK

Background: Von Willebrand disease (VWD) is caused by the dysfunction of, or reduction in concentration of, von Willebrand factor (VWF). An accurate measure of the functional activity of VWF is essential for both the classification of VWD and response following replacement VWF therapy. Traditional activity assays, utilising ristocetin, such as automated platelet aggregometry or manual visual agglutination (MVA) are laborious to perform and notoriously subject

to a high degree of assay variation. A new Siemens (Marburg, Germany) activity assay, Innovance VWF Activity, has recently been introduced which uses polystyrene particles coated with a monoclonal antibody against GP1b to bind to recombinant GP1b and the VWF in the test sample. Agglutination is measured turbidometrically.

Objectives: To evaluate the new automated Innovance VWF activity assay on the CS2100i analyser and compare it to the manual visual agglutination (MVA) assay in normal donors and VWD patients prior to and following treatment with DDAVP or VWF concentrates.

Results: Thirty-eight normal subjects (21 female and 17 male) were used to establish the reference range; all blood groups were included. The mean Innovance activity was 101 IU/dL (49–167 IU/dL) median 98 IU/dL, SD 0.30.

Inter and intra assay imprecision, at normal (88 IU/dL) and low levels (30 IU/dL) was < 2.7% and at very low levels (4 IU/dL) was 10%. The imprecision of our current MVA method is 7%.

Thirty-three patient samples were tested prior to and following treatment. Thirteen patients with type 1 VWD were treated with either DDAVP ($n = 12$) or Haemate P ($n = 1$). The mean activity prior to treatment was 29 IU/dL (median 27 IU/dL) for the MVA method and 34 IU/dL (median 37 IU/dL) for Innovance whilst following treatment was 112 and 136 IU/dL (medians 104 and 126 IU/dL) respectively.

Twenty patients with types 2 or 3 VWD were treated with DDAVP ($n = 4$), Haemate P ($n = 12$), Wilate ($n = 3$) or Alphanate ($n = 1$). The mean activity prior to treatment was 12 IU/dL (median 7 IU/dL) by the MVA method and 14 IU/dL (median 10 IU/dL) using Innovance and following treatment was 77 and 80 IU/dL (medians 77 and 81 IU/dL) respectively. Although no difference was found in normal subjects, a statistically significant difference between MVA and Innovance in pre treatment samples ($P < 0.05$) was observed due to some very low levels. Following treatment, the difference was not statistically significant ($P > 0.05$).

In type 1 VWD, with all treatment types, there was a mean 3.8 fold (median 3.9 fold) increase in MVA activity and 3.9 fold (median 3.4) increase for Innovance activity following treatment. In types 2 or 3 VWD with all treatment types, there was a mean 6.5 fold (median 11.8 fold) increase in MVA activity and 5.9 fold (median 8.1) increase in Innovance activity.

Conclusion: The Innovance activity assay is a rapid, easy to use automated test with improved imprecision compared to our manual VWF activity assay. The Innovance assay is suitable for monitoring treatment of both DDAVP and concentrates in patients with VWD.

PA 3.11-6
Effekt of rivaroxaban on clot formation kinetics

Siegemund T[1], Scholz U[2] and Siegemund A[2]
[1]*The Scripps Research Institute, La Jolla, CA, USA;* [2]*MVZ Labor Dr. Reising-Ackermann und Partner, Leipzig, Germany*

Background: Patients with thrombophilia show increased and accelerated thrombin formation. Antithrombotic therapy reduces thrombin generation or directly inhibits thrombin. Rivaroxaban, a direct fXa inhibitor, reduces the prothrombinase activity and subsequently thrombin generation velocity, expressed as peak. Thrombin generation assays are expensive and time consuming. Clot waveform analysis bases on an aPTT measurement, which is inexpensive, fast and fully automated. Using an optical detection system, the fibrin formation curve and its subsequent derivatives provide further information about the clot formation process.

Aim: The aim of the study was to investigate the effect of rivaroxaban on clot formation with different methods: in patients with thrombophilic conditions. The focus is laid on clot waveform analysis to investigate the kinetics of fibrin generation.

Methods: More than 200 patients with hereditary thrombophilia or pregnancy in comparison with non-pregnant healthy controls were included in the study after an informed consent was obtained. The effects of rivaroxaban were determined in plasma samples spiked with different amounts of the anticoagulant (between 0 and 500 nM) using thrombin generation assays ETP (Siemens Healthcare Diagnostics, Marburg, Germany) and Technothrombin TGA (Technoclone, Vienna, Austria). Clot waveform analysis is measured using an ACL TOP (Instrumentation Laboratory, Kirchheim, Germany), using a Synthasil-activated aPTT assay (Instrumentation Laboratory). Measured optical data were processed using the Savitzky-Golay algorithm. The concentration of rivaroxaban was determined using an anti Xa-assay.

Results: All used methods showed a clear dose-response relationship for rivaroxaban. Healthy controls needed less rivaroxaban to reduce thrombin generation than patients with thrombophilia or pregnancy. This difference increased with the severity of the underlying prothrombotic state. Nevertheless, rivaroxaban reduced thrombin formation significantly also for patients with extraordinary high thrombin generation.

The reduction of the prothrombinase activity can be observed using clot waveform analysis, and showed an almost linear relationship over the concentration range of the anticoagulant.

Conclusions: It is possible to estimate the amount of Rivaroxaban to reduce thrombin generation to a certain value. As expected from higher initial thrombin generation values, patients with thrombophilia or pregnancy need more fXa inhibitor to reduce TG compared to healthy controls. This effect was consistent using thrombin generation or clot waveform analysis. However, these estimations lie within clinically relevant rivaroxaban levels. Clot waveform analysis might emerge as a inexpensive und convenient alternative to thrombin generation measurements. The second derivative of the fibrin formation curve is a good measure for anti Xa activity.

PA3.12 – Blood Coagulation System – III

PA 3.12-1
Impact of BDNF Val66Met polymorphism on thrombosis

Barbieri SS[1], Amadio P[2], Gianellini S[1], Tarantino E[2], Banfi C[1], Lee FS[3] and Tremoli E[1]
[1]*Centro Cardiologico Monzino;* [2]*Università degli Studi di Milano, Milan, Italy;* [3]*Weill Cornell Medical College, New York, NY, USA*

Background: Brain-derived neurotrophic factor (BDNF) is a neurotrophin that plays a key role in neuron plasticity and vascular development. A single nucleotide polymorphism in the BDNF gene (BDNF Val66Met) has been associated with depression, and recently, it has been proposed as a genetic risk factor for cardiovascular disease. Intriguingly, reduced BDNF levels are detected in subjects with depression, and they seem associated with increased in patients affected by acute coronary syndrome. No Information, however, is available concerning the potential influence of the BDNF Val66Met polymorphism in thrombotic processes.

Aims: In this study we have assessed the impact of BDNF Val66Met polymorphism on haemostatic system and its relationship to thrombosis experimentally induced.

Methods: To assess the role of BDNF Val66Met polymorphism in thrombosis, ferric Chloride ($FeCl_3$) carotid arterial injury and thromboembolism, induced by injection of collagen and epinephrine, were carried out in BDNF knock-in mice generated with a homozygous BDNF variant (Met/Met), and then compared to Val/Val control mice. Thromboelastometry analyses (by ROTEM®) and platelet/leukocyte interactions (by cytofluorimetry) were performed in citrated blood. Levels of fibrinogen, and activities of plasminogen activator inhibitor 1 (PAI-1), tissue plasminogen activator (tPA), thrombospondin-1 (TSP-1), and coagulation factors were measured in plasma. TF activity of circulating leukocytes and carotid artery was performed by

one-stage plasma recalcification time assay. Finally, clot retraction test, an indicator of platelet function, was carried out in platelet rich plasma.

Results: Genetic BDNF Met/Met variant accelerated carotid artery thrombus formation in response to $FeCl_3$ and increased mortality after collagen/epinephrine injection. Recalcification tests, carried out in whole blood of Met/Met mice by NATEM thromboelastography test, showed a significant increase both in clot firmness and clot elasticity, and a reduction in the clot formation time compared to Val/Val mice. Activation of the extrinsic or intrinsic pathways (EXTEM and INTEM respectively) suggested that BDNF Knock-in mice have hyper reactivity of platelets and higher levels of fibrinogen, but normal levels of coagulation factors. Indeed, specific analyses indicated that Met/Met mice have higher levels of TSP-1, a major secretory product of activated platelets, a shorter clot retraction time, and an increase in circulating platelet/leukocyte aggregates compared to control mice. Levels of factors VIII, IX, XI, XII, PAI-1 activity and antigen, and tPA activity were similar in the two groups. In addition, platelet and withe blood cell counts were increased in BDNF Knock-in mice. Importantly, TF, the key activator of blood coagulation, was elevated both in circulating leukocytes and in carotid arteries of Met/Met mice.

Summary/Conclusion: The increased basal activation of haemostatic system associated with increased platelet activation and vascular TF activity observed in BNDF Met/Met mice may partly explain the predisposition of this mouse model to thrombosis. Therefore, genetic BDNF Val66Met variant may thus play a key role to increase the susceptibility to thrombotic events.

PA 3.12-2

Mutation of Thr-211 to Pro in the activation peptide of factor X in a bleeding patient is associated with a molecular defect in the intrinsic pathway

Rezaie AR[1], Ding Q[2], Shen Y[2], Yang L[1] and Wang X[2]

[1]St. Louis University School of Medicine, St. Louis, MO, USA; [2]Shanghai Jiao Tong University School of Medicine, Shanghai, China

Background: Thrombin is the final serine protease of the clotting cascade which is responsible for cleaving fibrinogen to form insoluble fibrin clots at the vascular injury sites. Thrombin can be generated by either intrinsic or extrinsic pathway in the clotting cascade. In both pathways, the vitamin K-dependent coagulation zymogen in plasma factor X (FX) needs to be activated to its active form (FXa) which is followed by the assembly of FXa into the prothrombinase complex and activation of prothrombin to thrombin. FX can be activated by either one of the physiological activators: the factor VIIa-tissue factor complex or the factor IXa-factor VIIIa complex in the extrinsic and intrinsic pathways, respectively. A deficiency in either one of these activation pathways can be associated with bleeding disorders. We recently identified a bleeding patient who exhibited clotting defect only in the intrinsic pathway.

Aim: The aim of this study was to elucidate the molecular basis of the clotting defect in the bleeding patient and to identify the coagulation factor responsible for the clotting defect specifically in the intrinsic pathway.

Methods: Exome sequencing was used to determine whether the patient carries a genetic defect in one of the known clotting factor genes and if so to use recombinant DNA methods to express the cDNA carrying the identified genetic defect in a mammalian expression system.

Results: Exome sequencing revealed that the patient carries a novel homozygous FX mutation that results in the substitution of Thr-211 with a Pro on the activation peptide of the FX zymogen. The residue Thr-211 is the site of an O-linked glycosylation in the activation peptide of FX. Thus, we postulated that the elimination of carbohydrate residues of Thr-211 due to a Pro substitution may specifically impacts the activation of FX by FIXa in the intrinsic Xase complex, thereby impairing thrombin generation in the subject. To test this hypothesis, we expressed a FX cDNA containing this mutation in HEK-293 cells and following the purification of the zymogen to homogeneity characterized its biochemical properties in both purified and plasma based assay systems. The results suggested that the activation of the physiological concentration of the FX mutant by the FIXa-FVIIIa complex, but not by the FVIIa-TF complex, has been markedly impaired.

Conclusions: Analysis of the results suggests that the loss of Thr-211 glycosylation site renders the FX mutant specifically a poor substrate for FIXa in the intrinsic Xase complex, thus explaining the bleeding phenotype of the patient carrying this mutation.

PA 3.12-3

Additional effect of BβArg448Lys polymorphism on fibrin clot structure/fibrinolysis and cardiovascular complications in subjects with type 2 diabetes

Greenhalgh KA[1], Alzahrani S[1], Price JF[2], Strachan M[3], Baxter P[1], Kurdee Z[1], Grant PJ[1] and Ajjan RA[1]

[1]University of Leeds, Leeds; [2]University of Edinburgh; [3]Western General Hospital, Edinburgh, UK

Background: Fibrinogen BβArg448Lys polymorphism affects clot structure and fibrinolysis, potentially explaining the association with coronary artery disease and stroke. Despite the increased risk of atherothrombosis in diabetes, the role of this polymorphism on clot structure and ischaemic events in this condition has not been studied.

Aims: This work investigates the potential additional effects of BβArg448Lys polymorphism on fibrin clot structure/fibrinolysis and predisposition to vascular events in individuals with diabetes.

Methods: Genotyping for BβArg448Lys was carried out in 822 individuals with type 2 diabetes participating in the population-based Edinburgh Type 2 Diabetes Study (mean age 68 ± 0.14, 422 males) using standard techniques. Clot maximum absorbance and lysis time were measured by validated turbidimetric assays, with confocal and scanning electron microscopy used to visualise the fibrin networks. Both individual plasma samples and pooled plasma purified fibrinogen were investigated. T-test and Mann–Whitney analysis were used for normally distributed and non-parametric data, respectively. The interaction between the polymorphism and ischemic events was investigated using regression models, with and without adjustment for traditional risk factors.

Results: Bβ448Lys variant was present in 31.5% of subjects with similar frequency in men and women. Mean age of subjects with Bβ448Lys was lower compared with Bβ448Arg (67.5 ± 0.26 and 68.3 ± 0.18 years, respectively, $P = 0.02$). Clot density in Bβ448Lys subjects was higher than Bβ448Arg (0.37 ± 0.007 vs. 0.35 ± 0.004 au, respectively, $P < 0.05$) and lysis time was longer (761 ± 20 vs. 719 ± 15 s, respectively, $P < 0.05$). These changes were still significant after adjusting for fibrinogen levels. Bβ448Lys was associated with a previous history of stroke and transient ischaemic attack (TIA) in the whole group [OR 1.93 (1.15, 3.24)], which was still evident after adjusting for traditional vascular risk factors [OR 1.98 (1.16, 3.37)]. The predictive value of Bβ448Lys for stroke/TIA was only significant in females, suggesting a possible interaction between gender, polymorphism and disease [OR 4.18 (1.56, 11.22)]. Purified fibrinogen showed differences in clot density for Arg/Arg, Arg/Lys and Lys/Lys variants at 0.046 ± 0.0007, 0.040 ± 0.0005 and 0.036 ± 0.0002 au, respectively ($P < 0.001$), accompanied by changes in clot lysis time at 13.9 ± 0.5, 17.0 ± 0.3 and 18.6 ± 0.4 min, respectively ($P < 0.001$). Differences in clot structure between these genetic variants of fibrinogen were further confirmed by both confocal and scanning electron microscopy.

Discussion: Bβ448Lys variant of fibrinogen is present in around a third of people with diabetes and confers additional risk in these subjects, probably related to the formation of more compact fibrin clots, which

are resistant to fibrinolysis. People with diabetes and fibrinogen Bβ448Lys may have reduced life expectancy and women have a higher risk of cerebrovascular disease. These data may have important clinical implications for patient clinical management and future prospective studies are warranted to fully understand the role of BβArg448Lys in predisposition to ischaemic events in diabetes.

PA 3.12-4

Acute and severe coagulopathy in adult mice following silencing of hepatic antithrombin and protein C production

Safdar H, Cheung K, Salvatori D, Versteeg HH, Laghmani EH, Wagenaar GTM, Reitsma PH and Van Vlijmen BJM
Leiden University Medical Center, Leiden, The Netherlands

Background: Mice deficient in the natural anticoagulants antithrombin (*Serpinc1*) or protein C (*Proc*) display early lethality due to thrombosis-related coagulopathy, thereby precluding their use in gene function studies or thrombosis models.
Methods: RNA interference was used to silence antithrombin (si*Serpinc1*) and/or protein C (si*Proc*) in normal adult mice (dose siRNA 3.5 or 7 mg/kg body weight). Mice were sacrificed within 2–5 days after siRNA administration. Liver *Serpinc1* and *Proc* transcript level, plasma antithrombin, protein C, and fibrinogen levels, and tissue fibrin deposition, were analyzed. Full necropsy was performed, tissues were formalin fixed, and microscopical analysis was performed on HE-stained 5-μm sections.
Results: Severe coagulopathy was observed following combined 'knockdown' of antithrombin and protein C. Two days after si*Serpinc1*/si*Proc* injection, (occlusive) thrombi were observed in (large) vessels in multiple tissues (head, leg and liver), and hemorrhages were prominent in the ocular, mandibular, and maxillary areas. In total 19 out of 19 si*Serpinc1*/si*Proc* (sum of animals for 3.5 and 7 mg/kg dose) vs. 0 out of 11 siNEG-treated animals featured abnormalities ($P < 0.0001$, Fisher's exact test). si*Serpinc1*/si*Proc*-treated animals at 3.5 or 7 mg/siRNA/kg demonstrated evident fibrin deposition (111 ± 129 $P < 0.0001$ and 1574 ± 1364 ng/mg $P = 0.0005$ vs. 5.4 ± 2.7 ng/mg in control siNEG injected animals). This coincided with reduced plasma fibrinogen levels in si*Serpinc1*/si*Proc*-treated mice (−43% $P = 0.012$ and −96% $P = 0.002$ for 3.5 or 7 mg/siRNA/kg group, respectively). The thrombin inhibitor dabigatran etexilate fully prevented coagulopathy in si*Serpinc1*/si*Proc*-treated mice (3.5 mg siRNA/kg), including formation of thrombi in head, livers and legs, liver fibrin deposition, lowering of plasma fibrinogen. Silencing *Serpinc1* alone yielded a comparable but milder phenotype with a later onset. The phenotype was absent when targeting *Proc* alone.
Conclusion: We conclude that RNA interference of *Serpinc1* and/or *Proc* allows studying the function of these genes *in vivo*, and provides a novel, controlled mouse model for spontaneous venous thrombosis.

PA 3.12-5

Platelet-derived microparticles attenuate the procoagulant nature of platelet-associated prothrombinase

Haynes LM and Tracy PB
University of Vermont, Burlington, VT, USA

Background: Due to their procoagulant nature, platelet-derived microparticles have been implicated in several thrombotic processes. Their increased expression of procoagulant activity is due, in part, to the enrichment of anionic phosphatidylserine headgroups on their outer membrane leaflets that mediate the binding of several coagulation enzyme complexes including Prothrombinase. The prothrombinase complex, composed of the serine protease factor Xa and its protein co-factor factor Va assembled on an appropriate membrane, activates the zymogen prothrombin to the serine protease α-thrombin 'the key enzyme of the hemostatic process as it lies at the crossroads of both the pro- and anti-coagulant pathways. The activation of prothrombin is the result of two proteolytic cleavages at Arg271 and Arg320. Initial cleavage at Arg271 results in the formation of the non-catalytically active intermediate prethrombin-2, while cleavage at Arg320 results in the formation of the catalytically active species meizothrombin. In contrast to α-thrombin, meizothrombin is an anticoagulant, having considerably decreased activity towards platelets, fibrinogen, factor V, and factor VIII, while activating protein C more readily when complexed with thrombomodulin.
Aims: Platelet-associated prothrombinase maximizes procoagulant activity as it activates prothrombin via the more procoagulant prethrombin-2 pathway, as opposed to Prothrombinase assembled on phospholipid vesicles of defined content that utilize the more anticoagulant meizothrombin pathway. Given these differences, the goal of the current study was to determine if platelet-derived microparticles support Prothrombinase that promotes the prethrombin-2 or meizothrombin activation pathway.
Methods: Platelet-derived microparticles were formed using calcium ionophore A23187 or by extruding thrombin-activated platelets through a 0.2 μm filter. The activation pathway utilized by Prothrombinase assembled on each surface was monitored by gel electrophoresis.
Results: When Prothrombinase was assembled on microparticles derived from platelet activation effected by calcium ionophore A23187, it utilized both the prethrombin-2 and meizothrombin pathways of thrombin generation, suggesting that upon microparticle formation, the less procoagulant meizothrombin pathway is upregulated. We hypothesize that this is a direct consequence of increased phosphatidylserine expression on the platelet's outer leaflet resulting in a surface that is akin to phospholipid vesicles of defined content. However, as microparticles contain most of the membrane proteins of their parent cells, the continued use of the prethrombin-2 pathway of prothrombin activation is likely due to the presence of intact membrane microenvironments surrounding factor Va and factor Xa receptors, which define the unique structural features of platelet-associated Prothrombinase. In contrast, when thrombin-activated platelets were extruded through a 0.2 μm filter, the microparticles generated almost exclusively supported Prothrombinase that utilized the meizothrombin pathway of prothrombin activation. The lack of utilization of the prethrombin-2 pathway, suggests that extrusion of the platelets alters the membrane microenvironment of the factor Va and Xa receptors, such that the only available pool of microparticle-associated Prothrombinase stems from the increased phosphatidylserine present on the outer leaflet.
Summary/Conclusions: These data suggest that, depending upon the precipitating events leading to microparticle formation, populations can be formed that express a wide range of procoagulant activity, the degree of which may impact their role in pathological, as well as physiological, processes.

PA 3.12-6

Contraction of whole blood clots: platelets and fibrin are on the exterior and compress erythrocytes into close-packed polyhedra on the interior

Weisel JW[1], Lebedeva T[1], Nagaswami C[1], Hayes V[1], Massefski W[2], Rauova L[1], Lowery TJ[2] and Cines DB[1]
[1]University of Pennsylvania, Philadelphia, PA; [2]T2 Biosystems, Lexington, MA, USA

Background: Contraction of blood clots is necessary for hemostasis, wound healing and to restore flow past obstructive thrombi. However, little has been known about the structure of contracted clots and mechanisms of contraction. Erythrocytes, biconcave cells that are

highly deformable to allow their passage through the microvasculature, are abundant in venous thrombi, and to a lesser extent in arterial thrombi. Erythrocytes promote hemostasis, but their participation in clot contraction has not been reported.

Aims: To understand the mechanisms of clot contraction and the roles of erythrocytes, platelets and fibrin.

Methods: We examined the structure and composition of contracted whole blood clots by scanning electron microscopy and confocal light microscopy. Whole blood was clotted by recalcification and addition of thrombin or kaolin, while following the process of clotting, including contraction, with a new technique using T2 magnetic resonance.

Results: Contracted clots display a remarkable structure, with a tessellated array (or mosaic tiling of space) of compressed polyhedral erythrocytes within and a meshwork of fibrin and platelet aggregates on the exterior. Little fibin and few platelets were found on the interior of the contracted clots. The same results were obtained with both thrombin and kaolin as activators of clotting and also with reconstituted human blood and clots prepared from mouse blood. Confocal microscopy of hydrated clots confirms the results of scanning electron microscopy. Platelets (with their cytoskeletal motility proteins) and fibrin(ogen) (as the substrate bridging platelets for contraction) are required to generate the forces necessary to segregate platelets/fibrin from erythrocytes and to compress erythrocytes into a closely packed polyhedral array. To assess the density of packing of the polyhedral erythrocytes, we replaced the water surrounding the clots with D_2O and observed by T2 magnetic resonance that hydrogen/deuterium exchange for the contracted clots was very slow, consistent with their very tightly packed, almost impermeable structure.

Summary/Conclusions: We have observed a new erythrocyte morphology, closely packed polyhedra, in contracted clots, and an unexpected spatial redistribution of platelets and fibrin that occurs during contraction. Clot contraction is an essential part of hemostasis, since both human genetic disorders of platelet myosin IIA and megakaryocyte myosin IIA-knock out mice show a bleeding phenotype. These observations on contracted clots imply that they are stiff, rigid structures that can form an impermeable, watertight seal. On the one hand, contraction of clots within the vasculature may relieve obstruction of blood vessels and allow recanalization, especially in the venous system. On the other hand, these results account for long-standing clinical observations that fibrinolysis is greatly prolonged following clot contraction, since perfusion or diffusion of lytic enzymes into these tightly packed polyhedral erythrocytes would be nearly impossible (NIH grants HL030954/HL090774 to JWW, and HL090697 to DBC, and HL110860 to DBC/LR/JWW).

PA3.13 – Acquired Coagulation Disorders – IV

PA 3.13-1

Thrombin generation in obese patients

Campello E[1], Eva Z[2], Luca S[1], Sabrina G[1], Barry W[3], Paolo P[1], Roberto V[2] and Paolo S[1]

[1]Department of Cardiologic, Throcacic and Vascular Science, University of Padua; [2]Department of Medical and Surgical Sciences, University of Padua, Padova, Italy; [3]HaemaCon Ltd, Bromley, UK

Background: It was found that obesity is associated with a hypercoagulable state either due to an increase of clotting factors plasma levels and/or the impairment of the fibrinolytic pathway. Several studies reported that elevated levels of coagulation factors such as PAI-1, prothrombin, factors VII and VIII, and fibrinogen were observed in patients suffering from obesity. These investigations were based on a limited number of subjects and did not specifically look at differences in fat amount and distribution. The measurement of capability of generating thrombin is very useful as an expression of prothrombotic phenotypes compared to conventional coagulation tests. The thrombin activity can be measured in plasma by continuous cleavage of chromogenic or fluorescent substrates, and can be registered in a curve (Thrombin generation Test [TGT]). Various parameters can be considered, including the time until thrombin burst (lag phase), the peak amount of thrombin generation (peak thrombin) and the total amount of thrombin generated [endogenous thrombin potential (ETP)]. The ETP defines the pro- and anticoagulant balance as a global function test of clotting. Increased ETP levels were seen in obesity associated myocardial infarction, stroke, and pulmonary embolism. However, ETP in asymptomatic obese subjects remains to be clarified.

Aim: The aim of this study is to determine whether any differences in the coagulation system between obese patients with different degree of obesity and normal weight subjects exist with the use of TGT.

Methods: Eighty consecutive patients referred to our Department, of whom 20 were overweight [BMI = 25–29.9 kg/m^2], 20 with I degree obesity [BMI = 30–34.9 kg/m^2], 20 with II degree obesity [BMI = 35–39.9 kg/m^2] and 20 with III degree [BMI > 40 kg/m^2]) were enrolled. Eighty age (± 3 years) and gender-matched normal weight healthy individuals acted as controls. TGT was determined in Platelet Poor Plasma (PPP) by means of CAT method, using 80 μL of PPP together with 20 μL of PPP-Reagent, a mixture of Tissue Factor (5 pM) and synthetic phospholipids (4 μM). TG curves were described in terms of Lag time (min), C max (Peak, nM) and ETP (nM*min), where shortened lag-times and elevated values of both peak thrombin and ETP are indexes of hypercoagulability.

Results: TG test showed that obese patients had shorter lag time (2.55 ± 0.3 min; $P = 0.04$), higher peak thrombin (300.9 ± 84.7 nM; $P < 0.001$) and ETP (1791.2 ± 362.0 nM*min; $P = 0.04$) than healthy controls (2.84 ± 0.55 min, 1411.5 ± 174.1 nM, 254.3 ± 58.3 nM*min, respectively). In particular, patients suffering from 3rd degree obesity showed a significantly shorter lag time ($P = 0.047$) and a significantly higher peak thrombin ($P < 0.0001$) and ETP ($P = 0.018$) than healthy controls.

BMI and waist circumference inversely correlated with the lag time ($r = -0.40$ and -0.49; $P < 0.001$, respectively) and positively with the Peak and ETP values ($r = 0.52$ and 0.58; $P < 0.0001$, respectively).

Conclusions: TGT seems to be a reliable test to identify the hypercoagulable state observed in patients suffering from obesity. Significant correlation between degree of obesity and TGT parameters suggested a growing prothrombotic potential with the increase of fat mass. Larger studies are needed to confirm our observation.

PA 3.13-2

Predictors of vascular thrombotic events in pediatric liver transplantation

Massicotte P, Bauman M, Bruce AK and Bauman ME

University of Alberta/Stollery Childrens Hospital, Edmonton, AB, Canada

Background: Liver transplantation (LT) is increasingly performed in children with liver failure. With state of the art multidisciplinary and comprehensive care, the survival rates in pediatric LT (PLT) patients have increased to 88% at 10 years. However, vascular thrombotic events (VTE) occur in up to 30% of PLT patients. These VTE often result in significant morbidity and mortality. The identified risk predictors for VTE in PLT population are inconsistent and vary according to the study methodology and reporting, and have not adequately and systematically studied.

Aim: To identify the predictors for VTE in PLT.

Methods: A retrospective cohort study was performed on all pediatric patients undergoing first LT at University of Alberta, Canada between January 2001 and July 2012. Demographic data, clinical data, graft, donor and recipient parameters, surgical details and serial radiological imaging data were recorded in a comprehensive predesigned proforma and analysed. The KIDCLOT© pediatric thrombosis group at Stollery Children's Hospital introduced an anticoagulation protocol in Novem-

ber 2006. Thus, for the purpose of analysis, patients were evaluated in two groups (before and after November 2006) and as a whole group.
Risk factors associated with VTE were analysed by univariate and multivariate regression analysis. A '*P*' value of < 0.05 was considered significant.
Results: Over the last 10 years, 91 (era 1: 30, era 2: 61) patients underwent first LT. The mean age at LT in the entire cohort was 4.5 ± 4.9 years. Forty-four patients were < 10 kg at the time of PLT. Biliary atresia (BA) with failed Kasai procedure was the most frequent (39.6%, *n* = 36) indication in both era 1 (43.3%) and era 2 (37.7%).
There were 30 VTE events in 25 (27.5%) patients: 11 hepatic artery thrombosis (HAT), 15 portal venous thrombosis (PVT), four hepatic venous thrombosis (HVT). In era 1, 10 (33.3%) patients had 10 VTE: five HAT, four PVT, 1 HVT. In era 2, 15 (24.6%) patients had 20 VTE: six HAT, 11 PVT, three HVT.
Comparative analysis was done between each of the clinical parameters, laboratory features, graft parameters and surgical factors in patients with and without VTE in Era 1, 2 and the entire group. No significant predictors of VTE were identified in era 1 patients, potentially due to small numbers. In era 2, age ≤ 2 years ($P = 0.01$), weight ≤ 10 kg ($P = 0.002$) and diagnosis of BA ($P = 0.01$) were significantly associated with VTE on univariate analysis. In the entire group, age ≤ 2 years ($P = 0.007$), weight ≤ 10 kg ($P = 0.001$), diagnosis of BA ($P = 0.001$) were significantly associated with VTE.
In multivariate analysis weight ≤ 10 kg was the only independent predictor of VTE ($P = 0.020$, OR: 4.251 (95% CI: 1.254–14.4).
Conclusion: This study demonstrates conclusively, that weight < 10 kg is the sole predictor of VTE in PLT, despite a multitude of clinical, graft and surgical factors potentially contributing to VTE. This observation indicates the critical need of close clinical and radiological monitoring and suggests more aggressive prophylactic postoperative anticoagulation in PLT patients ≤ 10 kg.

PA 3.13-3
A prospective study to evaluate early clauss fibrinogen and fibtem as predictors of progression of major obstetric haemorrhage

Precious EM, Alikhan R, Lilley G, Burckett-St Laurent D, Rayment R, Collis R and Collins PW
University Hospital Wales, Cardiff, UK

Background: Postpartum haemorrhage (PPH) accounts for 75% of severe maternal morbidity in the UK. The normal range for fibrinogen at the time of delivery is about 4–6 g/L. Clauss fibrinogen has been shown to be a useful biomarker for predicting progression of early PPH to the need for transfusion and invasive procedures. Our retrospective data confirms that clauss fibrinogen is predictive for the need for ≥ 4 units red blood cell (RBC) with a receiver operator characteristics (ROC) curve AUC (95% CI) of 0.85 (0.78–0.93). Clauss fibrinogen often takes too long to be clinically useful in the context of treating PPH. Fibtem® measured on a ROTEM® machine can provide a rapidly available near patient estimate of fibrinogen.
Aims: To establish whether Fibtem analysis had a similar utility to clauss fibrinogen for predicting progression of PPH.
Methods: After ethical approval consecutive women admitted toCardiffwho had either a PPH of ≥ 1500 or ≥ 1000 mL in association with a precipitant were enrolled. On identification of PPH, a paired clauss fibrinogen and Fibtem assay were taken. Data recorded included measured blood loss, units of RBC transfused and the need for invasive procedures. ROC analysis was used to examine the utility of fibrinogen and Fibtem maximum clot firmness (MCF) to predict progression to transfusion with any RBC, ≥ 4 units of RBC, or the need for invasive procedures.
Results: From April to September 2012, PPH fitting the entry criteria was identified in 179/3200 births (5.6/100), progressing to ≥ 1500 mL in 84 and ≥ 2500 mL in 17 patients. Forty-two women received RBC transfusion and 10 receiving ≥ 4 units. The ROC curve AUC values were significant for all three outcomes as predicted by both clauss fibrinogen and Fibtem®. The AUC (95% CI, *P* value) for progression to any RBC transfusion was 0.72 (0.6–0.84, $P < 0.01$) for fibrinogen and 0.74 (0.63–0.86, $P < 0.01$) for Fibtem, ≥ 4 units of RBC transfusion was 0.84 (0.7–1.0, $P < 0.01$) for fibrinogen and 0.80 (0.6–1.0, $P < 0.01$) for Fibtem®, and for progression to invasive procedures 0.93 ($P < 0.01$) and 0.89 ($P < 0.01$) respectively. A Fibtem MCF < 18 mm, equivalent to fibrinogen about 2.5–3 g/L, associated with ongoing bleeding, had a positive predictive value (95% CI) of 89 (67–98)%, and a negative predictive value of 84 (78–90)% for the need for any RBC transfusion.
Conclusions: In this prospective observational study, Fibtem was found to be as useful as laboratory fibrinogen for predicting the need for any RBC, ≥ 4 units RBC transfusion and the need for invasive procedures. Fibtem, however, was available substantially sooner than laboratory fibrinogen and might therefore be more useful to trigger intervention. These data provide further evidence for the utility of fibrinogen as an early biomarker for progression of PPH and demonstrate that the Fibtem assay can be used in a similar way. Given the value of low peripartum Fibtem for predicting progression of PPH, the study team are undertaking an interventional trial to establish whether the correction of Fibtem to normal peripartum levels reduces bleeding and the need for transfusion.

PA 3.13-4
Early cytokine secretion may predict response to treatment in acquired hemophilia

Escobar MA[1], Csencsits-Smith K[2] and Donnachie M[1]
[1]*University of Texas Health Science Center and Gulf States Hemophilia Center;* [2]*University of Texas Health Science Center at Houston, Houston, TX, USA*

Acquired hemophilia (AH) is a rare, life-threatening, bleeding disorder caused by autoantibodies that inhibit the clotting function of FVIII (Inhibitors). A major challenge in AH management is that patients vary in their responses to treatments (immunosuppressive agents such as cyclophosphamide, corticosteriods, azothioprine, and rituximab; alone or in combination). To date, no definite biomarker exists that can predict responsiveness of AH patients to a specific therapy, and study of this population has been hampered by the low incidence of the disease ($1{:}1 \times 10^6$) as well as the presence of co-morbidities including autoimmune disorders and malignancies.
The aim of the study was to determine immune factors associated with outcome of anti FVIII inhibitor antibody treatment in AH patients. After IRB approval and informed consent, blood samples were collected at the start of therapy and at various time points during treatment and follow-up (up to 806 days post treatment). B-cell activating factor (BAFF) levels were determined by ELISA (R&D Systems). The remaining cytokine and chemokine levels were determined using a 18-plex Milliplex MAP assay (Millipore) and analyzed using a Bio-plex 200 (Biorad). Inhibitor levels were determined by Bethesda assay and anti-FVIII IgG subclasses were determined by ELISA. Data were stratified according to time post-treatment and plasma measurements of cytokines and inhibitor levels were compared between non-responders (NR) and complete responders (CR) using logistic regression analysis. Statistical significance was confirmed via two-sample Mann–Whitney test (Stata/IC).
Fifty percent of the patients were male and the average age was 62.5 (range 51–88). The underlying disorder was idiopathic in 6/12 of patients, autoimmune in 4/12, and cancer in 2/12. Of 12 patients, 11 were treated with rituximab, either alone or in combination with cyclophosphamide and/or corticosteroids. One patient achieved spontaneous remission. Six patients demonstrated a complete response to treatment, and their inhibitor level returned to 0 BU/mL at an average of 153 days (± 61 days). IgG4 anti-FVIII antibody was found in 9/11

patients. Within the group of treated CR patients, titers of all subclasses of anti-FVIII Ab decreased following treatment, surprisingly, detectable anti-FVIII IgG titers returned in four patients at their last follow-up, despite a remission in inhibitor and remaining asymptomatic. A higher baseline secretion of plasma GCSF was associated with NR (median 66.1 vs. 34.6 pg/mL, $P = 0.04$). Within the first 30 days of treatment, an increase in the chemokine MCP-1(CCL2) was associated with NR (median 361 vs. 268 pg/mL, $P = 0.04$). Comparison of plasma cytokine secretion between patients post-treatment revealed that only BAFF concentrations at later time points (> 1 year) were increased in NR (median 3397 vs. 1890 pg/mL, $P = 0.02$).

Conclusions: Though the overall trends in kinetics and levels of cytokine secretion were similar between CR and NR patients, the combination of specific cellular signals within 30 days following the initiation of treatment may determine final outcome. Tracking of plasma GCSF and MCP-1 secretion in patients may provide a realistic predictor of outcome.

PA 3.13-5

Real time assessment of hemostatic alterations induced by cardiopulmonary bypass surgery

Hoffmann T, Sixt SU, Urbanski K, Albert A, Kamiya H, Barnscheidt M, Pannen B, Lichtenberg A and Scharf RE

Heinrich Heine University Medical Center, Duesseldorf, Germany

The heterogeneity of hemostatic alterations, which cause hemorrhage in cardiopulmonary bypass surgery (CPBS), is still poorly understood. In search of clarification, different hemostatic components were systematically assessed by point-of-care methods. The hemostatic capacity in the reperfusion phase (RP) of CPBS was compared to preoperative conditions at surgery preparation. To focus on hemostatic changes induced by CBPS, the time of reperfusion (rather than end of surgery) was chosen in order to exclude any effects of pronounced bleeding and subsequent hemotherapy at the end of surgery.

Methods: A total of 69 patients was investigated. The extrinsic coagulation pathway was tested by use of the thrombelastometric clotting time (CT-EXTEM, ROTEM®). High-dose heparin during CPB hinders the assessment of the intrinsic pathway, but FVIII was determined by a chromogenic assay (Siemens®). Both fibrinogen levels (Clauss method; Siemens Multifibren®) and maximal clot formation (MCF-FIBTEM, ROTEM®) together with FXIII activity (Siemens Berichrom®) were used to assess clot substrates. Primary hemostasis was examined by platelet aggregometry (Multiplate® ADP, ASPI, TRAP), von Willebrand factor (vWF) activity (Siemens BC®) and vWF antigen (Instrumentation Laboratories®). Fibrinolytic activity was probed by D-dimers (Siemens Innovance®).

Results: Mean clotting time (CT-EXTEM) from start to reperfusion increased by 20 ± 22 s (mean + SD), but pathologic prolongation occurred in only eight of 67 patients (11.9%) at RP (0% at starting point). vWF activity was reduced in three of 65 patients (4.6%) at starting point and normalized or remained normal in all. Similar results were found regarding FVIII activity. Fibrinogen levels decreased by 29% (Clauss method) and 33% (MCF-FIBTEM), respectively. At start, eight of 64 patients (12.5%) exhibited pathologically low MCF-FIBTEM values, as compared to 28 of 64 patients (43.8%) in RP. Reduced FXIII levels were observed in 19 of 61 patients (31.2%) at start and in 54 of 61 of patients (88.5%) in RP, respectively. Increased fibrinolysis as defined by a D-dimer cut-off of 5 mg/L was present in only six of 64 patients (9.4%) in RP, all of whom had elevated values already at surgery preparation. The pattern of platelet aggregation (PA) in response to ADP/TRAP was variable: (i) in 25 of 47 patients (53.2%) PA was normal at start and remained unaffected during CPB, (ii) in nine of 47 patients (19.1%), PA was normal and became pathologic, (iii) in four of 47 patients (8.5%), PA was pathologic at start and became normal and (iv) in nine of 47 patients (19.1%), PA was pathologic throughout.

Conclusion: Hemostatic alterations associated with CPBS are predominantly characterized by changes in fibrinogen and FXIII levels. In contrast, the extrinsic pathway is affected to a lesser degree. Fibrinolysis does not appear to contribute to CPB coagulopathy, which may result from the application of heparin and tranexamic acid during CPB. Likewise, changes in FVIII or vWF appear to be irrelevant. Platelet function in CPBS reveals different patterns including a subgroup of patients in whom reduced platelet aggregability is restored during CPB. The data of this pilot study provide a rationale for differential hemotherapy of bleeding in CBPS.

PA 3.13-6

Novel detection of heparin-like substance as a cause of activated partial thromboplastin time prolongation in dengue hemorrhagic fever

Suwanawiboon B, Ruchutrakool T, Chinthammitr Y and Nakkinkun Y

Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand

Background: Dengue hemorrhagic fever is a major public health concern in tropical and subtropical countries. Hemorrhagic complication due to dengue virus infection can result in significant morbidity and mortality of the patients. In addition to thrombocytopenia, other hemostatic parameter derangements, for example, activated partial thromboplastin time (aPTT) prolongation has been reported in dengue hemorrhagic fever. However, the mechanism of abnormal aPTT observed in dengue virus infection is unclear. According to our previous observation in bleeding patients with dengue infection, aPTT prolongation was not corrected by a mixing study. Moreover, the fibrinogen activity was low. Therefore, we hypothesized that heparin-like substance could be responsible for this finding.

Aims: To investigate the presence of heparin-like substance in dengue hemorrhagic fever as a cause of aPTT prolongation.

Methods: Six plasma samples from five patients with dengue hemorrhagic fever and aPTT prolongation were obtained. Mixing study and fibrinogen activity assays were performed in all samples. In addition, protamine titration was examined in both the patients' plasma and in the control (normal plasma spiked with heparin).

Results: The median aPTT was 65.0 s (range 35.4–88.6 s; normal 24.1–30.9 s). Mixing study showed uncorrectable aPTT in four samples. Two samples from a patient with severe hepatic injury showed prolonged prothrombin time. Fibrinogen activity assays revealed decreased fibrinogen activity in five out of six patients. Interestingly, we found that the fibrinogen activity gradually increased with serial testing at different time interval at room temperature, which was similar to the pattern seen in plasma contaminated with heparin. The median level of fibrinogen activity at baseline, 60 and 90 min were 160.6 mg/dL (range 20.94–243.6), 352.6 mg/dL (range 220.4–588.1) and 446.1 mg/dL (range 256.4–455.4), respectively (normal 200–400 mg/dL). The protamine titration demonstrated the normalization of aPTT prolongation in all samples. The median concentration of protamine used to correct the aPTT was 0.05 mg/mL (range 0.02–0.055). Therefore, the results of mixing study, fibrinogen activity and protamine titration suggested the presence of heparin-like substance in the patients' plasma. Hence, protamine sulfate was given to two patients who sustained severe gastrointestinal bleeding and prolonged aPTT, which failed to improve after fresh frozen plasma and cryoprecipitate transfusions but responded to protamine sulfate with shortening of aPTT.

Conclusion: Heparin-like substance was demonstrated in plasma samples obtaining from patients with dengue hemorrhagic fever. Further study is required to validate current findings, which could be useful for the future management of hemorrhagic complication in patients diagnosed with dengue hemorrhagic fever.

PA3.14 – Coagulation Factor XI – II

Enhanced factor XI-dependent thrombin generation by nanoparticle-bound polyphosphate

Smith SA[1], Kudela D[2], May-Masnou A[2], Braun G[3], Pallaoro A[2], Chuong T[2], Stucky GD[2] and H Morrissey J[1]

[1]*University of Illinois at Urbana-Champaign, Urbana, IL;* [2]*University of California, Santa Barbara, Santa Barbara, CA;* [3]*Sanford-Burnham Medical Research Institute, La Jolla, CA, USA*

Background: Inorganic polyphosphates (polyP) are negatively charged, linear phosphate polymers that are secreted from platelet dense granules. We previously reported (Choi et al, Blood 2011;118:6963–6970) that polyP supports both autoactivation of factor XI (FXI) and back-activation of FXI by thrombin. Thus, platelet polyP is likely a physiologically relevant cofactor for FXI activation *in vivo*.
Aims: Evaluate the ability of nanoparticle-bound polyP to support FXI-dependent thrombin generation.
Methods: Silica nanoparticles (SNP) with covalently bound polyP (SNP-polyP) were prepared by a modified Stöber process, based on the hydrolysis and condensation of tetraethyl orthosilicate in ethanol, using ammonium hydroxide as catalyst. Product was approximately 85 nm diameter nanoparticles with covalently attached long-chain polyP (300–1300 phosphates long, mode approximately 700mer). Thrombin generation (CAT) assays were conducted with factor (FXII)- or FXI-deficient plasma containing 20 mM phospholipids, 20 nM β-thrombin, and either: soluble polyP (0–70 μM phosphate monomer), SNP-polyP (0–100 mg/mL particles with 0–7 μM polyP), or SNP without polyP (0–100 mg/mL particles).
Results: Minimal thrombin generation was observed in FXII-deficient plasma in the presence of SNP lacking polyP. Adding either soluble polyP or SNP-polyP to plasma shortened the time to peak thrombin and greatly increased both the peak thrombin and the endogenous thrombin potential (ETP). Over the range of polyP concentrations evaluated, SNP-polyP was about tenfold more potent than soluble polyP in enhancing thrombin generation. In contrast, insignificant levels of thrombin were generated when either polyP or SNP-polyP were added to FXI-deficient plasma.
Conclusions: PolyP attached to nanoparticles was tenfold more potent than polyP in solution at stimulating thrombin generation under our assay conditions (in which polyP-stimulated thrombin generation is completely dependent on FXI). Such particles may be useful in enhancing thrombin generation at sites of injury *in vivo*.

Identification and characterization of a highly specific FXIa inhibitor from Bungarus fasciatus venom

Chen W, Kang TS and Kini MR

National University of Singapore, Singapore, Singapore

Background: The high risk of excessive bleeding associated with most anti-thrombotic drugs available in the market has made it necessary to discover new anticoagulants with minimal bleeding side effects. Inhibitors targeting the intrinsic coagulation pathway while leaving the extrinsic and common pathways unaffected are potential candidates of such new anticoagulants.
Aims: (i) Identification and purification of novel peptides from *Bungarus fasciatus* venom, capable of specifically targeting the intrinsic coagulation pathway. (ii) Functional characterization of identified peptides.
Methods: *Bungarus fasciatus* venom was fractionated and examined for effects on prothrombin time (PT) and activated partial thromboplastin time (APTT) of human plasma. Fractions that prolonged APTT and left PT unaffected were further analyzed by mass spectrometry, protein sequencing, and circular dichroism spectroscopy and screened for specificity against different coagulation enzymes. Isolated candidate peptide was further characterized by a series of functional assays including inhibition kinetics, western blotting, surface plasmon resonance and blood coagulation assays.
Results: A kunitz-type protease inhibitor (termed BF01) showing highly specific inhibition of FXIa was purified. The protein was recombinantly expressed in *Escherichia coli* system, and purified by Ni-NTA beads. BF01 prolonged APTT and was demonstrated to interact and inhibit FXIa in a dose-and time-dependent manner from 50 nM to 5 μM and marginally inhibited Activated Protein C at > 10 μM, while inhibition of other protease in the coagulation pathways (Kallikrein, FXIIa, FXIa, FXa, FIXa, FVIIa, Urokinase, alpha-Thrombin) were not observed at doses up to 100 μM. BF01's inhibitory effect on the cleavage of FIX by FXIa was observed using western blotting through probing for FIX and FIXa.
Conclusions: We have identified and characterized the first FXIa-specific inhibitor from exogenous sources, which differs significantly from FXIa's physicological inhibitor Protease Nexin 2. This peptide may potentially be used as template for designing novel inhibitors against FXIa.

The type I mutation causing factor XI deficiency in Ashkenazi Jews is a founder mutation of recent Eastern European origin

Peretz H[1], Salomon O[2], Mor-Cohen R[2], Usher S[1], Michal Z[2], Zivelin A[2] and Seligsohn U[2]

[1]*Sourasky Medical Center, Tel Aviv, Israel;* [2]*Amalia Biron Research Institute of Thrombosis and Hemostasis, Tel Hashomer, Israel*

Background: Factor XI (FXI) deficiency is one of the most frequent inherited disorders in Ashkenazi Jews (AJ). Two predominant founder mutations termed type II (p.Glu117Stop) and type III (p.Phe283Leu) account for most cases. The different ethnic distribution and the estimated coalescence times suggest there is an ancient Middle Eastern origin for type II mutation and a more recent European origin for type III mutation.
Aims: To investigate clinical and genetic aspects of a less common type I mutation (c.1716 + 1G>A) in AJ.
Methods: Bleeding manifestations, FXI levels and geographic origin of members of 13 unrelated families harboring type I mutation were determined. Eight intragenic polymorphisms and five polymorphisms flanking the *F11* gene, together spanning 1.43 Mb, were analysed in families with type I mutation, 16 unrelated type II homozygotes, 23 unrelated type III homozygotes and 438 AJ controls. Haplotype analysis was used to define a founder effect. The age of type I mutation was estimated by DMLE+2.0 software program.
Results: Among 414 unrelated Jewish patients with severe FXI deficiency (FXI level < 15 U/dL), the allele frequency of type I mutation was 1.21% compared to 53.9% and 43.8% for type II and type III mutations, respectively. Four of 16 type I heterozygotes (25%) and six of 12 (50%) compound heterozygotes for type I mutation (I/II or I/III), and a type I homozygote had bleeding manifestations mostly at injury sites expressing high fibrinolytic activity. Haplotype analysis disclosed that type I is a founder mutation that occurred approximately 600 years ago. The origin of the families carrying the type I mutation was from an Eastern European region surrounding the Carpathian mountains.
Summary: The type I mutation is a third founder mutation causing factor XI deficiency in AJ. The estimated ages of the three Jewish founder mutations reflect major landmarks in the history of the Jews. While the type II mutation occurred in early antiquity during the formation of the Jewish nation in the Middle East, and the type III mutation occurred in the middle ages during the consolidation of the AJ in Central Europe, the type I mutation occurred more recently when the Eastern European AJ communities were founded.

Interim results (3-year) of a French non-interventional study to assess the long-term safety and efficacy of BeneFIX

Rothschild C[1], Trossaert M[2], Claeyssens-Donadel S[3], Lambert T[4], Hassoun A[5], Volot F[6] and Attal S[7]

[1]Hopital Necker, Paris; [2]Hôtel-Dieu Hospital, Nantes; [3]Purpan Hospital, Toulouse; [4]Kremlin bicetre hospital, Paris; [5]Simone Veil Hospital, Montmorency; [6]Bocage Hospital, Dijon; [7]Pfizer, Paris, France

Background: Clinical studies have demonstrated the efficacy and safety of BeneFIX for on-demand treatment and prophylaxis. However, these studies can present limitations concerning extrapolation of their results to routine clinical practice and a non-interventional study with high quality standards is an appropriate mean to assess the long-term safety and efficacy in an unselected population of patients.
Aim: To evaluate the safety and efficacy of long-term BeneFIX therapy in the usual care settings in French patients with haemophilia B.
Methods: All patients receiving BeneFIX can be included in this non-interventional study. Data are collected on standardized case-report forms and monitoring visits are performed regularly to ensure high data quality.
Results: The study started in 2009. By January 2013, 56 patients from 17 sites were enrolled and evaluable for safety (median age: 18.06 years; range: 0.2–66.9). Among the 37 patients contributing to the efficacy analysis (FIX: C $\leq$ 1%, no inhibitor, $\geq$ 1 follow-up visit, sufficient diary information), 22 had at least a period of prophylactic treatment (median duration: 662 days) and 21 had at least a period of on demand treatment (median duration: 722 days). The mean dose per infusion for prophylactic treatment was 46.3 $\pm$ 12.38 IU/kg (median 45.7; range: 25–68). The annualized mean number of bleeding episodes was respectively 4.4 $\pm$ 3.7 (median 4.4) and 12.8 $\pm$ 11.8 (median 8.6) during prophylaxis and on-demand treatment. A total of 627 bleeding episodes occurred, mostly in a joint (42.6%). Overall, 84.2% of bleeding episodes were resolved with 1–2 injections. The mean dose per infusion for all bleeding episodes was 48.4 $\pm$ 12.8 IU/kg (median 49.7; range: 29–74). All subjective evaluations of efficacy were rated by the physician/patient as 'excellent' or 'good'. One previously untreated child with severe haemophilia B after 14 ED (11 in prophylactic and four on demand) with 83 UI/kg/twice a week BeneFIX consumption, developed inhibitor antibody at 1.7 Bethesda units (BU) titers. FIX gene analysis demonstrated complete deletion of the FIX gene. Development of inhibitory antibodies was not associated with severe allergic or even anaphylactic reactions following infusion of factor IX concentrates. Prophylactic treatment with rFactor VIIa (Eptacog alfa) was administrated until inhibitor disappeared.
Conclusions: This three-year interim analysis of this non interventional study supports the safety and efficacy of treatment with BeneFIX under usual care settings. Inhibitors against factor IX (FIX) are not very common, being reported in < 2% of patients with haemophilia B with a strong link between complete deletions and inhibitor development as described in literature.

PA 3.14-5

FXI deficiency and Gaucher disease: a potentiated bleeding risk?

Thomas AS, Hughes A, Mehta AB and Gomez K

Royal Free Hospital & Unversity College London, London, UK

Background: Gaucher disease (GD) is an autosomal recessive deficiency of the enzyme glucocerebrosidase, required for the degradation of glycosphingolipids. Clinical features, consequent primarily on the effects of storage of un-degraded glycosphingolipid within the reticuloendothelial system include bone pain, hepatosplenomegaly, peripheral blood cytopenias and a poorly defined bleeding diathesis. Symptoms are highly variable and onset is often insidious and non-specific resulting in a prolonged time course from symptom onset to diagnosis. It is a pan-ethnic disorder, with an overall prevalence rate of one in 75,000 live birth; however, it is far more common in the Ashkenazi Jewish population with a carrier rate in 1 in 12. FXI deficiency similarly has an increased carrier rate of 1 in 8 in the Jewish population and has a highly variable bleeding phenotype. FXI deficiency may have an increased prevalence amongst patients with GD and there may be a synergistic effect that increases the prevalence of bleeding symptoms.
Aims: To ascertain the prevalence and nature of bleeding symptoms and prevalence of defined bleeding disorders/factor deficiencies with a cohort of GD patients.
Methods: A single centre cohort of patients with GD was evaluated. A retrospective review of clinical notes and laboratory data at diagnosis was undertaken. Prospective data regarding bleeding scores was obtained. Factor assays were performed using a standard 1 stage APTT-based assay. The study was approved by the local ethics committee.
Results: Amongst the cohort of 98 GD patients, 54% had bleeding symptoms at presentation: bruising (45%), epistaxis (11%), post-operative bleeding (8%), menorrhagia (2%). Bleeding was the primary presenting symptom in 19%. Sixty-five percent of patients were diagnosed by haematologists, including five patients who presented initially to haemophilia centres. Seventeen percent of patients were found to have reduced FXI levels within the heterozygous range (mean 56 IU/dL, range 39–68), 2% reduced von Willebrand antigen and activity and one a platelet storage pool defect. 6/17 (35%) of the patients with FXI deficiency were of known Jewish ethnicity, compared to 29/98 (28%) of the overall cohort. 14/17 (83%) of those with FXI deficiency had bleeding symptoms, with six suffering post-operative bleeding. This is in marked contrast to published cohorts of patients with partial/heterozygous FXI deficiency, of whom only 35% exhibit bleeding symptoms (Gomez & Bolton-Maggs, 2008). In GD, mild-moderate thrombocytopenia (mean 71 $\times$ 10^9/L, range 35–121) and cellular dysfunction secondary to lipid storage may act as modifiers of the bleeding phenotype.
Conclusions: GD commonly presents with bleeding symptoms and thus may initially present to haemostasis specialists. Patients with GD commonly have low FXI levels, within the heterozygous deficiency range, at presentation; bleeding symptoms are more prevalent in these patients than expected for patients with partial FXI deficiency. The diagnosis of GD should be considered in any patient with unexplained bleeding or bleeding out of keeping with the degree of a coagulation factor deficiency.

Structure of coagulation FXI bound to a peptide derived from laminin

Wong SS[1], Emsley J[1] and Stennicke HR[2]

[1]University of Nottingham, Nottingham, UK; [2]Novo Nordisk A/S, Måløv, Denmark

Background: Coagulation factor XI (FXI) is the zymogen of the enzyme FXIa that contributes to haemostasis by activating factor IX (FXI). Laminin is an extracellular matrix protein which is an essential component of the basement membrane structure and becomes exposed when the vasculature is damaged. Recent work has shown that laminin can contribute to coagulation via activation of the contact system as well as through interaction with platelets [1–3]. The best characterised interaction of a coagulation factor with a matrix protein is the FIX (a FXIa substrate) interaction with collagen IV which is also a critical component of the basement membrane. The interaction of the FIX with collagen IV was shown to contribute to haemostasis *in vivo* and loss of this interaction has been characterised as a haemophilia [4].
Aims: To investigate the molecular basis of FXI ligand binding we crystallised a peptide derived from laminin with FXI.

Methods: We have determined the structure of a short peptide from laminin bound to the apple domain of the FXI zymogen using protein X-ray crystallography and molecular replacement techniques.
Results: The laminin peptide binds along a hydrophobic groove on the underside of the apple domains of FXI. A hydrogen bond network between the laminin peptide and residues on the apple domain surface is important in mediating this interaction.
Conclusion: *The FXI-laminin complex crystal structure is the first complex structure reported between a coagulation factor and an extracellular matrix protein.* The structure reveals a key binding site for laminin and also proposes a similar interaction between laminin and the FXI homolog prekallikrein. The interaction of FXI with laminin may represent another means to localise coagulation factors onto a surface formed by the basement membrane together with FIX.

DNA and RNA promote kallikrein-mediated activation of fXII and are cofactors for fXI feedback activation by thrombin

Vu T, Zhou J, Leslie BA, Stafford AR, Fredenburgh JC and Weitz JI
McMaster University, Hamilton, ON, Canada

Background: Polyanionic surfaces, such as dextran sulfate and kaolin, mediate contact activation in plasma by binding factor (f) XII and high molecular weight kininogen (HK). Interaction of fXII with a surface promotes its autoactivation. HK bridges fXI and prekallikrein (PK) to the surface. Generation of kallikrein activates additional fXII and augments production of fXIa, leading to enhanced thrombin generation. Thrombin also activates fXI, in a positive feedback step that also is surface-dependent. Recent studies have identified physiological activators of the contact system. Extracellular DNA and RNA have been shown to activate the contact pathway, but the mechanisms by which they promote activation are unclear.
Objective: To identify the mechanisms by which DNA and RNA promote contact activation.
Methods: DNA and RNA were isolated from mammalian cells. Binding of fXII, HK, fXI, Phe-Pro-Arg-chloromethyl ketone (FPRck)-fXIa and FPRck-thrombin to biotinylated-DNA and -RNA was quantified using surface plasmon resonance (SPR). The effects of DNA and RNA on contact activation were evaluated with chromogenic assays.
Results: Binding studies using SPR reveal that DNA and RNA bind fXII with K_d values of 30–200 nM, whereas HK binds with a K_d of 35–40 nM. Although DNA and RNA do not significantly promote fXII autoactivation on their own, they enhance fXIIa generation by fivefold in the presence of PK alone and 30-fold in the presence of both PK and HK. In the individual reactions, DNA augments both kallikrein activation of fXII and fXIIa activation of PK by 2-3-fold. In the feedback pathway, fXI (K_d of 0.6–4 nM), FPRck-fXIa (K_d of 11–14 nM) bind DNA and RNA with greater affinity than FPRck-thrombin (K_d of 600–1100 nM). DNA and RNA accelerate thrombin activation of fXI by 8- and 11-fold, respectively. However, DNA does not stimulate thrombin chromogenic activity.
Conclusion: Contact pathway factors (fXII, HK and fXI/fXIa) bind DNA and RNA with high affinity. Although they have little effect on fXII autoactivation on their own, DNA and RNA promote fXIIa generation in the presence of PK and/or HK, indicating that fXII activation by DNA and RNA is dependent on the plasma kallikrein system. DNA and RNA bind fXI and fXIa in an HK-independent manner and serve as cofactors for feedback activation of fXI by thrombin. Collectively, these results suggest that in addition to localizing and concentrating the contact proteins onto the surface to initiate contact activation, DNA and RNA also amplify the procoagulant response by promoting feedback activation of fXI by thrombin.

PA 3.15-2

Ongoing contact activation in patients with hereditary angioedema

Konings J[1], Cugno M[2], Suffritti C[3], Ten Cate H[1], Cicardi M[3] and Govers-Riemslag JWP[1]
[1]CARIM, Maastricht University Medical Centre, Maastricht, The Netherlands; [2]Department of Pathophysiology and Transplantation, University of Milan; [3]Department of Biomedical and Clinical Sciences L. Sacco, University of Milan, Milan, Italy

Background: Hereditary angioedema (HAE) is caused by a deficiency in C1-esterase inhibitor (C1INH). C1INH is the main inhibitor of the contact system and inhibits activated FXII (FXIIa), FXIa and kallikrein. Attacks of angioedema are caused by the release of bradykinin from high-molecular-weight kininogen, mainly mediated by kallikrein. Activation of FXII leads to the formation of α-FXIIa and β-FXIIa. Both enzymes can convert prekallikrein into kallikrein, but only α-FXIIa can initiate the intrinsic pathway of coagulation.
Hypothesis: In HAE patients the thrombotic risk is not increased during attacks. We hypothesized that contact activation preferentially leads to kallikrein and bradykinin formation and less to activation of the coagulation cascade via FXI activation in these patients.
Methods: In plasma samples of healthy controls ($N = 10$) and HAE patients ($N = 30$, 17 during remission and 13 during acute attack), we measured activation of the contact system as (i) the levels of C1INH-complexed with these enzymes (ii) the *in vitro* potential of the plasma to form inhibitory complexes when contact system is completely activated with a FXII trigger. Furthermore, the capacity of the plasma to inhibit kallikrein and the spontaneous kallikrein activity was measured.
Results: The basal levels of enzyme-inhibitor complexes were comparable between controls and patients during attack as well as during remission. There was no uninhibited FXIIa, FXIa or kallikrein present in the sample, since addition of C1INH did not change the complex levels. After *in vitro* activation of the plasma samples the levels of kallikrein-C1INH correlated positively with the capacity of the plasma to inhibit kallikrein ($r = 0.74$, $P < 0.001$), and negatively with the spontaneous kallikrein activity ($r = -0.54$, $P = 0.029$). Furthermore, the levels of FXIIa-C1INH, FXIa-C1INH and kallikrein-C1INH were at least 52% lower in samples taken during remission and 70% lower in samples taken during attack compared to samples from controls. The levels of FXIa-α_1-antitrypsin were more than 30% higher in patients compared to controls. Reconstitution of C1-esterase inhibitor after activation led to an increase in levels of FXIIa-C1INH and FXIa-C1INH, which, however, were 33% and 43% lower than in controls, while the levels of kallikrein-C1INH did not change.
Summary/Conclusion: In the basal samples we did not detect contact activation, even after correction of C1INH to normal levels for optimal enzyme inhibitor complex formation. After activation of the plasma samples *in vitro*, we found lower levels of all enzyme-C1INH

complexes in samples from HAE patients compared to controls, also in the presence of additional C1INH. The lowest levels were found in samples from patients during acute attack. In concert, this could indicate an ambient activation of the contact system and minor depletion of contact factors. Our results do not allow to demonstrate a preferential generation of kallikrein over FXIa. Regulation of the activity of FXIa and other enzymes of the coagulation cascade after a low degree of contact activation by other inhibitors is probably sufficient to prevent thrombosis.

PA 3.15-3

Binding and activation of coagulation factor XII by activated platelet subpopulations and microparticles

Zakharova NV, Artemenko E, Podoplelova NA, Ataullakhanov F and Panteleev MA

Center for Theoretical Problems of Physicochemical Pharmacology, RAS, Moscow, Russian Federation

Factor XII (fXII) has recently been implicated as having important roles in thrombosis, but the mechanisms of its physiological activation remain obscure. Stimulated platelets or platelet-derived material are the main candidate suspects for this.

In this study, fXII was activated by platelets stimulated with thrombin, collagen-related peptide, or calcium ionophore A23187; but not with 2-MeS-ADP, or non-stimulated. Activation proceeded in citrated plasma and in buffer with purified fXII, with an apparent K_m of 52 ± 14.4 nM. Inhibition of platelet-dependent fXII activation by annexin V and preferential fXII binding to phosphatidylserine-positive platelets (630 ± 90 molecules/platelet under physiological conditions) and procoagulant platelet-released microparticles implied essential role of the phosphatidylserine-expressing platelet subpopulation. Calpain inhibitors also significantly decreased fXII-activating activity of platelets stimulated with A23187 and thrombin that was coincident with the inhibition of microparticle production. Unexpectedly, platelet granule-secreted material did not activate fXII, but was found to inhibit fXIIa.

These results demonstrate that stimulated platelets regulate fXII activation in a complicated manner very similar to their regulation of thrombin generation: they activate fXII on their surface but produce soluble fXIIa inhibitor(s) thus creating a balancing system able to shift both ways. This can either serve to confine the clotting processes to the platelet surface, or as a flow-sensitive trigger that allows platelet-dependent coagulation onset when platelet-secreted inhibitors are removed by flow. This could explain why fXII is important in thrombosis, but not hemostasis.

PA 3.15-4

Neutrophil extracellular traps (NETs) and factor XII activation; a possible mechanism for increasing thrombotic risk during extracorporeal membrane oxygenation (ECMO)

Davidson SJ[1], Britton G[1], Mumby S[2], Griffiths M[1] and Quinlan G[2]

[1]Royal Brompton Hospital; [2]Imperial College, London, UK

Background: Bleeding and thrombosis are risks associated with ECMO and may be linked to extracellular material released from neutrophils. Neutrophil extracellular traps (NETs) are a self-defence phenomenon and part of the innate immune response against microbial invasion. This novel activation pathway induces neutrophils to release decondensed nuclear DNA (polyphosphate PolyP) laced with histones that have antimicrobial properties. Links between NETs and autoimmune diseases and thrombosis have been established. Platelets also produce PolyP, which have been shown to induce NETosis in a dose response manner and can activate factor XII. The evidence suggests that increased NET activation in thrombosis may in fact be an aberrant over-shooting of the immune defence.

Aims: Our hypothesis was that NET activation as shown by increased extracellular DNA causes increase activation of factor XII which in turn increases the thrombotic risk in respiratory patients subjected to ECMO.

Methods: We measured extracellular DNA (plasQuant IT[TRADEMARK] picogreen kit), factor XIIa (UnitestTM FXIIa assay) and thrombin generation microparticle assay using the Tecan fluorescent plate reader with i-control software (Technothrombin® TGA assay). We studied 26 H1N1 patients with acute respiratory failure on ECMO. There were 12 males and 14 females, age range 19–55 years. Of those 26 patients 18/26 survived and 8/26 did not survive. Ethical approval had been given by the Biomedical Research Unit at the hospital.

Results: Extracellular DNA at admission was 1099 and 203 ng/mL at end of stay (normal plasma 136 mg/mL). Factor XIIa at admission was median 62.4 U/L (IQR 38.2–86.0 U/L) and at the end of the ECMO run was 77.5 U/L (IQR 32.1–181.8 U/L). This data shows no significance overall, Kruskal-Wallis $P = 0.831$. If however the XIIa data is split between survivors and non survivors the XIIa data for survivors shows a decreasing trend in activation with duration of extracorporeal support. In non-survivors an opposing trend of increasing activation from admission to the end of stay was seen. Thrombin generation at admission was 62.9 and 105.9 nM at the end of stay. A negative correlation was found between thrombin generation and extracellular DNA ($P = 0.0274$). There was a positive correlation between DNA and neutrophil count ($P < 0.0001$). Extracellular DNA levels were greater in non-survivors than survivors ($P = 0.0001$). Factor XIIa was associated with mortality ($P = 0.048$).

Conclusions: Increasing levels of factor XIIa and extracellular DNA appear to be poor prognostic indicators in patients on ECMO for H1N1. Post-modification of extracellular DNA appears to play an important role in modulating the coagulation response in this clinical setting. It is tempting to suggest factor XII could provide a therapeutic target to prevent or reduce thrombotic risk during ECMO without the additional bleeding side-effects seen with Heparin anticoagulation.

PA 3.15-5

Activation of coagulation factor XII is on the dextran sulfate surface is predominantly an autoactivation via a free substrate mechanism

Terentyeva V and Panteleev MA

Research Center for Hematology, Moscow, Russian Federation

Background: Surface-induced activation of factor XII (fXII) is a crucial event of the internal pathway of blood plasma coagulation. Binding of fXII to the surface causes conformational change which leads to the fXII activation. Although presence of negatively charged surface is known to be necessary for this, the mechanism of this process remains unclear.

Aim: We used mathematical modelling and computer simulations to analyze possible mechanisms of fXII interactions with the surface and identify the correct activation pathway.

Methods: We assumed that there are two steps: spontaneous surface-induced activation of fXII, and consequent autoactovation of fXII by fXIIa. So surface is considered both as a trigger of contact activation and as an immobilization substrate for active form of f XII. Our model is notable for explicit account taken of role of surface concentration and molecular interactions with fXII. The models were solved using MATLAB (the MathWorks, Inc.).

Results: We developed two mathematical models for autoactivation of fXII. The first model required fXII first to bind the surface before it may interact with the surface-bound fXIIa via two-dimensional diffusion and become activated ('bound-substrate model'). According to the second model, surface-bound fXIIa activated a fluid-delivered form of factor XII ('free-substrate model').

We described these events in buffer system which contained pure fXII, trace amounts of factor XIIa (from 0% to 0.01% of total amount of fXII), activation surface (dextran sulfate) and albumin. We evaluated both these models and established that both of them fit with the majority of experimental data. Still, only the 'free-substrate model' was able to describe system's behavior in wide range of surface concentration and to obtain distinctive bell-shaped curve 'rate of activation vs. concentration of surface'.
Conclusion: Analysis of the present study suggests that 'free-substrate model' is the main mechanism of fXII activation during the initial stages of contact activation.

PA 3.15-6

Randomized trial of a quantitative, computerized pretest probability of acute coronary syndrome and pulmonary embolism in emergency department patients: safety, radiation exposure, and cost of care

Kline JA[1], Shapiro N[2], Jones AE[3], Hernandez J[4], Hogg M[4] and Troyer JI[5]

[1]Indiana University, Indianapolis, IN; [2]Harvard School of Medicine, Boston, MA; [3]University of Mississippi, Jackson, MS; [4]Carolinas Medical Center; [5]University of North Carolina, Charlotte, Charlotte, NC, USA

Background: Overtesting for acute coronary syndrome (ACS) and pulmonary embolism (PE) can harm patients.
Objective: Test the hypothesis that Pretest Consult, a validated, computerized method to estimate the pretest probability of both ACS and PE could safely reduce unnecessary exposure to medical radiation and wasted resource use.
Methods: Four center, prospective, randomized trial of medical device efficacy. Inclusions: age > 18, charted evidence of chest pain and dyspnea with a non-diagnostic electrocardiogram. Exclusions: known current diagnosis of ACS or PE, pre-arrival plan for admission from another physician, cocaine use, pregnancy and social situation precluding follow-up. Clinicians entered patient predictor data into Pretest Consult (the device) which randomly assigned to device output or sham. Device output showed estimated probabilities of ACS and PE, linked to specific diagnostic recommendations to minimize radiation exposure and to produce a posterior probability < 1%. Shams received nothing. Protocol-defined 90-day outcomes: (i) Dose (mSv) of chest radiation exposure with attention to the proportion with > 5 mSv radiation to the chest; (ii) Serious adverse events (SAEs) including delayed diagnoses; (iii) Same day admission rate with no significant cardiopulmonary diagnosis and length of stay (LOS); (iv) Readmission rate; (v) Direct costs and charges; (vi) Patient satisfaction. Sample size of 550 estimated to find a 10% difference in proportion with > 5 mSv chest radiation with $\alpha = 0.05$ and $\beta = 0.20$. Two-sided Ps from Mann–Whitney *U* or Exact test.
Results: Data complete for 541 patients. Means of ages and pretest probabilities were well matched between groups. Within 90 days, 16 (3%) patients had ACS and 11 (2%) had PE. No ACS, PE, or any other significant CP diagnosis was found in 236/277 (89%) vs. 242/264 (87%). The following compares the device ($n = 264$) vs. sham ($n = 277$) groups for the five predefined important outcomes: (i) The frequency of diagnosis of ACS or PE tended to be lower with use of the device vs. the sham 9/264 (3.3%) vs. 18/277 (6.5%), $P = 0.07$. (ii) The frequency of all-cause serious adverse events within 90 days tended to be lower with the device: 29/264 (11%) vs. 45/277 (16%) $P = 0.06$ and rate of delayed diagnosis was not different between groups (one had delayed ACS with device and one had delayed PE with sham). (iii) The same-day admission rate of patients who ultimately had no significant cardiopulmonary diagnosis was 104/264 (39%) vs. 119/277 (43%), $P = 0.38$. (iv) The 90 day readmission rate within 90 days was 8% with device vs. 10.5% with sham ($P = 0.3$). (v) The median chest radiation dose was 0.12 vs. 0.62 mSv ($P = 0.04$) and 30% vs. 37% of patients with no significant CP diagnosis had > 5 mSv ($P = 0.1$). (vi) Median costs were \$954 vs. \$1259 ($P = 0.03$) and charges were \$6299 vs. \$7565 ($P = 0.006$). (vii) Patients answered all questions 'very satisfied' in 20 vs. 22% ($P = 0.4$).
Conclusions: During a single encounter, the integration of Pretest Consult into the emergency care of patients with chest pain and dyspnea was safe and resulted in lowered median per patient radiation exposure with significantly lower costs and charges over the next 90 days.

Thrombin and fibrinogen support prostate tumor growth in mice

N Adams G, Miller WM, Rosenfeldt L, Kombrinck KW and Palumbo J

Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

Background: Prostate cancer is the most common form of cancer in men and is second only to lung cancer as a leading cause of cancer related death in men. A role for hemostatic system components in this disease is suggested by previous studies where pharmacological anticoagulants limited prostate cancer growth in mice. Moreover, several clinical studies have shown that men on chronic anticoagulation therapy as well as men with hemophilia have a decreased incidence of prostate cancer, suggesting that hemostatic factors plays an important role in the development and/or progression of this malignancy.
Aim: Test the hypothesis that thrombin-mediated procoagulant function drives prostate cancer growth.
Methods: A transplantable prostate tumor cell line derived from a TRAMP (transgenic adenocarcinoma of the mouse prostate) mouse was inoculated into the dorsal subcutis of congenic C57Bl/6-derived mice with genetically-imposed alterations/deletions in prothrombin, thrombomodulin or fibrinogen.
Results: To determine the role of prothrombin in prostate cancer growth, cohorts of mice with genetically imposed low levels of prothrombin expression (approximately 10%) and wildtype mice were inoculated with TRAMP cells in parallel. Tumor growth was significantly diminished in mice with low prothrombin levels, resulting in an approximately 3-fold genotype-dependent difference in tumor mass by the end of the 3 week study period. Detailed histological analyses of tumor tissue showed a significant diminution in the mitotic index of tumors harvested from mice with low prothrombin levels, suggesting that thrombin function supports the proliferation of prostate cancer cells *in vivo*. Complementary studies of prostate tumor growth were performed in mice carrying a mutation in the native thrombomodulin gene that limits thrombin binding and protein C activation (TM^{Pro}). Here, the shift toward thrombin-mediated procoagulant function imposed by the TM^{Pro} mutation resulted in a significantly increased tumor growth rate relative to mice with normal thrombomodulin. Paralleling results in mice with a quantitative defect in prothrombin, comparisons of prostate tumor growth in fibrinogen-deficient and -sufficient mice revealed that the genetic elimination of this provisional matrix protein significantly limited prostate tumor growth.
Summary: These findings suggest that thrombin-mediated procoagulant function supports prostate tumor growth through at least one mechanism dependent on fibrinogen. These studies also suggest that therapies targeting thrombin or thrombin targets could limit prostate cancer progression.

PA 3.16-2

Effect of heaprins on the progression of tumor growth in mouse lewis lung carcinoma model

Hoppensteadt D, Chaudhry A, Gray A, Hejna M and Fareed J
Loyola University Medical Center, Maywood, IL, USA

Background: Heparin and low molecular weight heparin interact with growth factors and cellular receptors. Preclinical evidence suggests that heparins have an effect on tumor progression independent of anticoagulant activity. This study investigated whether heparin derivatives are able to inhibit tumor growth in a Lewis Lung carcinoma model.
Methods: C57BL/6 mice (6–8 weeks of age) were implanted with 5×10^5 LN7 tumor cells by dorsal subcutaneous injection in the upper back. Once tumors were palpable (7–10 days of growth), mice were treated with subcutaneous injections of heparin, enoxaparin, semuloparin or saline, daily for 2 weeks at approximately 1 cm away from the tumor site, in a dose range of 0.25–1.0 mg/kg. After the treatment period, animals were sacrificed and tumor weight, tumor volume, spleen weight and spleen size were measured. Plasma VEGF levels were measured by ELISA.
Results: At the 1.0 and 0.5 mg/kg dosages, enoxaparin and semuloparin decreased tumor volume compared to the saline control ($P < 0.01$). At the 1.0 mg/kg dosage heparin reduced the tumor size but mortality was higher due to bleeding. At a dosage of 0.25 mg/kg, semuloparin reduced tumor size and weight in comparison to saline control ($P < 0.01$). No significant differences among the agents were noted in spleen weight or size. Mortality rates of enoxaparin and semuloparin treated mice were low (< 10%) and were comparable between the two groups. A significant reduction in VEGF levels in the semuloparin group was observed.
Conclusions: Enoxaparin and semuloparin are more effective at reducing tumor growth compared to heparin. Enoxaparin and semuloparin were safer than heparin at the 1.0 and 0.5 mg dosages in terms of bleeding. Semuloparin downregulated VEGF levels in comparison to the other groups suggesting that this mechanism potentially plays a role in the control of the tumor growth. Therefore semuloparin may be a better alternate for the management of cancer associated thrombosis.

TFPIa and TFPIβ inhibit tumor growth and associate with invasive tumor phenotypes

Tinholt M[1], Stavik B[2], Wiiger MT[3], Louch WE[4], Sletten M[5], Skretting G[2], Mælandsmo GM[3], Sandset PM[2] and Iversen N[5]
[1]Oslo University Hospital; [2]Research Institute of Internal Medicine, Oslo University Hospital; [3]Institute for Cancer Research, Oslo University Hospital; [4]Institute for Experimental Medical Research, Oslo University Hospital; [5]Department of Medical Genetics, Oslo University Hospital and University of Oslo, Oslo, Norway

Background: It is now recognized that tissue factor (TF) is not only expressed in normal tissue cells and trigger blood coagulation, but is expressed by many cancer cells and promotes tumor progression. Targeting TF in cancer may therefore be of dual benefit: (i) prevention of thrombosis, which is common in cancer, and (ii) suppression of tumor progression. TF pathway inhibitor (TFPI) modulates TF induced coagulation. TFPI is mainly expressed by the vascular endothelium, but is also found in cancer cells in two isoforms, TFPIα and TFPIβ. Both isoforms exert antitumor effects, such as increased apoptosis, and reduced proliferation and invasion in cell models.
Aims: To substantiate the role of TFPI in cancer biology, through studying TFPIα and TFPIβ expression- and cell surface association in various breast cancer cells, in relation to invasiveness, TF status and anticoagulant activity. Moreover, we attempt to replicate the antitumor effects of TFPI previously shown in cell models, by *in vivo* tumor growth, in nude mice.
Methods: TFPIα, TFPIβ and TF mRNA expression was measured by qRT-PCR, whereas protein levels were determined by ELISA. TFPI cell association was assessed by flow cytometry, Western blotting and immunofluorescence after phosphatidylinositol-phospholipase C (PI-PLC) treatment, and siRNA knock down of syndecan 1–4. Procoagulant activity was determined in a FXa activity assay. Nude mice were subcutaneously injected with MDA-MB-231 epithelial breast cancer cells with stable TFPI knock down, and tumor growth (mm^3) was monitored for 50 days after injection.
Results: Both TFPIα and TFPIβ mRNA were expressed in breast cancer cells, and expression of the two isoforms were highly correlated ($r = 0.94$, $P < 0.001$). Consistently, TFPIα represented the major isoform expressed, and correlated positively with TF both at mRNA and protein level. High TFPI expression was found in cells from basal-like, invasive tumor subtypes, whereas cells from luminal, non-invasive subtypes showed low TFPI expression.
Approximately 80% of the cell surface attached TFPI was bound through glycosylphosphatidylinositol (GPI), and although such anchoring was evident for both isoforms, TFPIβ represented the main GPI-bound isoform. The GPI-anchored TFPI demonstrated TF-FVIIa inhibitory activity. Additionally, we found that TFPIα was associated with the heparan sulphate proteoglycan syndecan 3, revealing GPI-independent cell association of this isoform in breast cancer cells.
In vivo, significantly smaller tumor sizes were detected in mice injected with breast cancer cells with high endogenous TFPI expression, compared to TFPI knock down cells. This effect was evident for both isoforms. Knock down of TFPI was confirmed in tumor xenograft samples.
Conclusion: From both cell- and animal models, we hereby reveal a biological importance of both TFPI isoforms in cancer. We show that anticoagulant active TFPIα and TFPIβ are expressed in breast cancer cells, and that TFPI is cell associated both through GPI-anchors, and GPI-independent binding to syndecan 3. Tumor growth suppressing effects of both isoforms of TFPI were seen *in vivo* in mice models. Our findings demonstrate a potential dual effect of TFPI in cancer development, both as a tumor suppressor, but also as a counterbalance to the procoagulant activity of TF positive malignant cells.

PA 3.16-4

Endothelial cell protein C receptor attenuates tissue factor-promoted tumor growth of malignant pleural mesothelioma

Pendurthi UR, Pendurthi UR, Keshava S and Rao LVM
The University of Texas Health Science Center at Tyler, Tyler, TX, USA

Background: Tumor cell-associated tissue factor (TF) is known to contribute to tumor growth and metastasis. Recent studies showed that TF contributes to tumor growth in breast cancer through activation of TF-FVIIa-induced PAR2-mediated signaling. However, it is unclear at present whether TF-FVIIa-PAR2 signaling is responsible for TF-driven tumor growth in other types of cancers. Further, it is not entirely clear whether and how other hemostatic receptors present on tumor cells influence TF-dependent tumor growth.
Aim: The aim of the present study is to investigate the role of TF, endothelial cell protein C receptor (EPCR) and protease activated receptor-1 (PAR1) on tumor growth of malignant pleural mesothelioma (MPM) by utilizing MPM cells that lack or express TF, EPCR or PAR1, and a murine orthotopic model of MPM.
Methods: REN, MS-1 and M9K MPM cells were characterized for the expression of TF, EPCR, tissue factor pathway inhibitor (TFPI), thrombomodulin (TM), PAR1 and PAR2 by western blot analysis and/or in functional assays. TF, PAR1 or EPCR was either selectively

knocked-in or knocked-out in aggressive REN MPM cells and non-aggressive MS-1 and M9K MPM cells by stable transfection of plasmid DNA containing TF or EPCR cDNA, or specific shRNA constructs. REN, MS-1 or M9K MPM cells, or their variants (10^6 cells) were injected into the pleural cavity of nude mice (BALB/c, NU/J). Mice were sacrificed between 28 and 30 days following tumor cell implantation, the chest cavities were photographed, tumors were counted, weighed, and their volumes were calculated by measuring their dimensions. Tumor tissue samples were fixed and processed for immunohistochemistry.

Results: REN MPM cells express TF but not TFPI, EPCR or TM. MS-1 cells express TFPI, EPCR but not TF or TM. M9K MPM cells express TFPI, EPCR, TM but not TF. All three MPM cell types express PAR1 but not PAR2. Intrapleural administration of REN MPM cells in nude mice generated large tumors in the pleural cavity, some of tumors reaching the size of the heart. In contrast, intrapleural administration of MS-1 or M9K MPM cells resulted in relatively few tumors, and they barely reached the size of 2 mm. Suppression of TF or PAR1 expression in REN MPM cells markedly reduced the tumor growth. However, overexpression of TF in MS-1 or M9K MPM cells failed to promote the tumorigenicity of these cells. More importantly, introduction of EPCR expression in aggressive REN MPM cells attenuated the tumor growth completely. Conversely, EPCR silencing in MS-1 and M9K MPM cells overexpressing TF dramatically increased the tumorigenicity of these non-aggressive MPM cells. EPCR silencing in native MS-1 or M9K MPM cells did not significantly alter the low growth potential of these cells. Immunohistochemistry of tumor sections revealed that EPCR expression in MPM cells reduced tumor cell proliferation and increased tumor cell apoptosis.

Summary/Conclusions: Overall, our data indicate that TF promotes tumor growth of MPM in a PAR1-dependent mechanism, but expression of EPCR in TF-bearing MPM cells suppresses tumor growth. Our data suggest that EPCR acts as a tumor growth suppressor, at least in MPM.

PA 3.16-5

Role of thrombomodulin in melanoma progression

Oliveira AS[1], Yang L[2], Monteiro Q[1] and Rezaie AR[2]

[1]*Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil;* [2]*Saint Louis University, St. Louis, MO, USA*

Background: Thrombomodulin (TM) is a thrombin receptor that plays critical modulatory roles in inflammation, thrombosis, and carcinogenesis. The expression of thrombomodulin (TM) has been reported to negatively correlate with the metastatic potential of tumor cells. Thus, low TM expression has been found to be associated with high-malignancy phenotypes in oesophageal, lung and liver cancers. Melanoma, the most common fatal form of skin cancer, is an aggressive, therapy-resistant malignancy of melanocytes. The prognosis of patients diagnosed with metastatic melanoma is very poor and treatment alternatives are limited.

Aim: We propose that down-regulation of TM plays an important role in melanocyte transformation and melanoma progression.

Methods/Results: In this study, we monitored the expression of TM in murine and human melanoma cell lines in different stages of aggressiveness. The murine melanoma cell lines TM1 and B16F10, showed higher TM mRNA levels than melan-a (murine melanocyte), as analyzed by real-time PCR. We further analyzed two human melanoma cell lines displaying low (WM35) or high (A375) aggressive phenotypes. The mRNA expression level of TM was modestly (WM35) or dramatically (A375) down-regulated in melanoma cells as compared to human primary melanocytes, The lower expression of TM correlated with their degree of aggressiveness as determined by a migration assay which monitors the transmigration of human melanoma cells across an endothelial cell monolayer in a two chamber transwell plate. Interestingly, the over-expression of TM in A375 cell line reverted its aggressive phenotype as determined by the *in vitro* migration assay. Migration properties of A375 melanoma cells across endothelial monolayer stimulated with either thrombin or activated protein C (APC) were also investigated. The pretreatment of endothelial cells with thrombin significantly improved the migratory properties of A375 cells. By contrast, APC exhibited a protective activity by significantly inhibiting the migration of melanoma cells across the APC-pretreated endothelial cell monolayer.

Conclusion: These results suggest that TM plays a protective role in preventing melanocyte progression to melanoma and that its expression level may be used as an indicator in the prognosis of different stages of metastatic melanoma.

Cisplatin increases tissue factor (TF) procoagulant activity on NT2 germ-cell tumor cells by a mechanism independent of apoptosis induction

Langer F[1], Jacobsen C[1], Spath B[1], Oechsle K[1], Bokemeyer C[1], Ruf W[2] and Honecker F[1]

[1]*University Medical Center Eppendorf, Hamburg, Germany;* [2]*The Scripps Research Institute, La Jolla, CA, USA*

Background: Patients with germ-cell tumors (GCTs) are at increased risk of venous thromboembolism (VTE). Consequently, testicular cancer is categorized as a high-risk tumor entity in the Khorana score for the prediction of VTE risk in ambulatory cancer patients. Furthermore, cisplatin-based chemotherapy has been repeatedly shown to be independently associated with adverse cardiovascular events, suggesting that this cytotoxic drug elicits thrombogenic signals in leukocytes, endothelial and/or tumor cells. However, the molecular mechanisms underlying cisplatin-induced hypercoagulability remain obscure.

Aims: The aim of this study were to characterize constitutive TF expression by four different GCT cell lines and to study the effects of exposure to cisplatin on TF expression by NT2 cells.

Methods: Cell-associated TF procoagulant activity (PCA) was measured by single-stage clotting and fluorogenic thrombin generation assay in the presence or absence of inhibitory TF monoclonal antibody. Surface and total cellular TF antigen were analyzed by single-color flow cytometry and ELISA, respectively. Flow cytometric analysis of annexin V-FITC binding was used to assess phosphatidylserine (PS) membrane exposure on apoptotic cells.

Results: We found that three nonseminoma (NT2, 2102Ep, NCCIT) and one seminoma cell line (TCam-2) displayed significant TF-specific PCA by clotting and thrombin generation assay. Furthermore, all four cell lines stained positive for TF antigen by flow cytometry. Incubation of NT2 cells with 0.4 μM cisplatin (corresponding to the IC_{50} according to MTT cytotoxicity assay) for 48 h enhanced PS membrane exposure from 24 ± 11% to 38 ± 15% positive cells and increased cellular TF PCA 4.5-fold compared to vehicle-treated controls ($P < 0.01$). Interestingly, flow cytometry revealed enhanced TF antigen expression on both apoptotic and non-apoptotic cells, suggesting a mechanism of cisplatin-induced TF PCA expression independent of TF de-encryption during cell death. In line with this hypothesis, incubation of cisplatin-resistant NT2-R cells with 0.4 μM cisplatin had no effect on PS exposure (positive cells, 24 ± 5% vs. 25 ± 7%, $P = 0.4$), but dramatically increased cell-associated thrombin generation in a TF-dependent manner and induced TF-specific PCA 3.7-fold by single-stage clotting assay ($P < 0.01$), an effect accompanied by enhanced surface TF antigen staining (TF-positive cells, 15 ± 5% vs. 7 ± 3%; $P < 0.01$). Quantification of total TF antigen in cell lysates by ELISA revealed a 1.9- and 2.2-fold increase in cisplatin-treated NT2 and NT2-R cells, respectively, a finding that was also confirmed by Western blot analysis.

Conclusion: Constitutive TF expression may be a characteristic feature of GCT cells, possibly contributing to the elevated VTE risk in affected patients. Moreover, cisplatin-based chemotherapy may further potentiate this risk by increasing tumor cellular TF PCA indepen-

dently of apoptosis induction, e.g. via de-novo protein synthesis and/or inhibition of TF recycling.

Thrombophilia and outcomes of ART procedures: a prospective Italian cohort study

Villani M[1], Tiscia G[1], Dentali F[2], Colaizzo D[1], Cappucci F[1], Fischetti L[1], Ageno W[2], Margaglione M[3] and Grandone E[1]
[1]*Casa Sollievo della Sofferenza, San Giovanni Rotondo;* [2]*University of Insubria, Varese;* [3]*University of Foggia, Foggia, Italy*

Background: Clinical pregnancy rate after Assisted reproductive technologies ART (ART) is low (20–35% per cycle started). Venous thromboembolism (VTE) and arterial thrombosis can occur after administration of drugs for ovulation induction. It is still controversial whether the presence of a thrombophilia could predispose women to infertility or to an adverse obstetric outcome following an ART cycle. However, many Infertility Clinics prescribe thrombophilia tests to all the women approaching this type of procedure, independently of the presence of additional risk factors. Low Molecular Weight Heparin (LMWH)and aspirin have been hypothesised to be effective in increasing clinical pregnancies rate in patients undergoing ART.
Aims: (i) To evaluate the prevalence of inherited and acquired thrombophilias in a large cohort of women suffering from infertility; (ii) to compare obstetric outcomes *before* and *after* performing screening and according to the presence and type of thrombophilia observed; (iii) to prospectively evaluate obstetric outcomes and thrombotic risk in women undergone thrombophilia screening according to the use of antithrombotic treatments.
Methods: Participants were 1107 women with fertility problems and a valid indication for ART treatment consecutively referred to our Atherosclerosis and Thrombosis Unit, between March 1998 and July 2011. All the participants were investigated for inherited and acquired thrombophilias. Before the thrombophilia screening data regarding maternal age, previous pregnancies and indication for treatment were collected. For each woman following information was collected for analysis: number of cycles and type of treatment (IUI/IVF/ICSI), antithrombotic prophylaxis (yes/no), antithrombotic drugs (low-dose aspirin, LMWH or both), period of prophylaxis and treatment outcomes.
The study was approved by the local ethics committee and complies with Declaration of Helsinki. Participants gave their written informed consent for present and future use of the clinical data.
Results: Median follow-up was 34.53 months (range 2–143 months). At the enrolment, 327 women (29.5%) have experienced 946 ART cycles. One hundred and twenty-two (37.3%) women obtained a clinical pregnancy (176 pregnancies), with 21(16%) live- born children. Overall, 115 (10.4%) women carried al least one thrombophilia (45 the FVL, 57 the PTm, 13 severe thrombophilias).
After screening, 595 (53.8%) underwent at least one attempt (1268 cycles, 27 lost to follow-up). In 424 (33.4%) cycles an antithrombotic prophylaxis (342 treated with aspirin, 66 with LMWH, 16 with aspirin + LMWH) was used. Pregnancy rate was 21.4% (265/1241 cycles) with 171 (13.8%) live-born children. A clinical pregnancy was obtained in 96 out of 424 (22.6%) treated cycles (*P*: 0.42, OR: 1.1, 95%CI: 0.8–1.5 vs. pregnancy rate in untreated cycles). The rate of live-born was not significantly different in treated vs. untreated cycles (*P*: 0.73, OR: 0.9, 95% CI: 0.6–1.3) prophylaxis. Overall, seven thrombotic events (three PE, three DVT, one arterial thrombosis; six of them in untreated women) were observed. Among them, 4 (0.3%, 2 DVT, 2 PE) occurred after screening, only one during LMWH prophylaxis.
Summary/Conclusions: The use of antithrombotic prophylaxis is not associated with an improved pregnancy rate or live-born children after ART. Thrombotic complications are less frequent in women receiving an antithrombotic prophylaxis.

PA 3.17-2

Unfractionated heparin, not enoxaparin, prevents down-regulation of endothelial protein C receptor by a pro-inflammatory cytokine on first trimester trophoblasts

Faioni EM, Fontana G, Razzari C, Calvi E, Avagliano L, Bulfamante G and Marconi AM
University of Milano, Milano, Italy

Background: Human first trimester trophoblasts must differentiate and invade the maternal endometrium, as well as give rise to placental villi. They come into contact with the maternal blood, contribute to changes in the maternal spiral arteries, and possibly participate in immune tolerance. Though anticoagulation and control of inflammation were shown to be strongly interconnected in many cell systems, to our knowledge no studies addressing directly the function and modulation of the anticoagulant pathway in human trophoblasts have been published. The importance of gaining basic knowledge on the anticoagulant functions of human trophoblasts has important clinical implications, because heparin prophylaxis is often given, albeit with no clear evidence-based benefit, to women with placenta-mediated obstetric complications (recurrent abortion, abruptio placentae, intrauterine growth restriction, late fetal death, pre-eclampsia) that may involve, at some point, a thrombotic event in the placental vessels.
Aims: To identify components of the protein C pathway on human first trimester trophoblasts, to evaluate protein C activating capacity on the trophoblast cell surface, and to test the effect of inflammatory mediators in the absence or in the presence of heparin on the expression of the anticoagulant pathway components on these cells.
Methods: Trophoblasts were isolated from first trimester placental tissue by sequential purification steps (99% purity). They were cultured in the presence or absence of various agents (TNF alpha, unfractionated heparin UFH, enoxaparin, alone and in combination) for maximum 24 h. Expression of thrombomodulin (TM) and endothelial protein C receptor (EPCR) was evaluated by flow citometry, RT-PCR and Western blot. Protein C (50 nM) activation was measured by a colorimetric assay, after thrombin addition (2 nM) to cultured trophoblasts.
Results: Human first trimester trophoblasts (cytokeratin seven positive, vimentin negative, HLA-G positive or negative) express EPCR and TM with variable intensity as mRNA, at the protein level and on the cell surface. Cultured, freshly isolated human trophoblasts activate protein C (1.1×10^{-7} nM/min/cell) at least to the same extent as HUVECs (1.56×10^{-14} nM/min/cell). When stimulated with the pro-inflammatory cytokine TNF-alpha (1 nM), EPCR but not TM expression was down-regulated by approximately 20%. EPCR downregulation was completely prevented by addition of UFH (1 IU/mL), but not by enoxaparin.
Summary/Conclusion: Human first trimester trophoblasts express a functional protein C anticoagulant pathway that can be modulated by inflammatory mediators such as TNF alpha, as in other tissues. Unfractionated heparin, but not enoxaparin, protects the trophoblast from TNF alpha-mediated down-regulation. If confirmed by further studies, these results may have important clinical implications.

PA 3.17-3

Prospective crossover trial of oral tranexamic acid and combined oral contraceptives in adolescent menorrhagia – interim report of a pilot study

Srivaths LV[1], Dietrich JE[1], Yee DL[1], Sangi-Haghpeykar S[2] and Mahoney D Jr[1]

[1]*Texas Children's Hospital/Baylor College of Medicine, Pearland, TX;* [2]*Baylor College of Medicine, Houston, TX, USA*

Background: Oral tranexamic acid (TA), an anti-fibrinolytic agent, has been shown to be more efficacious than progesterone-only hormonal therapy for menorrhagia in adult women. In adolescents with menorrhagia, TA has not been formally compared to the commonly prescribed combined oral contraceptive pills (COCP).

Aim: Among adolescents with menorrhagia, we hypothesized that oral TA would have equal or greater efficacy in reducing menstrual blood loss and improving quality of life when compared to COCP.

Method: Among adolescents with menorrhagia without an underlying bleeding disorder, organic pelvic pathology or thyroid disorder, a cross-over trial was undertaken as approved by the Institutional Review Board, to study the efficacy of TA (given according to FDA label for adult women at 1300 mg tid for 5 days, off-label use for adolescents < 18 years of age) vs. COCP (30 μg ethinyl estradiol/0.3 mg norgestrel daily, 21 days on/7 days off per cycle). This study was funded by Texas Children's Hospital's Pediatric Pilot Award. Informed consent was obtained from study participants/parents. Each medication was prescribed for three menstrual cycles with a 1 month wash out in-between medications. Menstrual cycle length, Periodic Blood Assessment Chart (PBAC) score for menstrual blood loss estimation, and quality of life assessment with PedsQL questionnaire was assessed at baseline and at the end of each medication arm. Data was analyzed using the mixed models repeated measure design in SAS.

Results: Seventeen patients were enrolled after obtaining informed consent; the mean age was 14.2 years (range 11.7–16.7). Five completed both arms of the study; two each are completing the first and second arm, resulting in nine currently evaluable patients. Eight patients were withdrawn from the study (2- due to adverse events, six for other reasons related primarily to study compliance).

When compared to baseline, significant improvement ($P < 0.05$) was demonstrated by both TA and COCP, in the length of menstrual cycle (mean reduction of 8.4 and 6.7 days), PBAC scores (mean score decrease of 578 and 552), and quality of life (mean score decrease of 17 and 14), though there were no statistically significant differences between TA and COCP ($P > 0.05$). All patients on TA reported 100% compliance while 57% on COCP reported periods of non-compliance. Seven patients (41%) experienced adverse events that were possibly drug-related – two on TA (28%; all mild – breakthrough bleeding/vomiting, lack of sleep) and five on COCP (62%; three mild – breakthrough bleeding, headache/weight gain, mood swings, two severe – seizure, generalized rash). None developed thrombosis.

Summary/Conclusion: This study is ongoing with four actively enrolled patients. Preliminary analysis of this ongoing pilot study suggests that TA may have efficacy comparable to COCP and holds promise for better control of menstrual bleeding, better quality of life, less toxicity and higher compliance likely due to the shorter duration of medication administration. Larger studies are needed to confirm these benefits of oral TA in menorrhagic adolescents as observed in our pilot study.

PA 3.17-4

Low-molecular-weight heparin added to aspirin in the prevention of recurrent early-onset preeclampsia in women with antiphospholipid antibodies

Van Hoorn M[1], Hague WM[2], Van Pampus MG[3], Bezemer P[1] and De Vries JI[1]

[1]*VU University Medical Centre, Amsterdam, The Netherlands;* [2]*Robinson Institute, University of Adelaide, Adelaide, SA, Australia;* [3]*University Medical Centre, Groningen, The Netherlands*

Background: Early-onset hypertensive disorders (HD) and small-for-gestational age infants (SGA) are associated with placental vascular thrombosis, inheritable thrombophilia and antiphospholipid antibodies. Aspirin reduces the recurrence risk. Recently we reported the results of the FRUIT-RCT (ISRCTN 87325378) in women with a previous delivery for HD/SGA < 34 weeks and shown to have an inheritable thrombophilia without antiphospholipid antibodies: adding low-molecular-weight heparin (LMWH) to aspirin before 12 weeks gestation reduces recurrent HD onset < 34 weeks gestation. Here we present the results on women with antiphospholipid antibodies and no inheritable thrombophilia.

Aims: Adding LMWH to aspirin to reduce HD in women with previous early-onset HD (preeclampsia, HELLP syndrome, eclampsia) and/or SGA in the context of antiphospholipid antibodies.

Methods: In a multicentre RCT, 30 women were included before 12 weeks gestation. *Inclusion criteria*: previous delivery < 34 weeks gestation with HD and/or SGA; antiphospholipid antibodies (anti-cardiolipin antibodies > 10 GPL and/or MPL and/or lupus anticoagulant). *Intervention*: either daily LMWH (dalteparin, 5000 IU weight adjusted dosage) with aspirin 80 mg or aspirin 80 mg alone. *Primary outcomes*: recurrent HD onset (i) < 34 weeks and (ii) irrespective of gestational age. *Secondary outcomes*: recurrent SGA, preterm birth, maternal/neonatal hospitalization, spontaneous abortion and individual HD. *Analysis* by intention-to-treat. *Power calculations*: based on recurrence rate of 60% in Dutch population, 84 women needed to be randomized to detect a 50% reduction (two-tailed, an alpha of 0.05 and a power of 80%) and 66 inclusions for one-tailed, expecting no worsening of the outcome by LMWH.

Results: After the conclusion of the inheritable thrombophilia arm of the trial and given the low inclusion rate of women with antiphospholipid antibodies, an interim analysis was performed after delivery of 29 women, resulting in the advice to cease recruitment since accrual was low and the incidence of early onset HD was far lower than expected. The final analysis, performed on 30 women, did not reveal a reduction in the primary outcomes in the LMWH-and-aspirin arm, although there were no cases of HD. In the aspirin-only arm, there were two cases of HD, one before 34 weeks. Secondary outcomes did not differ between arms. No woman withdrew as result of adverse effects. Fourteen eligible women refused enrolment. Per-protocol analysis on 32 women did not alter the results.

The mean gestational age at delivery of the index pregnancies was 29 weeks, with 18 children born alive. The trial pregnancies had a mean gestational age at delivery of 37 weeks with all infants alive at birth. A single case of placental abruption occurred in the aspirin-only arm at 27^6 weeks in a woman hospitalized for fetal growth restriction and no HD; her index pregnancy had been terminated at 26^2 weeks for placental abruption and HD.

Conclusion: Adding LMWH to aspirin before 12 weeks gestation in women with antiphospholipid antibodies and prior delivery for HD/SGA < 34 weeks did not reduce recurrent HD either < 34 weeks or irrespective of gestational age.

PA 3.17-5

The minimal effective dose of tranexamic acid in women with menorrhagia

Price VE[1], VanOosten S[2], Conlon R[2], Richard J[2], Hawes SA[1], MacDonald T[1], Wenning J[3], Van Eyk N[3], Abdolell M[4] and Robinson KS[5]

[1]IWK Health Centre; [2]Divison Of Hematology, Queen Elizabeth II Health Sciences Centre; [7]Department of Diagnostic Radiology, Dalhousie University; [5]Queen Elizabeth II Health Sciences Centre, Halifax, NS, Canada

Background: Menorrhagia is a common problem, affecting up to 15% of premenopausal women, that negatively impacts health and quality of life. Ten-30% of these women will have underlying bleeding disorders that are often not diagnosed until adulthood. Antifibrinolytic therapy with tranexamic acid (TA) represents a non-hormonal treatment option that reduces menstrual blood loss by up to 50%. However, its use is limited by dose dependent side effects and cost. The recommended dose is 3000–6000 mg/day, but in our experience a lower dose, with less side effects, is efficacious for the majority of women.

Aims: To determine if the minimal effective and tolerated dose (MED) of tranexamic acid for women with menorrhagia who have bleeding disorders is lower than the recommended dose in Canada of 4000 mg/day. A secondary objective is to determine if there is a difference in the MED of women with and without a bleeding disorder.

Methods: An open-label, uncontrolled, prospective dose escalation study is underway. Women 15–50 years with objective menorrhagia as defined by a and Pictorial Blood Assessment Chart (PBAC) score > 100, referred to a Hematology or Gynecology clinic are eligible for inclusion. The starting dose of TA is 1000 mg/day and may be escalated twice per cycle for a maximum of three cycles to a maximum dose of 6000 mg/day. Criteria for escalation are based on a quality of life assessment PBAC score. Any side effects are monitored. The MED is defined as the dose at which the PBAC score is < 100 or a percentage decrease in the PBAC score that is associated with the ability to continue normal daily activities. All women who had menorrhagia from menarche, and/or iron deficiency and/or any other bleeding history are investigated for an underlying bleeding disorder.

Results: We report the analysis of 71 women who have participated in the study to date. The mean age is 37.7 years (range 15.6–50.2 years). There are 16/71 (22.5%) with bleeding disorders, including 6 -Von Willebrand Disease (1 type 3, 5 type 1), 1-Hemophilia A carrier, 1-Immune thrombocytopenia 1-Plasminogen activator inhibitor-1 deficiency and 7-platelet dysfunction. The mean PBAC score at study entry for the entire group is 320 (range 104–1340), and for those with bleeding disorders, 353 (157–954). The mean end of study PBAC score for the entire cohort is 163 (range 15–664).The mean MED for the entire group was 2000 mg/day (1000 mg BID) and there was no difference between those with and without bleeding disorders. Iron deficiency was common with 69/71 women having s-ferritin < 30 μg/L. Tranexmaic acid was well tolerated and none of the participants stopped the medication prior to completion of the study.

Conclusion: Tranexamic Acid is an effective medication for women with menorrhagia and appears to be equally effective in women with underlying bleeding disorders. The mean MED was 50% less than the recommended dose in Canada for women with and without bleeding disorders. These preliminary findings may support the use of tranexamic acid at a lower than recommended dose and therefore be of benefit to a greater proportion of women with menorrhagia.

Oral contraceptive use and tamoxifen therapy are not associated with increased levels of thrombin or impaired endogenous APC formation

Rühl H[1], Schröder L[1], Müller J[1], Fimmers R[1], Sukhitashvili S[1], Welz J[1], Kuhn W[1], Oldenburg J[1], Rudlowski C[2] and Pötzsch B[1]

[1]University Hospital Bonn, Bonn; [2]Evangelisches Krankenhaus Bergisch Gladbach, Bergisch Gladbach, Germany

Background: Acquired resistance to activated protein C (APC) is a common phenotype in women receiving estrogen containing oral contraceptives (OC) or a selective estrogen receptor modulator (SERM).

Aims: To study if acquired APC resistance is associated with increased levels of thrombin formation we measured plasma levels of free thrombin and thrombin generation markers before and during OC use or SERM treatment. Simultaneously, plasma levels of APC were measured to identify a hormone associated endothelial cell dysfunction leading to impaired APC generation rates.

Methods: Blood samples were taken from women before starting with estrogen containing OC use or therapy with the SERM tamoxifen and in the first 3 months of application on a monthly basis. Thrombin and APC plasma levels were determined using recently developed oligonucleotide-enzyme capture assays (OECA) showing limits of detection of thrombin and of APC of 0.47 pM (17 pg/mL) and 0.39 pM (22 pg/mL), respectively. APC sensitivity was evaluated on basis of the effect of APC on the endogenous thrombin generation potential (ETP). In addition, plasma levels of coagulation factors fibrinogen, II, V, VII, VIII, IX, X, XI, XIII and of antithrombin (AT), protein C, d-dimer, prothrombin fragment 1 + 2 (F1 + 2), thrombin-AT-(TAT)-complexes, plasmin-α2-antiplasmin-(PAP)-complexes, and tissue-type plasminogen activator (t-PA) were measured using routinely established assays.

Results: Twenty-one women of the OC group (mean age, range: 21, 15–40 years) and 25 patients of the tamoxifen group (51, 28–71 years) were available for analysis. In both cohorts similar numbers of blood samples showed thrombin or APC levels above the respective limits of detection. OC use and SERM treatment were not associated with increased thrombin levels or a decrease in APC levels. APC sensitivity was significantly reduced in blood samples taken after 1 month of OC use ($P = 9 \times 10^{-6}$) or tamoxifen therapy ($P = 0.002$) in comparison to baseline results. The levels of indirect markers of thrombin formation F1 + 2, and TAT-complexes did not change significantly under OC or tamoxifen application. Observed changes of other parameters were consistent with previous reports. Coagulation factors, protein C, and PAP-complexes increased after start of OC use while AT and t-PA decreased. Under tamoxifen therapy coagulation factors, inhibitors, PAP-complexes, and d-dimer decreased over time while t-PA remained unchanged.

Summary/Conclusion: This study demonstrates that the hormone-induced APC-resistance phenotype is not regularly associated with increased rates of thrombin formation. As there was no dysbalance between plasma levels of thrombin and of APC, it seems unlikely that a hormone-induced endothelial cell dysfunction leading to impaired APC formation is involved in the pathogenesis of hormone related thrombosis.

Alterations of neutrophils production and functions at early stage of metabolic syndrome in a high fructose rat model

Tagzirt M[1], Corseaux D[2], Pasquesoone L[2], Mouquet F[2], Ung A[2], Elkalioubie A[2], Jude B[2], Van Belle E[2], Susen S[2] and Dupont A[2]
[1]*Faculté de Médecine;* [2]*EA2693, Lille, France*

1 In recent years, it became clear that the inflammatory response is intrinsically linked to metabolic pathways in vertebrates. Thus, a chronic and systemic low-grade inflammatory state is observed in metabolic syndrome (MetS) defined by a cluster of metabolic abnomalies including intra-abdominal adiposity, dyslipidemia, high blood pressure and altered glucose tolerance. This common disorder represents a major risk factor for atherosclerotic cardiovascular disease. The prevalence of MetS has dramatically increased worldwide due to a modern lifestyle and an increased of consumption of high-sugar diets especially fructose. By contrast to macrophage, neutrophils have classically received only little attention in MetS because these inflammatory cells were rarely detected in adipose tissue (AT).

2 We hypothesized that neutrophils' infiltration into AT may occur at early stage of MetS, in association with modulation of their major functions (activation, reactive oxygen species production, phagocytosis, apoptosis) and of their bone marrow production.

3 To test these hypotheses, we analyzed circulating neutrophil functions, their AT infiltration levels and the bone marrow efficiency in producing neutrophils at early stage in a high-fructose-fed Sprague-Dawley rat model. Male Sprague–Dawley rats were on regular (control rats [CR]) or fructose-enriched (60%) (fructose-fed rats [FFR]) diet during 6 weeks.

4 Compared to the CR group, the FFR group developed MetS i.e, hypertension, hypertriglyceridemia, fasting hyperglycemia and greater intra-abdominal AT volume and presented higher neutrophils infiltration in intra-abdominal AT ($+1.9 \pm 0.04$ fold increase, $P = 0.03$).

At resting state, no significant difference for circulating neutrophils functions was observed between two rats groups. In contrast, stimulated-neutrophils from the FFR group exhibited higher responses for all studied functions, compared to the CR group. Regarding PMA (1 μM) -activated neutrophils, CD18 (1.5 ± 0.04 fold increase, $P = 0.01$) and CD11b (1.3 ± 0.03 fold increase, $P = 0.02$) surface expression, and ROS production (1.5 ± 0.01 fold increase, $P = 0.001$) were significantly higher in the FFR group compared to the CR group. After activation with opsonized E. coli, significantly increased neutrophil phagocytic activity was observed in the FFR compared to the CR group (1.3 ± 0.02 fold increase, $P = 0.002$). These results suggest that early MetS induces circulating neutrophils priming.

In parallel, in bone marrow from FFR group, we observed a diminished clonal capacity of neutrophils progenitors (154.6 ± 12.77 vs. 206.5 ± 14.83, $P = 0.02$) and a higher proportion of apoptotic cells in granulocytic population (2.1 ± 0.03 fold increase, $P = 0.01$).

1. In conclusion, the results of this study provide evidence that at early stage of MetS, production, phenotype and function of neutrophils are modified that may explain the higher neutrophils infiltration in intra-abdominal AT infiltration. Understanding the contribution of neutrophils at early stage of MetS would help in development of novel therapies strategies against detrimental effects of this syndrome.

PA 3.18-2

The role of plasmin(ogen) in the pathogenesis of inflammatory bowel diseases

Inaba S[1], Kanno Y[1], Kawashita E[1], Okada K[2], Ueshima S[2], Matsuo O[2] and Matsuno H[1]
[1]*Doshisha Women's Collage of Liberal Arts, Kyo-Tanabe;* [2]*Kinki University School of Medicine, Sayama, Japan*

Background and Aim: Inflammatory bowel diseases (IBD) are characterized by a chronic inflammation of the gastrointestinal tract, and are associated with defects in innate and adaptive immune pathways. However, the primary cause of IBD remains unclear. Plasmin(ogen) is an extracellular serine protease (zymogen), resulting in the activation of latent growth factors and matrix metalloproteases, degradation of extracellular matrix components, and fibrin clearance. It has reported that plasminogen (Plg) deficiency in mice results in spontaneous gastrointestinal ulceration. Plasmin(ogen) may play an important role in the pathogenesis of IBD. Therefore, we investigated the role of plasmin(ogen) in the pathogenesis of IBD.

Methods: We evaluated the parameters of intestinal inflammation in the wild type (Plg $^{+/+}$) and Plg deficient (Plg $^{-/-}$) mice. In addition, we examined that the effect of plasmin in intestinal epithelial Caco-2 cells.

Results: Plg deficiency in mice caused the reduction of colon lengths, and the increase of fecal IgA, proinflammatory cytokines expression, macrophages and T cells infiltration in colon. In addition, we found that Plg deficiency in mice promoted the increase of microfold cells (M cells) which acts as gatekeepers to the mucosal immune system. We also found that plasmin attenuated interleukin-1β (IL-1β)-induced the expression of receptor activator NF-κB ligand (RANKL) which regulates M cells differentiation in Caco-2 cells. Moreover, plasmin attenuated RANKL-induced M cells differentiation.

Conclusion: Plasmin(ogen) is associated with M cells differentiation by regulating the RANKL expression and RANKL-stimulated signal pathways. The excessive production of M cells by the defect of plasmin(ogen) might play an important role in the pathogenesis of IBD, and the regulation of plasmin(ogen) expression might provide a novel therapeutic approach to IBD.

SMTP-7, a novel anti-inflammatory thrombolytic, treats serious cardioembolic stroke in a monkey model

Nishimura N[1], Sawada N[1], Hasegawa K[1] and Hasumi K[2]
[1]*TMS Co., Ltd.;* [2]*Tokyo University of Agriculture and Technology, Tokyo, Japan*

Background: Stroke is one of the major causes of death in industrialized countries. From WHO statistics, more than 6 million peoples die from stroke every year, and 80% of which is due to ischemic stroke. Moreover, it is also a problem of long-term hospitalization and sequelae. For the treatment of the acute cerebral infarction, rt-PA has been used as the standard drug. However, since rt-PA may cause serious hemorrhage side effect, only a few percent of the stroke patients benefits from rt-PA therapy. SMTP-7, a novel small molecule produced by a fungus, *Stachybotrys microspore*, promotes clot clearance and suppression of inflammatory and oxidative responses *in vivo*.

Aims: We attempted to obtain insights into therapeutic potential of SMTP-7 in comparison with rt-PA in a serious cardioembolic stroke model in a primate (cynomolgus monkey).

Methods: The monkey model of cerebral infarction was produced by injecting a blood clot that was generated from autologous blood into the middle cerebral artery. Three hours after injection of the clot, SMTP-7 (10 mg/kg, iv), rt-PA (3 mg/kg, iv) or saline were infused for 30 or 60 min.

Results: Cerebral infarct volume, neurological deficit score, and rate of cerebral edema were examined at 24 h after the thrombus injection.

The mean cerebral infarction volume was 10.12% in the SMTP-7 treated monkeys, 29.2% in the saline group, and 17.4% in the rt-PA group. The total of the neurological deficit score was 43 points in the SMTP-7 group, while 47 points in both the saline and rt-PA groups. The rate of cerebral edema in the SMTP-7 group was lower than those of in the saline and rt-PA group. Further, in the SMTP-7 treated monkeys, bleeding time was comparable to the saline group.
Conclusions: Our results showed that SMTP-7 is more effective and less hemorrhagic than rt-PA in a serious cardioembolic stroke model in monkeys. Taking that SMTP-7 has dual mode of action, thrombolytic and anti-inflammatory, this drug is clearly distinct from rt-PA in its molecular mechanism of action. This notion is supported by the present experiments using a primate model. Thus SMTP-7 can be the first, innovative one in a new category of drugs that treat acute ischemic stroke.

PA 3.18-4
Platelet-mediated innate immunity via toll-like receptor 2 stimulation and subsequent serotonin release

Duerschmied D[1], Canault M[2], Koch P[1], Peter K[3], Alessie M-C[2], Bode C[1] and Ahrens I[1]
[1]*Heart Center Freiburg University, Freiburg, Germany;* [2]*Université de la Méditerranée, Marseille, France;* [3]*Baker IDI, Melbourne, Vic., Australia*

Introduction: The innate immunity-mediating toll-like receptors (TLRs) influence the course of atherosclerosis. Platelets are involved in early and late stages of atherosclerosis and the stimulation of platelet TLR2 at high agonist concentrations induces platelet activation. It was previously shown that platelet serotonin induces activation of platelet tumor necrosis factor alpha converting enzyme (TACE), resulting in shedding of the adhesion molecule glycoprotein (GP)Ibalpha. We hypothesized that immunological platelet stimulation via TLR2 regulates serotonin release.
Methods: Platelet TLR2 was stimulated by incubation of human platelets with the TLR2 agonist Pam3CSK4 and compared to platelet activation by adenosine diphosphate (ADP, 20 μM), thrombin receptor activating peptide (TRAP, 30 μM), and phenylmaleinine phenylmaleic anhydride (PMA, 75 nM). Expression of surface markers was quantified by flow cytometry. Serotonin release was measured by high-sensitivity ELISA and dense granule release by electron microscopy. Leukocyte-endothelial interactions were analyzed by intravital microscopy.
Results: Incubation of platelets in the presence but not absence of plasma with Pam3CSK4 resulted in a dose-dependent increase of the surface expression of P-selectin and activated GPIIb/IIIa (up to 10-fold increase after incubation with 10–100 μg/mL Pam3CSK4, $P < 0.01$, $n = 8$). High-dose Pam3CSK4 also induced shedding of the TACE substrate GPIbalpha (50% decrease with 50 μg/mL Pam3CSK4, $P < 0.01$, $n = 8$) and exposure of phosphatidylserine (annexin V binding with > 10 μg/mL Pam3CSK4). Serotonin release was triggered by TLR2 stimulation with much higher potency: doses of Pam3CSK4 (0.1 μg/mL) that did not change P-selectin, GPIIb/IIIa activation, or GPIbalpha induced strong serotonin release ($P < 0.01$, $n = 8$). Perseverance of intact dense granules that did not undergo exocytosis suggested active serotonin release via membrane transporters.
Conclusion: Platelet TLR2 stimulation induces serotonin release much more potently than regular, 'hemostatic' platelet activation. This mechanism may constitute a novel innate immune function of platelets via selective release of the immuno-modulator serotonin.

PA 3.18-5
The role of a2AP in the development of renal interstitial fibrosis

Kanno Y[1], Kokado A[1], Kawashita E[1], Tani M[1], Okada K[2], Ueshima S[2], Matsuo O[2] and Matsuno H[1]
[1]*Doshisha Women's College of Liberal Arts, Kyoto, Japan;* [2]*Kinki University School of Medicine, Sayama, Japan*

Background and Aim: Renal interstitial fibrosis is characterized by the excessive production, deposition and contraction of the extracellular matrix (ECM) protein, and is associated with macrophages infiltration and myofibroblats accumulation. In the process, the macrophages induce myofibroblats differentiation through the production of profibrotic factors, such as transforming growth factor-β (TGF-β) and connective tissue growth factor (CTGF), and then myofibroblasts promote the excessive production of the extracellular matrix (ECM) protein. However, the detailed mechanism remains unclear. We herein investigated the role of alpha 2-antiplasmin (α2AP) in the development of renal interstitial fibrosis in the obstructed kidney.
Methods: Renal interstitial fibrosis was induced by using unilateral ureteral obstruction (UUO) model in the wild type (α2AP+/+) and α2AP deficient (α2AP−/−) mice, and then we examined collagen deposition (Srius Red staining), myofibroblast differentiation (α-smooth muscle actin staining), macrophages infiltration (F4/80 staining) and the expression of α2AP. In addition, primary cultured macrophages from the α2AP+/+ or α2AP−/− mice were co-cultured with fibroblasts, and then we examined the degree of myofibroblast differentiation in fibroblasts.
Results: We found that the accumulation of α2AP was induced in the obstructed kidney, and α2AP deficiency in mice attenuated UUO-induced renal interstitial fibrosis. In addition, although α2AP deficiency did not affect UUO-induced macrophages infiltration, the degree of the myofibroblats differentiation in the co-culture of fibroblasts and α2AP−/− macrophages was significantly less than that in α2AP+/+ mice. We also found that CTGF induced the production of α2AP through integrin β3, ERK1/2, and JNK pathways in macrophages.
Conclusion: CTGF induced the expression of α2AP in macrophages, and CTGF-induced α2AP is associated with the development of renal interstitial fibrosis. The inhibition of α2AP-initiated pathways might provide a novel therapeutic approach to fibrotic diseases.

PA3.19 – Non-Inherited Risk Factors VT – IV

Prediction of risk of venous thrombosis after cast immobilization of the lower extremity

Nemeth B[1], Van Adrichem RA[1], Le Cessie S[1], Van Hylckama Vlieg A[1], Bucciarelli P[2], Martinelli I[2], Baglin TPT[3], Rosendaal FR[1] and Cannegieter SC[1]
[1]*Leiden University Medical Center, Leiden, The Netherlands;* [2]*Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy;* [3]*Addenbrookes Hospital, Cambridge, UK*

Background: Guidelines and clinical practice vary considerably with respect to antithrombotic treatment during plaster cast immobilisation of the lower extremity. This is partly due to the wide range of incidence rates that have been reported (asymptomatic venous thrombosis (VT): 4.3–36%; symptomatic VT: 0–5.5%). Knowledge on factors associated with an increased risk would provide a better basis to decide on individual thromboprophylaxis use.
Aims: To investigate the predictive value of genetic and acquired risk factors, levels of coagulation factors and other biomarkers on the occurrence of VT after cast immobilisation of the lower extremity.

Methods: We used data from a large population based case-control study (MEGA study, 4468 cases, 6156 controls, consent and ethical approval obtained) into risk factors for a first VT. Identification of predictor variables to be included in the model was mainly based on reported associations in the literature or on a relative risk (RR) > 1.2 or $P \leq 0.25$ in the univariate analysis. Using multivariate logistic regression several prediction models were created to determine the additional predictive value of genetic factors and biomarkers. In addition to the complete model (all variables), a reduced model (minimum number of predictors with a maximum predictive value) and a clinical model (acquired risk factors only, no blood draw and assays required) were created. To determine the discriminatory power, the area under the curve (AUC) was calculated by means of a receiver operating characteristic. Validation was performed in another case control study into the aetiology of VT (THE VTE study, 784 cases, 523 controls with valid information on all acquired risk factors, Leiden/Cambridge) and is about to be repeated in a third (the Milan study 1765 cases, 2088 controls).
Results: The complete prediction model consisted of 30 predictors including three genetic factors and six biomarkers. For this model, an AUC of 0.89 (95% CI; 0.85–0.94) was found in subjects with plaster cast of the lower extremity compared with an AUC of 0.84 (95% CI; 0.78–0.90) for the clinical model (consisting of only 13 acquired predictors). The addition of biomarkers to the clinical model resulted in a higher AUC than addition of genetic risk factors, with an AUC of 0.88 (95% CI; 0.84–0.93) vs. an AUC of 0.870 (95% CI; 0.82–0.92). The reduced model (containing 10 predictors including one genetic and three biomarkers) resulted in an AUC of 0.88 (95% CI; 0.84–0.92). Validation in THE VTE data showed good performance with an AUC of 0.83 (95% CI; 0.66–0.99) for the clinical model. The complete model and the reduced model will be validated in the Milan study because THE VTE study currently lacks data on biomarkers.
Conclusion: These results show that information on acquired risk factors, coagulation factors and genetic determinants in patients with plaster casts leads to an improved accuracy in the prediction of VT risk. In daily practice, the clinical model may be the preferred model as its factors are most easy to determine, while the model still has good predictive quality. When sufficiently validated, this model may be helpful in clinical decisions on thromboprophylaxis.

PA 3.19-2

Chronic VTE treatment VTE with rivaroxaban. Updated results of the prospective Dresden NOAC registry (NCT01588119)

Beyer-Westendorf J, Ebertz F, Förster K, Werth S, Gelbricht V, Tittl L and Köhler C

Dresden University Hospital "Carl Gustav Carus", Dresden, Germany

Background: In the EINSTEIN extension trial, rivaroxaban was superior over placebo in long-term prevention of recurrent venous thromboembolism (VTE) with low rates of bleeding complications. However, patients in RCT's present a selected population treated under a strict protocol and followed for a short period of time. Consequently, efficacy and safety of new oral anticoagulants (NOAC) need to be confirmed in cohorts of unselected patients in daily care.
Aims: To evaluate the efficacy, safety and management issues of rivaroxaban anticoagulation in chronic VTE treatment in daily care.
Patients and Methods: The Dresden NOAC registry is a prospective, non-interventional registry. A network of more than 230 physicians from private practice and hospitals enrol eligible patients, who are centrally followed by the registry office. Inclusion criteria are: (i) indication for therapeutic NOAC anticoagulation > 3 month; (ii) age > 18 years; (iii) written informed consent; (iv) availability for follow-up. No Exclusion criteria apply. In the registry, up to 2000 patients will receive prospective follow up (FU) by phone visits at day 30 day and quarterly thereafter to collect efficacy and safety data. All events are centrally adjudicated based on copies of reports, patient charts, autopsy reports and death certificates and using standard definitions.
Results: Until December 31th 2012, 1665 patients were registered. Of these, 168 patients were registered to receive rivaroxaban for chronic VTE treatment (index event > 6 month previous). Mean age is 62.5 years and, therefore, older than the EINSTEIN extension population (58.2 years). 43.5% of patients receive prolonged treatment for their first VTE event and 56.5% for recurrent VTE.
During follow-up, one recurrent VTE event occurred (phlebitis; 0.8 per 100 patient years). Four patients (3.2 per 100 patient years) had major cardiovascular events (1 ACS, 1 TIA, 1 stroke, 1 retinal artery thrombosis). Furthermore, 45 patients (35.7 per 100 patient years) had bleeding complications, in one case major bleeding according to ISTH definition (0.8 per 100 patient years, non-fatal hematemesis). One patient (0.8 per 100 patient years) died of terminal malignant disease.
At 6 month after enrolment, 88.5% of patients were still taking rivaroxaban. The remaining patients had planned end of treatment (2.5%) or were switched to other anticoagulants (9.0%, mostly for side effects or cost issues).
Conclusions: In unselected patients in daily care, chronic VTE treatment with rivaroxaban is effective and safe with low rates of cardiovascular or bleeding events. Overall, adherence to rivaroxaban therapy is over 90% and unplanned discontinuations occur in < 10%, mainly because of side effects, cost issues or concomitant diseases.
For presentation at the ISTH meeting, updated results on demographic and clinical characteristics at baseline, cardiovascular and bleeding event rates will be provided.

PA 3.19-3

Physicians' compliance with the Padua Prediction Score for preventing venous thromboembolism among hospitalized medical patients

Rossetto V, Barbar S, Vedovetto V, Milan M and Prandoni P

University Hospital of Padua, Padua, Italy

Background: Hospitalization for acute medical illnesses confers an eight-fold increased risk of venous thromboembolic (VTE) disorders that persists for up to 3 months. We have recently identified and validated a suitable and effective risk assessment model, the Padua Prediction Score (PPS), for optimal stratification of the thrombotic risk in hospitalized medical patients (Barbar et al, J Thromb 2010;8:2450–7). For the purpose of that investigation, attending physicians were not informed about the thrombotic risk of their patients and, as a result, < 40% managed their patients correctly.
Aims: In an attempt to assess whether awareness of the thrombotic risk – as assessed with the PPS – has the potential to increase the rate of appropriate thromboprophylaxis in high-risk medical patients, we performed a second prospective investigation within the same framework as the first.
Methods: Attending physicians were alerted about the thrombotic risk of their patients, and the orders for the related drugs were recorded. In addition, the thrombotic and haemorrhagic events occurring up to 90 days after patients' recruitment were registered.
Results: Out of 1600 consecutive patients admitted to the Second Division of Internal Medicine of the University Hospital of Padua (Italy) between January 2010 and December 2011, 803 patients met the inclusion criteria, of whom 296 (39.6%) at high risk and 507 at low risk of VTE based on the PPS. Of the 296 high-risk patients, 262 (88.5%) received adequate pharmacological prophylaxis during hospitalization, this proportion being more than twice as high as that (186/469, 39.6%; $P < 0.00001$) recorded in the previous study. VTE complications developed in seven of the 296 high risk patients (2.3%): four in the group of 262 (1.5%) who received prophylaxis and three in the group of 34 (8.8%) who did not, leading to an absolute difference of 7.3 (95% CI, 2.3–16.9), which is fully consistent with that (8.8; 95%

CI, 4.8–13.1) recorded in the previous study. Non-fatal bleeding complications were observed in three out of the 262 patients (1.1%) who received prophylaxis, and in none of those who did not.
Conclusions: Awareness of the thrombotic risk, as conferred by a self-explanatory, easy and suitable risk assessment model has the potential to remarkably increase the rate of appropriate VTE prophylaxis among hospitalized medical patients. The adoption of adequate prophylaxis strategies in high-risk patients eventually improves their outcome.

PA 3.19-4
Exposure to air pollution increases the risk of isolated pulmonary embolism relative to deep vein thrombosis

Spiezia L, Campello E, Pelizzaro E, Bon M, Maggiolo S and Simioni P
University of Padova, Padova, Italy

Background: Exposure to inhaled particulates has been associated with increasing morbidity and mortality. Recently, there has been a growing interest in the effect of air pollution as a possible risk factor for venous thromboembolism (VTE) and links between air pollution and arterial and venous thrombosis are currently under investigation.
Aims: This study investigated the role of elevated levels of fine particulate matter (PM) in the development of isolated (without deep vein thrombosis) pulmonary embolism (PE).
Methods: The cases included 105 patients (M/F 35/70, age range 22–95 years) consecutively admitted to our Thrombosis Unit, between February 2008 and October 2012, with a diagnosis of first episode of PE without deep vein thrombosis (DVT). The control group included 161 patients (M/F 72/89, age range 20–89 years) consecutively referred to our Thrombosis Unit with objectively proven DVT without PE. Mean concentration of PM10 and PM2.5 were computed using data from monitors located at two different sites of Padua City.
Results: Using the 95th percentile of PM10 and PM2.5 measured in patients with DVT without PE in the month (73 mg/m^3 in both cases) and trimester (64 and 56 mg/m^3, respectively) before the event we found a significant increased risk (OR 2.23, 95% confidence interval [CI]: 1.02–4.93, for month; OR 4.48, 95% CI: 1.97–10.17, for trimester) of PE for PM10 and a significant increased risk (OR 2.32, 95% confidence interval [CI]: 0.99–5.45, for month; OR 4.22, 95% CI: 1.85–9.64, for trimester) of PE for PM2.5. In the multivariate logistic regression analysis (considered as possible confounders: age, gender, type of presentation, thrombophilia, heart diseases, smoking status, distance from the monitor sites, social-economic status, presence of COPD or asthma) for the variable PM10 an OR of 2.45 (95% CI: 1.04–5.79) in the month before admission and 5.24 (95% CI: 2.21–12.43) in the trimester before admission was found. For the variable PM2.5 were obtained an OR of 2.69 (95% CI: 1.06–6.83) in the month before admission and an OR of 6.19 (95% CI: 2.55–10.05) in the trimester.
Conclusions: A significant association was found between PM10 and PM2.5 exposure and isolated PE. At present, it is only possible to hypothesize that air pollution may be involved in the generation of *in situ* thrombosis in the pulmonary artery. Larger prospective multicentre investigations are needed to confirm this finding and clarify the potential underlying mechanisms.

PA 3.19-5
Cerebral vein thrombosis: long-term recanalization rate and clinical outcome

Dentali F[1], Martinelli I[2], Poli D[3], Scoditti U[4], Passamonti SM[2], Di Minno MND[5], Rezoagli E[1], De Stefano V[6] and Ageno W[7]
[1]University of Insubria, Varese; [2]University of Milan, Milan; [3]AOU-Careggi, Firenze; [4]University of Parma, Parma; [5]Federico II University, Napoli; [6]Catholic University, Roma; [7]Insubria University, Varese, Italy

Background: Only few studies with very small sample sizes have investigated on the long-term recanalization rates of cerebral venous thrombosis (CVT) and on the role of recanalization on clinical outcomes in these patients.
Aim of the Study: To assess the recanalization rate and potential risk factors for residual thrombosis in patients with a first episode of CVT. To evaluate the role of a complete recanalization on long term clinical outcome of these patients.
Methods: CVT patients with follow-up imaging tests performed at 3 and(?) 12 months after the index event were included. Vessel status at follow-up was categorized as complete, partial, or no recanalization. A good clinical recovery was defined as a score of 0–1 on the modified Rankin Scale (mRS). The following potential predictors of absence of recanalization and of clinical outcome were evaluated: age, gender, previous venous thromboembolic event, hormone therapy, unprovoked nature of CVT.
Results: Three hundred and nine CVT patients (71.5% female, mean age 40.2 years) were included; complete and partial recanalization were detected in 143 patients at 3–6 months and in 166 patients 7–12 months (71.8% vs. 769%; $P > 0.2$). At univariate analysis, only age > 45 years was associated with a higher risk of no recanalization ($P < 0.05$). This result was confirmed at multivariate analysis with a per year Odds Ratio [OR] of 1.02 (95% confidence interval [CI] 1.00–1.04; P 0.02). mRS at the time of follow-up imaging was available for 248 patients (80.3%); 223 of these patients (89.9%) had a good recovery. Complete or partial recanalization and hormone therapy were associated with a better outcome at the univariate analysis and these results were confirmed at the multivariate analysis (OR 2.63, 95% CI 1.05–6.61, P 0.039 and OR 3.88, 95% CI 0.99–15.19, P 0.05 respectively).
Conclusions: About three forth of CVT patients have complete or partial recanalization in the first months after the index event. Age was the only independent predictor of absence of recanalization. Complete or partial recanalization, together with hormone therapy, is associated with a better outcome in these patients.

PA 3.19-6
The contribution of immobility risk factors to the risk of venous thrombosis in the older population

Engbers MJ[1], Blom JW[2], Cushman M[3], Rosendaal FR[2] and Van Hylckama Vlieg A[2]
[1]Department of Clinical Epidemiology, Leiden University Medical Center; [2]Leiden University Medical Center, Leiden, The Netherlands; [3]University of Vermont, Burlington, VT, USA

Background: Venous thrombosis is common in the older population. Assessment of risk factors is necessary in order to implement optimal preventive measures within this population.
Aims: In a population aged 70 and older, we determined associations between immobility-related risk factors and venous thrombosis, specifically, hospitalization, surgery, fracture, plaster cast (or splint) use, minor injuries, and transient immobility at home. Moreover, the contribution of these risk factors to the relative risk of thrombosis was assessed.

Methods: The Age and Thrombosis, Acquired and Genetic risk factors in the Elderly (AT-AGE) study is a two-center population-based case–control study performed between 2008 and 2011 in the Netherlands and the USA. Consecutive cases aged 70 years and older with a venous thrombosis and control subjects aged 70 years and older were included (consent en ethical approval obtained). Exclusion criteria were active malignancy and severe cognitive disorders. Participation in the cases was 476 (69%) and in the control subjects 461 (73%). For the current analyses, we only included cases with a first-time deep venous thrombosis in the leg or pulmonary embolism (n = 406) and control subjects without a history of thrombosis (n = 433). Odds ratios (OR) and population attributable risks (PAR) were calculated for in-hospital and out-of-hospital immobility. All ORs were adjusted for age, sex, body mass index and study center.
Results: There was a 15-fold (OR 14.8; CI 95 4.4–50.1) increased risk of thrombosis within 2 weeks of a hospital discharge and this risk extended for 3 months after discharge (OR 3.0; CI 95 1.7–5.3). Recent surgery yielded a 6.6 fold (OR 6.6; CI 95 3.7–11.7) fold increased risk. Moreover, out-hospital immobility defined as fractures (OR 12.6; CI 95 3.7–43.6), plaster cast (or splint) (OR 6.2; CI 95 2.0–18.8), minor leg injuries (OR 1.9; CI 95 1.1–3.3), and transient immobility at home (OR 5.0; CI 95 2.3–11.2) were all associated with thrombosis. A PAR of 27% for in-hospital immobility and 15% for out-of-hospital immobility was estimated.
Summary/Conclusions: In those over 70 years of age, immobility-related risk factors, including hospitalization, surgery, fracture, plaster cast (or splint), minor injury of the leg, and transient immobility at home were strong risk factors for venous thrombosis. Preventative measures should not focus solely on hospital settings.
Funding: Netherlands Heart Foundation (grant NHS 2009B50).

PA3.20 – Post-Thrombotic Syndrome

PA 3.20-1

Predictive value of the HAS-BLED score for major bleeding in patients with venous thromboembolism during anticoagulant treatment

Kooiman J[1], Van Hagen N[1], Iglesias del Sol A[2], Planken E[3], Lip GYH[4], Van Der Meer FJM[1], Cannegieter SC[1] and Huisman MV[1]
[1]Leiden University Medical Center, Leiden; [2]Rijnland Ziekenhuis, Leiderdorp; [3]Diaconessenhuis, Leiden, The Netherlands; [4]City Hospital, Birmingham, UK

Background: The HAS-BLED score enables a risk estimate of major bleeding in patients with atrial fibrillation on vitamin K-antagonists (VKA) treatment, but has never been validated in patients with venous thromboembolism (VTE).
Aim: We analyzed the predictive value of the HAS-BLED score in VTE patients on VKA treatment.
Methods: Medical records of 416 VTE (165/416 pulmonary embolism and 251/416 deep vein thrombosis) patients starting VKA treatment for VTE in 2006 were searched for items on the HAS-BLED score (hypertension; renal or liver disease; stroke; major bleeding or anemia; age >65 years; use of NSAIDs, anti-platelet therapy or alcohol) and major bleeding events. Data on labile INR (time within therapeutic range <60%) was not available. Area under the curve (AUC) of the receiver operating characteristic (ROC) was calculated for the endpoint of major bleeding during VKA therapy, according to the ISTH criteria. Follow-up was defined as time between initiation of VKA treatment and major bleeding, or discontinuation of VKA treatment, or death, or June 2012, which ever came first.
Results: Median follow-up time for the endpoint of major bleeding was 175 days (2.5–97.5 percentiles 9–2304 days). Major bleeding occurred in 18/416 (4.3%, 95%CI 2.7–6.8%) patients. The AUC for the HAS-BLED score was 0.73 (0.62–0.84). In a multivariate Cox regression analysis, age >65 years, renal and liver impairment were predictive of major bleeding, with hazard ratios of 6.5 (95%CI1.6–26.5), 9.0 (95%CI1.4–56.2) and 15.6 (95%CI 1.0–245.3), respectively.
Conclusion The HAS-BLED score offers useful prognostic capacity in predicting major bleeding in VTE patients on VKA therapy. These results should be confirmed by other larger cohorts of VTE patients.

PA 3.20-2

Post-thrombotic syndrome does not confer a hypercoagulable state as measured by thrombin generation

Roberts L, Patel RK, Bonner L and Arya R
King's College Hospital NHS Foundation Trust, London, UK

Background: Post-thrombotic syndrome (PTS) is a common complication of deep vein thrombosis (DVT). Its development has been associated with an increased risk of recurrent thrombosis.
Aims: We sought to establish whether the development of post-thrombotic syndrome conferred a hypercoagulable state following completion of anticoagulation for a first DVT.
Methods: This sub-study was undertaken in participants with a first DVT prospectively recruited to the Camberwell DVT outcomes study. DVT treatment comprised of 3 or 6 months anticoagulation for distal and proximal DVT respectively. Patients were clinically evaluated for PTS utilising the Villalta scale at 6 weeks and 6 months post end of anticoagulation. Plasma was collected for thrombin generation at the time of first clinical assessment. Thrombin generation was measured in platelet poor plasma using calibrated automated thrombography with a final tissue factor concentration of 5 pM and phospholipids 4 μM.
Results: One hundred and thirty-three patients were recruited, of which 107 completed anticoagulation and provided plasma for thrombin generation. Mean age of this cohort was 46.8 (± 15) years with males accounting for 51.4%. Fifty-seven percent were Caucasian, 33.6% African-Caribbean and the remainder mixed or other ethnicity. DVT involved the proximal vasculature in 51.4% with 57.0% having a provoking factor for DVT. Heritable thrombophilia was detected in 22.4%, with 51.4% having FVIII > 150 IU/L. During follow up, 29.0% developed mild PTS and 19.6% moderate or severe PTS. There was no significant difference in age, gender, BMI, presence of provoking factor or involvement of proximal vasculature between those with mild and those with moderate/severe PTS. There was no significant difference in thrombin generation parameters between those with and without PTS. On stratification by severity, those with moderate/severe PTS had significantly higher peak thrombin (389.5 nM) compared to those with mild PTS (345.7 nM; P = 0.023). This was no longer significant after adjustment for age, gender, BMI, ethnicity, presence of provoking factor and involvement of proximal vasculature; ethnicity demonstrated the strongest independent relationship to peak thrombin (P = 0.001). This led us to investigate ethnic differences in PTS; there was no significant difference in PTS development between Caucasians and African-Caribbeans. However, African-Caribbean ethnicity was significantly associated with increased moderate/severe PTS (33.3%) compared to Caucasians (13.1%; P = 0.023). On univariable analysis, African-Caribbean ethnicity was associated with moderate/severe PTS with OR 1.6 (95% CI 0.94–2.74, P = 0.081 [using no PTS as the reference]). After adjustment for age and involvement of the proximal vasculature, African-Caribbean ethnicity was significantly associated with moderate/severe PTS with OR 2.0 (95% CI 1.04–3.89, P = 0.036).
Summary/Conclusion: PTS does not confer a global hypercoagulable state as measured by thrombin generation. Its association with an increased risk of recurrence may be mediated by local hypercoagulability at the site of previous thrombus or by alternative mechanisms. African-Caribbean ethnicity was unexpectedly associated with an increased risk of moderate/severe PTS.

PA 3.20-3

Cost-effectiveness of additional catheter-directed thrombolysis for deep vein thrombosis

Enden TR[1], Resch S[2], White C[2], Wik HS[1], Klow NE[1] and Sandset PM[1]

[1]*Oslo University Hospital, Oslo, Norway;* [2]*Harvard School of Public Health, Boston, MA, USA*

Background: Following a proximal deep vein thrombosis (DVT) treated with standard anticoagulation and compression therapy at least 25% develop post-thrombotic syndrome (PTS). The CaVenT study was the first randomized controlled trial to evaluate additional catheter-directed thrombolysis (CDT) with alteplase and showed an absolute reduction in PTS of 15% after 2 years. However, in addition to this benefit CDT involves a small bleeding risk, lengthens inpatient stay, and consumes more resources.

Aims: Consequently, we aimed at performing a health economic evaluation using a decision model to assess the cost-effectiveness of additional CDT compared with standard treatment alone.

Methods: A Markov model with a third-party payer perspective and a lifetime horizon compared standard treatment with CDT in addition to standard treatment in a hypothetical cohort with high proximal DVT and low risk of bleeding. All patients received anticoagulation in the first 6 months' cycle of the model. In the subsequent cycles patients could transition to the health states (i) post DVT, (ii) PTS, (iii) severe PTS, (iv) permanently disabled from an intracranial bleeding, or v) dead. Model input data obtained from the CaVenT study included PTS development, risk of major bleeding from CDT, and utilities for post DVT states with and without PTS development. The remaining clinical inputs were obtained from the literature. Costs were obtained from the CaVenT study, hospital accounts and the literature.

We applied utilities and costs to each event and outcome over their expected durations. Results were expressed in monetary costs (April 2012 US $), quality adjusted life years (QALYs); both discounted at 3.0% annually, and incremental cost-effectiveness ratio (ICER). Model uncertainty was assessed with one-way and probabilistic sensitivity analyses.

Results: Base case analyses demonstrated that additional CDT accumulated 32.31 QALYs compared to 31.68 QALYs following standard treatment alone. Direct medical costs were $64,709 for additional CDT and $51,866 for standard treatment. The incremental cost-effectiveness ratio (ICER) was $20,429/QALY gained. Projected life expectancy was 30.9 years following standard treatment and 30.8 years in the CDT strategy, corresponding to a loss of 1.1 months or 32 days from the additional risks associated with CDT. One-way sensitivity analysis showed that the model was sensitive to the clinical efficacy of both treatment strategies, but the ICER remained < $55,000/QALY gained over the full range of all parameters. The probability that additional CDT is cost-effective was 82% at a willingness to pay threshold of $50,000/QALY gained.

Summary/Conclusion: Additional CDT is likely to be a cost-effective alternative to standard treatment for patients with high proximal DVT and low risk of bleeding.

PA 3.20-4

Role of inflammation, tissue remodeling, and vascular function in the development of post thrombotic syndrome: a case–control study

Bouman AC[1], Cheung YW[2], Van Schalkwijk CG[1], Spronk HMH[1], Ten Cate H[1], Ten Wolde M[2] and Ten Cate-Hoek AJ[1]

[1]*Maastricht University Medical Centre, Maastricht;* [2]*Flevohospital, Almere, The Netherlands*

Background: Post thrombotic syndrome (PTS) is a prevalent sequel of deep vein thrombosis (DVT) of the leg. PTS develops in 20–50% of patients and manifests itself with symptoms of heaviness, pain, cramps, itching, and tingling of the affected leg. In severe cases ulceration can occur. There is restricted knowledge on PTS aetiology and therapeutic options are limited. Insight in pathogenic processes involved in PTS could be gained by studying the relationship between biomarkers and PTS potentially leading to improved treatment options.

Aims: We aimed to investigate the role of inflammation, tissue remodelling, and vascular function in the aetiology of PTS using a panel of potential plasma biomarkers.

Methods: Patients with a history of DVT with PTS (Villalta ≥ 5) defined as cases and patients with a history of DVT without PTS defined as controls were selected from the outpatient clinic of the Maastricht University Medical Centre and the Flevohospital Almere, theNetherlands. To be included the required minimum time since DVT was 24 months. In addition, healthy individuals (HI) without a history of venous thromboembolism were invited to participate. Cases, controls, and HI were matched for gender, age, and BMI. Blood was collected and a panel of predefined markers was determined using enzyme-linked immunosorbent assays. Median levels of biomarkers were compared between the three categories with the Kruskal-Wallis test, and post hoc Bonferroni correction was applied (significance level < 0.0167).

Results: Ninety subjects were included. Blood collection was performed at a median follow up after first DVT of 83 months (range 53–102). Mean Villalta score was 8 (Standard deviation 4) for cases and 2 (1) for controls.

CRP showed a significant trend of increasing CRP in controls (1.4 μg/mL [0.7–3.3]), cases (2.5 μg/mL [1.3–4.8]), and consequently healthy individuals (3.1 μg/mL [1.1–9.1)] $P = 0.045$. Median levels of Thrombomodulin were found to be higher in controls (4.4 ng/mL [3.9–5.3]) compared to cases (4.2 ng/mL [3.2–4.7]) $P = 0.046$ and HI (3.8 ng/mL [3.4–4.2]) $P = 0.006$. Levels of von Willebrand Factor (vWF) were higher in patients compared to HI. This difference was significant comparing controls (205% [165–235]) and HI (153% [103–200]) $P = 0.005$, but not comparing cases (179% [150–201]) and HI $P = 0.115$.

No differences were found for: Il-6, Il-8, TNF-α, SAA, E-selectin, P-selectin, MMP-9, TIMP-1, sICAM-1, and sICAM-3.

Conclusions: There is marked absence of inflammatory activity in cases at this point in time. Higher levels of CRP as well as lower levels of Thrombomodulin in cases may be a reflection of compensatory anti-inflammatory mechanisms in the chronic phase after DVT. The higher levels of Thrombomodulin in controls, compared to cases and HI may be explained by the anti-inflammatory and anti-coagulant properties of Thrombomodulin resulting in a vasculoprotective effect in controls. High vWF in cases and controls reflects endothelial activation in patients vs. HI, but does not appear to be a marker for PTS.

PA 3.20-5

Venous thromboembolism and subsequent receipt of disability pension – a population-based prospective cohort study

Skjeldestad FE[1], Grosse SD[2], Okoroh E[2], Brækkan SK[1], Cannegieter SC[3], Næss IA[4], Krokstad S[5] and Hansen JB[1]

[1]*University of Tromsø, Tromsø, Norway;* [2]*Center for Disease Control and Prevention, Atlanta, GA, USA;* [3]*Department of Clinical Epidemiology, Leiden, The Netherlands;* [4]*Trondheim university hospital, Trondheim;* [5]*Norwegian University of Science and Technology, Levanger, Norway*

Background: Venous thromboembolism (VTE) is an important cause of morbidity and mortality. However, the burden of VTE in terms of permanent work disability has never been assessed at the population level.

Aims: To estimate the incidence of disability pension (DP) after a first event of VTE compared to subjects without VTE, and among provoked/unprovoked cases of VTE.
Methods: After passing all formal regulations (Institutional regulatory boards, the Norwegian Data Protection Authority), data from the Tromsø Study (baseline 1994–95) and the North-Trøndelag Health Study (HUNT) (baseline 1995–97) were merged by the 11-digit personal identification number with National Insurance Administration DP data from Statistics Norway. All participants, aged 25–64, in the two studies with no previous VTE and no prior DP or DP within 12 months from baseline were included. Study participants were followed from baseline through the end of 2007 for objectively verified diagnoses of VTE and the end of 2008 for DP, defined as a disability pension of 50% or more. Study subjects without DP were censored at age 65, at date of emigration or death, whichever came first. In total 60,580 subjects were included. Cumulative proportions of DP per 100 participants were analyzed in survival analyses by VTE exposure. Cox-regression models were used to calculate hazard ratios (HRs) for DP by VTE as main exposure with 95% confidence interval (CI). Age, sex, education, body mass index, cardiovascular diseases, cancer, muscle-skeletal diseases, psychiatric diseases, and self-perceived health assessed at study start were included in the regression models for potential confounding effects.
Results: At study end 75 of 357 (21%) incident VTE cases received DP relative to 9052 of 60,223 (15%) non-VTE subjects. The study subjects were observed over 8,240,118 study months, mean 136 (1–174 months). Within 10 years from baseline, the cumulative proportion of DP among VTE subjects was 16.3% (95% CI: 12.4–20.2) compared with 11.9% (95% CI: 11.6–12.3) among non-VTE subjects. The HR for DP among VTE to non-VTE cases changed from 1.45 (95% CI: 1.16–1.82) to 0.96 (95% CI: 0.76–1.20) when adjusted for age and self-perceived health. No other factors at baseline had a confounding effect on the association of VTE with DP. Within 3 and 6 years after VTE, the cumulative proportion of DP per 100 VTE subjects were 15.4 (95% CI: 11.4–19.4) and 21.3 (95% CI: 16.6–26.0). The HR for DP among VTE subjects aged 50–64 at time of VTE was 4.6 (95% CI: 2.3–8.9) relative to VTE subjects aged 25–49 years. There was no difference in DP for provoked and unprovoked VTE (HR 1.00; 95% CI: 0.94–1.07).
Conclusions: Within 6 years of first diagnosis of VTE more than 20% of Norwegians received DP, and the probability of receiving DP was higher among those aged 50 or more at time of diagnosis. After controlling for age and baseline self-reported health, DP was not received more often by VTE subjects. This study does not indicate that VTE is associated with permanent work disability.

PA 3.20-6

Prospective study to identify risk factors for post thrombotic syndrome and evaluate role of compression ultrasound sonography to decide discontinuation of anticoagulant

Mishra P[1], Agrawal N[2], Sharma S[2], Seth T[2] and Mahapatra M[2]
[1]All India Institute of Medical Sciences; [2]AIIMS, New Delhi, India

Background/Aim: To identify patients with unprovoked Deep vein thrombosis (DVT) where anticoagulation could be discontinued and identify possible risk factors for post thrombotic syndrome (PTS).
Methods: This was designed as a prospective randomized study which included patients of 12–75 years age presenting to our clinic with unprovoked lower limb proximal DVT. Patients with active malignancy, pulmonary embolism and sites of thrombus other than the lower limbs, DVT post surgery or bed ridden medical patients, other provoked DVT were excluded. Patients were anticoagulated and monitored as per standard procedures. Patients were advised to wear compression elastic stocking below knee from early morning to bed time for prevention of PTS. PTS was analysed and graded as per the Villalta PTS scale. Compression ultrasound sonography (CUS) of affected limb was done after 6 months of therapy and results of CUS were used to determine further treatment. CUS was done at two sites: Common femoral vein (CFV) just above the junction of saphenous vein to femoral vein and the popliteal vein (PV). Ratio of compressed to uncompressed diameter > 40% identified patients with significant residual thrombus whereas patients with < 40% were defined as patients with resolution of thrombus. Patients with significant residual thrombus were continued on anticoagulants in group A. Patients with resolution of thrombus were randomized to continue the drug in group B or assigned to drug discontinuation in group C. Adequacy of anticoagulation was assessed by INR of 2–3 on atleast 50% of visits. Events were recorded as a fresh episode of DVT in same limb or at other site confirmed on compression ultrasound, bleeding episodes, symptoms and signs related to PTS.
Results: Forty-four patients were enrolled. Of 44 patients (34 males, 10 females), median age 35 years (range 16–65 years), 25 patients (56.8%) showed significant resolution of thrombus at 6 months and were randomized into groups B (n = 13) and C (n = 12). Nineteen patients with residual thrombus were treated in arm A where anticoagulation was continued. None of the patients in any arm suffered a recurrence after a median followup of 12 months (range 11–17.8 months). However the post thrombotic syndrome was seen in a total of 17 patients (38.6%), 11 in arm A and six in arm B+C (P = 0.03). The grade of PTS was mild as per the Villalta PTS scale in all patients. Two of 13 patients in arm B developed PTS as compared to 4/12 patients in arm C. Inadequate anticoagulation in patients with or without PTS was 47% and 14.8% (P = 0.035, odds ratio 4.9, 95% CI 1.01–28.57) respectively. Mean duration of symptoms prior to starting anticoagulation was 2.52, 3.84 and 5.4 weeks in groups A, B and C respectively with no significant difference.
Conclusion: Absence of thrombus or a significant resolution of thrombus on followup CUS identifies group of patients in whom oral anticoagulation could be withdrawn. Inadequate anticoagulation after diagnosis of DVT identifies a group of patients who would be at risk for PTS. Risk of PTS is not dependent upon the duration of symptoms prior to diagnosis.

Tumor vascular disrupting agent DMXAA inhibits platelet activation and thrombosis via inhibition of TXA2 – TP signaling and PDE

Zhang S[1], Zhang Y[1], Shen J[2], Zhang S[1], Chen L[1], Mruk JM[3], Zhu L[4], Kunapuli SP[5] and Ding Z[1]
[1]Fudan University, Shanghai; [2]Soochow university, Suzhou, China; [3]University of Kansas, Witchita, KS, USA; [4]Soochow University, Suzhou, China; [5]Temple University, Philadelphia, PA, USA

Background: 5, 6-dimethylxanthenone-4-acetic acid (DMXAA) is a tumor vascular disrupting agent under clinical trials as an adjacent antitumor agent. DMXAA is structurally similar to flavone-8-acetic acid (FAA), an old tumor vascular disrupting agent with antiplatelet and antithrombotic effects. In contrast to FAA, which causes bleeding in tumor patients, no bleeding has been reported in patients receiving DMXAA. Whether DMXAA also affects platelet function is not clear.
Aims: We sought to investigate whether DMXAA also inhibits platelet activation and thrombus formation.
Methods: The antiplatelet effects of DMXAA were assessed using human washed platelets or platelet-rich plasma induced by multiple agonists. The TXB_2 levels were measured using an ELISA kit. The phosphorylation of Erk1/2 and Akt were measured using western blot. The assay for PDE activity was performed using HPLC. The antithrombotic effects were evaluated using both $FeCl_3$-injured mouse

mesenteric arterial thrombus model and laser-injured mouse cremaster arteriole thrombus model.

Results: Here we demonstrated that DMXAA concentration-dependently inhibited human platelet aggregation and ATP release induced by U46619, arachidonic acid, ADP, collagen or ristocetin. Moreover, DMXAA inhibited phosphorylation of Erk1/2 and Akt downstream of thromboxane synthase inhibition and TXA_2 receptor (TP) antagonism. DMXAA also inhibited phosphodiesterase (PDE). The antiplatelet effects were further confirmed using mice intravenously given DMXAA. DMXAA dramatically inhibited thrombus formation in $FeCl_3$-injured mouse mesenteric arterial thrombus model and laser-injured mouse cremaster arteriole thrombus model. Notably, DMXAA did not significantly increase bleeding at a dose achieving antithrombotic effects similar to clopidogrel in mice.

Summary/Conclusions: For the first time, we found that tumor vascular disrupting agent DMXAA has potent antiplatelet and antithrombotic effects without increased bleeding. As a well-evaluated antitumor agent with safe profile, DMXAA may be used as an efficacious and safe antiplatelet drug.

Antiplatelet activity of N,N'-substituted piperazines

Veselkina O[1], Vasina L[2], Tarkovskaja L[3], Papajan L[3] and Petrishchev N[4]

[1]Vertex, St. Petersburg, Russian Federation; [2]Almazov Federal Heart, Blood and Endocrinology Centre; [3]Russian Institute of Hematology and Transfusiology; [4]Saint Petersburg State Medical University n.a. I.P. Pavlov, St. Petersburg, Russian Federation

Background: Antiaggregant drugs play an important role in the prophylaxis and therapy of ischemic stroke and cardio-vascular deceases. Nevertheless the development of novel drugs possessing high therapeutical activity and safety with no pronounced resistance remains an actual topic.

Aims: The study investigates *in vitro* and *in vivo* pharmacobiological activity in a series of novel N,N'–substituted piperazines with different hydrophobicy and acid-base properties; the correlation between their phisycochemical properties and antiaggregant and vasodilatory activity.

Methods: Antiaggregant properties of N,N'–substituted piperazines were evaluated in donor blood based on their ability to reduce platelet aggregation induced by ADP, collagen, ristocetin, thrombin, epinephrine and arachidonic acid (CHRONO-LOG 490-4D); their influence on thromboelastogram of blood clot (thromboelastograph TEG 5000) and functional activity of regular blood elements; and by experimental rodent model of laser-induced arterial thrombosis coupled with intravenous or oral administration of the compounds. The dose – effect dependence was studied and the semi-inhibition constants of thrombocyte aggregation (ED50) were calculated. The results were compared with the ones from parallel studies with aspirin.

Results: It was experimentally determined that N,N'–substituted piperazines have antiaggregant properties when platelet aggregation is induced by ADP, collagen, ristocetin, thrombin, epinephrine and arachidonic acid. The study of N,N'–substituted piperazines chemical structure relation to their activity showed higher activity in the compounds having guanidine, sulfamide and tetramethoxyalkyl substituents (compounds VRV-0411, VRV-0511). The semi-inhibition constants of thrombocyte aggregation (ED50) in the tests of ADP, epinephrine, thrombin, and collagen induced aggregation for most active compounds VRV-0411, VRV-0511 were statistically significantly lower than the constants for model compound (aspirin). In the tests of arachidonic acid induced platelet aggregation the compounds VRV-0411, VRV-0511 had the constants comparable to the ones of aspirin. The compounds VRV-0411, VRV-0511 in the doses up to 2 mM/kg do not influence the functional activity of regular blood elements. Experiments according to rodent model of laser-induced arterial thrombosis showed that during the course of oral administration of compounds VRV-0411, VRV-0511, aspirin (7 days, once per day) ED50 equals to 0.0045, 0.0035, 0.0035 mM/kg, respectively. After the intravenous injection of compounds VRV-0411, VRV-0511, aspirin ED50 equals to 0.002, 0.009, 0.003 mM/kg, respectively.

Conclusion: The studies of antiaggregant properties of N,N'–substituted piperazines in donor blood and on experimental rodent model of laser-induced arterial thrombosis allowed to determine the relation of pharmacological activity of the compounds on their chemical structure and to define the compounds having wide spectrum of antiaggregant activities. Preclinical studies of the most effective N,N'–substituted piperazines are under way to introduce novel drugs to the market.

PA 4.01-3

PAR-1 antagonists inhibit thrombin-induced platelet activation whilst leaving the PAR4-mediated response intact

M Judge H[1], Jennings L[2], Moliterno D[3], Hord E[2], Ecob R[1], Tricoci P[4], Smyth S[3], Rorick T[5], Kotha J[2] and Storey RF[1]

[1]University of Sheffield, Sheffield, UK; [2]CirQuest Laboratories, Memphis, TN; [3]University of Kentucky, Lexington, KY; [4]Duke Cardiology; [5]Duke University, Durham, NC, USA

Background: Thrombin-induced platelet activation is initiated by PAR1 and PAR4 receptors. Vorapaxar, a PAR1 antagonist, has been assessed in patients with acute coronary syndromes (ACS) and stable atherosclerotic disease in addition to standard-of-care treatment. Significant benefit was seen in those with a prior history of myocardial infarction and vorapaxar was not associated with significantly increased CABG-related major bleeding or differences in reoperation for bleeding or fatal bleeding in patients undergoing CABG surgery, which is associated with excess thrombin generation.

Aims: Investigate the effects of selective PAR1 antagonism on thrombin-induced platelet activation.

Methods: All studies were conducted with informed consent and medical ethics approval. *In vitro* studies were performed using healthy volunteers. Samples were pre-incubated with the PAR-1 antagonist, SCH79797 (1 μM) or pre-exposed to PAR-4 agonist peptide (2 mM) to induce receptor desensitization. *Ex vivo* studies were also performed on ACS patients randomised in the TRACER study to receive vorapaxar (40 mg loading dose, 2.5 mg daily) (n = 13) or placebo (n = 17). Blood samples were taken from the patient group at baseline and 4 h, 1 and 4 months during drug administration. Platelet-rich plasma was prepared and the platelets labelled with fluo-4 AM. Thrombin-induced calcium mobilisation (0.1–1 U/mL) was assessed by flow cytometry in the presence of extracellular calcium (1 mM).

Results: Vorapaxar treatment significantly reduced the peak calcium response of 2608 ± 1962 and 4835 ± 3702–251 ± 407 and 613 ± 1070 (mean ± SD, $P < 0.001$) using 0.1 and 0.3 U/mL thrombin, respectively (4 h post vorapaxar), and extended the time to reach the peak calcium response (5.6 ± 2.4 and 9.7 ± 14.3–110.0 ± 23.4 and 61.3 ± 31.6 s ($P < 0.001$). There was residual, delayed calcium mobilisation in response to thrombin which was unaffected by vorapaxar treatment. These findings are consistent with calcium mobilisation mediated via the PAR-4 receptor and were reproduced *in vitro* using SCH79797. PAR-4 receptor desensitization, in combination with SCH79797, completely inhibited thrombin-induced calcium mobilisation confirming that the residual, delayed calcium mobilisation was mediated via PAR-4.

Conclusion: Vorapaxar selectively antagonises the PAR1-mediated component of thrombin-induced platelet activation, leaving the PAR4-mediated response intact. This result may explain why vorapaxar is well tolerated in patients undergoing CABG surgery since higher thrombin levels in this setting may override the effects of PAR1 antagonism through PAR4 activation and thus preserve haemostasis. Further assessment in this setting may be warranted.

PA 4.01-4

The role of glaucocalyxin A in inhibiting platelet activation and protecting against hypoxic ischemic brain injury

Zhu L, Tang X, Li Q, Yang F, Liu X, Ruan C, Xu X and Zhang J
Soochow University, Suzhou, China

Background: Platelets play a pivotal role in atherosthrombosis and antiplatelet agents prove to be useful in preventing acute clinical events, including myocardial ischemia and stroke.
Aims: In this study we investigate the antiplatelet and neuroprotection effect of glaucocalyxin A (GLA), a diterpenoid isolated from Rabdosia japonica (Burm F) Hara var glaucocalyx (Maxim) Hara (Labiatae).
Methods: GLA was purified and tested for its effect on platelet activation using washed platelets freshly isolated from peripheral blood of healthy donors. Experiments for platelet function used in this report include platelet aggregation, flow cytometry, microfluidic chamber, and clot retraction. Hypoxic-ischemic brain damage (HIBD) was induced by unilateral carotid ligation and 2.5 h of hypoxia in postnatal day 7 (P7) rat pups. GLA was administered immediately before hypoxia. The effect of GLA on infarct volume was evaluated at 48 h after HIBD by TTC staining.
Results: We showed that pretreatment of human platelets with GLA (0.01 and 0.1 μg/mL) selectively inhibited platelet aggregation induced by collagen ($P < 0.001$ and $P < 0.001$, respectively). This inhibition also occurs in other agonist-induced platelet aggregation when platelets were preincubated with higher doses of GLA (5, 50 μg/mL). Platelet inside-out signaling was inhibited by GLA as indicated by p-selectin secretion and Pac-1 binding assay. GLA reduced platelet adhesion on collagen surfaces and clot retraction, a process mediated by outside-in signaling. Further study showed that GLA inhibited collagen-stimulated tyrosine phosphorylation of Src, Syk and PLCγ2, the signaling events in collagen receptor GPVI pathway. We next examine whether GLA protected against hypoxic-ischemic brain damage (HIBD) in newborn rats. The infarct volume in the GLA (500 and 1 mg/kg)-treated animals ($29 \pm 0.37\%$, $n = 10$ and $27 \pm 0.69\%$, $n = 10$) was significant reduced compared with the vehicle group ($39 \pm 0.83\%$, $n = 10$) ($P < 0.05$). Underlying mechanistic study showed that GLA treatment significantly decreased cleaved caspase-3 levels ($P < 0.05$), a marker of apoptosis.
Summary: The present results provide the molecular basis for the inhibition by GLA of collagen-stimulated platelet activation and the evidence that GLA protects against hypoxic-ischemic brain injury in neonatal rats. Our data suggest that GLA could potentially be developed as a novel agent for the prevention of thrombosis and ischemia.
This work was supported in part by grants from the National Science Foundation of China (NSFC81071410) and Jiangsu Province's Key Discipline of Medicine (XK201118).

Plain pegylated liposomes inhibit platelet activation by HOCl modified albumin, thrombospondin peptide RFYVVMWK and high shear modified von Willebrand factor

Brodde MF[1], Nofer J-R[2] and Kehrel BE[2]
[1]OxProtect GmbH; [2]Universität Münster, Münster, Germany

Background: Although several anti-platelet drugs exist to prevent thrombosis, there still is a need for new strategies to protect against platelet-mediated atherothrombosis, as bleeding risk is a substantial limitation of current antiplatelet therapy. Proteins or peptides with amyloid-like structure activate platelets as shown by Herczenik et al. Modification of proteins like LDL, albumin, fibrinogen by HOCl, or of von Willebrand factor by shear conditions induce self-association, a hallmark of misfolded proteins. The amyloid-like carboxyterminal peptide RFYVVMWK that is conserved among the products of all five thrombospondin genes is known to activate platelets. All these proteins/peptides expose hydrophobic surface areas. Pegylated liposomes are in use for many years as a vehicle for drug delivery and targeting, without inducing bleeding problems. The presence of PEG on the surface of such liposomal carrier has been shown to extend blood-circulation time.
Aims: The effect of plain pegylated liposomes, with no drugs encapsulated into them and no molecules attached to their surface, on platelet adhesion to and activation by HOCl modified proteins (LDL, albumin, fibrinogen), thrombospondin peptide RFYVVMWK and high shear modified von Willebrand factor was studied.
Methods: Plain pegylated liposomes were synthesized using 1-palmitoyl-2-oleoyl phosphatidylcholine (POPC) and distearoyl phosphatidyl-ethanolamine methyl polyethylene glycol 2000 (DSPE-PEG 2000). The liposomes were filtered in an extruder apparatus through polycarbonate filters to form liposomes of 120–140 nm in size, according to Yatuv et al. The effect of plain pegylated liposomes on platelet adhesion, activation, secretion, aggregation, and thrombus formation was investigated by aggregometry, flow cytometry, thrombus formation in *in vitro* perfusion chambers, confocal laser scanning microscopy and plasmon resonance.
Results: Plain pegylated liposomes inhibited in a dose dependent manner platelet adhesion and aggregation on von Willebrand factor in a plate(let) and cone analyser at 1800/s. In addition the liposomes inhibited platelet adhesion, GPIIb/IIIa activation as tested by fibrinogen and PAC-1 binding, granule secretion (CD62P and CD63 surface exposure), aggregation, microparticle formation and association between platelets and monocytes induced by HOCl modified proteins (LDL, albumin, fibrinogen) and by thrombospondin peptide RFYVVMWK and inhibited thrombus formation on HOCl modified proteins in the BioFlux *in vitro* perfusion system.
Summary/Conclusion: As such pegylated liposomes have been already used in humans, for example together with recombinant factor VIII or G-CSF without adverse effects, they might be a promising new approach to be tested as anti-thrombotic therapy for acute intervention.

PA 4.01-6

Sildenafil reduces platelet activity via both NO synthase and NO synthase-independent pathways

Apostoli G, Solomon A and Emerson M
Imperial College London, London, UK

Introduction: Originally used primarily for the treatment of erectile dysfunction, sildenafil is now more widely applied in the treatment of a range of conditions that result in regional blood supply deficiencies. Sildenafil is a selective phosphodiesterase 5 (PDE5) inhibitor which enhances the nitric oxide (NO) pathway by preventing the breakdown of cyclic guanosine monophosphate (cGMP). NO signalling is an important inhibitory regulator of platelet function and it is known that platelets highly express PDE5. Platelet hyperactivity can lead to arterial thrombosis causing fatal ischaemic diseases. Platelets are conventionally thought to obtain most of their NO from endothelial nitric oxide synthase (eNOS) however more recently, reduced nitrate and nitrite from dietary sources (i.e green leafy vegetables) or NO metabolism have been suggested as alternative sources of bioactive NO.
Aims: The aim of this study were to investigate the effects of sildenafil on platelet function *in vitro* and *in vivo* and to identify the upstream sources of NO.
Methods: Collagen-induced human platelet aggregation responses to sildenafil citrate (phosphodiesterase 5 inhibitor), 1H-[1,2,4]oxadiazolo [4,3-a]quinoxalin-1-one (ODQ – soluble guanylyl cyclase (sGC) inhibitor), Nω-Nitro-L-arginine methyl ester hydrochloride (L-NAME, NOS inhibitor), $NaNO_2$ (nitrite) and ascorbic acid (reducing agent) were obtained via *in vitro* optical aggregometry. The effects of sildenafil and $NaNO_3$ (nitrate) on collagen-induced platelet aggregation were investigated *in vivo* in wild-type C57bl/6 and $eNOS^{-/-}$ mice by mea-

suring radiolabelled platelet thromboembolism in real-time via external scintillation probes connected to a spectrometer.
Results: *In vitro*, sildenafil caused significant, concentration-dependent inhibition of platelet aggregation which also occurred in the presence of L-NAME but was antagonised by ODQ. Ascorbic acid induced a concentration-dependent inhibition of platelet aggregation which was enhanced by $NaNO_2$ and blocked by ODQ. $NaNO_2$ caused a concentration-dependent inhibition of aggregation in the presence of a low concentration of sildenafil. *In vivo*, sildenafil caused a significant inhibition in platelet aggregation in wild-type but not $eNOS^{-/-}$ mice. $NaNO_3$ was associated with a non-significant trend towards inhibition of platelet aggregation in W.T mice and significantly inhibited aggregation in $eNOS^{-/-}$ mice.
Summary/Conclusions: Sildenafil induced sGC-dependent inhibition of platelet function *in vivo* and *in vitro* suggesting the presence of an upstream source of NO in both preparations. *In vitro*, sildenafil acted independently of NOS but was able to act downstream of reduced nitrite. The ability of nitrite to exert an inhibitory effect in the absence of exogenous reducing agents suggests an endogenous mechanism for reduction of nitrite to NO in platelets. In contrast, the effects of sildenafil *in vivo* were mediated predominantly via eNOS. During vascular dysfunction characterised by loss of eNOS, nitrate exerts an inhibitory effect upon platelet function *in vivo*, presumably due to reduction to NO. In conclusion, sildenafil and nitrite/nitrate may be beneficial in reducing the risk of platelet-driven cardiovascular diseases by enhancing NO-mediated inhibition of platelet function.

PA 4.02-1
Retinoic acids control translational events in platelets

Schwertz H[1] and Weyrich AS[2]
[1]*University Medicine Greifswald, Greifswald, Germany;*
[2]*University of Utah, Salt Lake City, UT, USA*

Background: Recently we were able to demonstrate that human platelets reproducibly form progeny, and continue to produce daughter cells in the circulation. This process occurs in freshly-isolated platelets as well as in stored platelets. In addition, the ability to produce progeny appears to depend on protein synthetic events. Retinoids are a group of naturally-occurring vitamin A derivatives that regulate cellular differentiation, growth, and therefore protein synthetic events. Some retinoid X receptor family members have previously been reported in platelets. All-trans retinoic acid (atRA) signals through the retinoic acid receptor (RAR), which is expressed by most cell types. The stereoisomer of atRA is 9-cis retinoic acid (9-cisRA), which is a high-affinity ligand for the retinoid X receptor family (RXR).
Aims: We wanted to examine if RAR and RXR family members are expressed and control translational events in platelets during progeny formation.
Methods: Freshly isolated human platelets were used for all experiments. Expression of RAR and RXR were examined on RNA and protein levels. Protein-protein-interactions and RNA binding capacities were studied by combining immune-precipitation and RNA binding assays.
Results: RNA coding for RAR and RXR family members were detected by next generation sequencing as well as by PCR approaches. In immunocytochemical studies we were able to detect expression of RAR and RXR family members in platelets that form new cell bodies. First, RARs showed co-localization with cytoskeletal proteins indicating regulatory functions in regards of cytoskeletal rearrangement during platelet progeny formation. Second, we demonstrated that RARs bind to mRNAs. The binding capacity was influenced by retinoid treatment. In addition, we were able to demonstrate translational regulation of target proteins due to retinoid treatment, providing mechanistic insights into regulatory processes involved in platelet progeny formation.
Conclusions: These data demonstrate that platelets utilize nuclear receptors for new functions like translational regulation. In addition, we show that progeny formation is a regulated process by internal or external cues.

Platelet Rap1 signaling, mediated by CalDAG-GEFI and P2Y12, contributes to atherosclerotic lesion development in mice

Boulaftali Y[1], Owens AP III[1], Beale A[1], Piatt R[1], Andre P[2], Conley PB[2], Mackman N[1] and Bergmeier W[1]
[1]*University of North Carolina Chapel Hill, Chapel Hill, NC;*
[2]*Portola Pharmaceuticals, South San Francisco, CA, USA*

Background: The development and progression of atherosclerotic lesions is mediated by various blood cell types, including platelets and neutrophils. We recently identified CalDAG-GEFI (CDGI), a guanine nucleotide exchange factor for Rap GTPases, as a critical component of integrin-mediated adhesion of platelets and neutrophils at sites of vascular injury. In platelets, signaling by CDGI mediates the early activation of Rap1, while the Gi-coupled receptor for ADP, P2Y12, the target of the clinically used drug Plavix, is required for sustained Rap1 activation and thrombus stability.
Aim: In this study, we evaluated lesion formation in atherosclerosis-prone low-density lipoprotein receptor deficient $Ldlr^{-/-}$ mice lacking CDGI and/or P2Y12 in hematopoietic cells only.
Methods: $Ldlr^{-/-}$ mice were irradiated and reconstituted with bone-marrow from wild-type (WT), CalDAG-$GEFI^{-/-}$ (CdgI), $P2y12^{-/-}$ (P2y12) or $CdgI^{-/-}$ $P2y12^{-/-}$ (DKO) mice. Reconstituted mice were fed a high-fat diet (21% fat, 0.2% cholesterol) for 12 weeks, ad libitum, and hearts and aortas were harvested. Oil Red O staining was performed on cross sections of the aortic sinus and the lesion size was quantified. After 8 weeks of high fat diet, blood was drawn from the retro-orbital plexus and blood cell counts as well as platelet activation were determined. Blood was also perfused over collagen in a microfluidics chamber system and integrin-mediated adhesion of platelets and neutrophils was studied.
Results: Atherosclerotic lesions in the aortic sinus of $Ldlr^{-/-}$;$CdgI^{-/-}$ chimeras were approximately 42% smaller than those in $Ldlr^{-/-}$;WT controls (0.18 ± 0.02 vs. 0.31 ± 0.05 mm^2,respectively) ($n = 13$, $P < 0.001$). Lesions in $Ldlr^{-/-}$;$P2y12^{-/-}$ chimeras were also significantly smaller than those in controls (0.22 ± 0.10 mm^2; $n = 13$, $P < 0.05$), confirming recent findings in $Apoe^{-/-}$; $P2y12^{-/-}$ mice. $Ldlr^{-/-}$;DKO chimeras had the smallest lesions, reduced by 48% compared with WT controls, (0.16 ± 0.02 vs. 0.31 ± 0.05 mm^2,respectively) ($n = 13$, $P < 0.001$), but they were not statistically different from $Ldlr^{-/-}$; $CdgI^{-/-}$ chimeras. Platelet counts were similar in blood from hypercholesterolemic $Ldlr^{-/-}$; $CdgI^{-/-}$, $Ldlr^{-/-}$; $P2y12^{-/-}$, and $Ldlr^{-/-}$; DKO chimeras. Consistent with previous findings, the fraction of neutrophils in relation to all white blood cells was elevated in $Ldlr^{-/-}$; $CdgI^{-/-}$ but not in $Ldlr^{-/-}$; $P2y12^{-/-}$ chimeras. Platelet adhesion and activation on collagen under flow was markedly impaired in $Ldlr^{-/-}$; $CdgI^{-/-}$ and $Ldlr^{-/-}$;DKO blood. In contrast, a partial defect in platelet adhesion and activation was seen in $Ldlr^{-/-}$; $P2y12^{-/-}$ blood. Consistently, firm neutrophil adhesion to collagen-bound platelets was reduced by > 90% in $Ldlr^{-/-}$;$CdgI^{-/-}$ and $Ldlr^{-/-}$; DKO blood, while no significant reduction was observed in $Ldlr^{-/-}$; $P2y12^{-/-}$ blood. Total cholesterol and triglyceride levels were similar among groups.
Summary/Conclusion: Our findings reveal a critical role for CDGI and P2Y12, and Rap1-dependent platelet activation, in promoting atherosclerotic lesion development in hypercholesterolemic mice. Further studies are required to determine if the observed protection in $Ldlr^{-/-}$; $CdgI^{-/-}$ chimeras is in part due to impaired neutrophil function.

PA 4.02-3

Antithrombotic actions of statins involve PECAM-1 signalling

Moraes LA, Vaiyapuri S, Sasikumar P, Kriek N, Sage T and Gibbins JM

Institute for Cardiovascular and Metabolic Research, University of Reading, Reading, UK

Background: Statins are widely prescribed cholesterol-lowering drugs that are a first-line treatment for coronary artery disease and atherosclerosis, reducing the incidence of thrombotic events such as myocardial infarction and stroke. Statins have been shown to reduce platelet activation, although the mechanism(s) through which this occurs is unclear.

Aims: Since several of the characteristic effects of statins on platelets are shared with those elicited by the inhibitory platelet adhesion receptor PECAM-1, we investigated a potential connection between the influence of statins on platelet function and PECAM-1 signalling.

Methods: Washed human platelets were treated for 5 min with increasing concentration of simvastatin or fluvastatin, prior stimulation for 90s with collagen-related peptide CRP-XL (0.5 mg/mL) and aggregation measured at 37 °C under constant stirring conditions. Changes in ATP concentration were used as a measure of dense-granule secretion and monitored simultaneously with aggregation in an optical lumi-aggregometer using a luciferase detection system. Flow cytometry was used to examine fibrinogen binding to integrin $a_{II}bb_3$ and a-granule secretion. Washed human platelets were incubated with simvastatin or control for 5 min prior to CRP-XL (1 mg/mL) stimulation in the presence of EGTA (10 mM), indomethacin (10 mM) and apyrase (2 U/mL). PECAM-1 was immunoprecipitated from lysates using anti-PECAM-1 antibody (WM59) and immunoblotted with an antiphosphotyrosine antibody (4G10). Analysis of thrombus formation under arterial flow conditions were performed using DIOC6 labelled human citrated blood and perfused over a collagen coated Vena8 BioChip (Cellix Ltd, Dublin, Ireland) with and without prior incubation with statins, at a shear rate of 20 dynes/cm^2. Z-stack images of thrombi were obtained every 30 s for up to 10 min using a Nikon eclipse (TE2000-U) microscope (Nikon, Surrey, UK). *In vivo* Thrombus formation was performed using C57BL/6 and PECAM-1 knockout mice, where platelets were fluorescently labeled by injection of Alexa488-conjugated anti-GPIb antibody. After laser injury of the cremaster muscle arterioles, accumulation of platelets was assessed. Images were captured prior to and after the injury by a Hamamatsu charged-coupled device camera C9300 in 640 × 480 format (Hamamatsu Photonics, UK) and analysed using slidebook5 software (Intelligent Imaging Innovations, Denver, USA).

Results: Statins were found to inhibit a range of platelet functional responses and thrombus formation *in vitro* and *in vivo*. Notably, these effects of statins on platelet function *in vitro* and *in vivo* were diminished in PECAM-1$^{-/-}$ platelets. Activation of PECAM-1 signalling results in its tyrosine phosphorylation, the recruitment and activation of tyrosine phosphatase SHP-2, the subsequent binding of phosphoinositol 3-kinase (PI3-K) and diminished PI3-K signalling. Statins resulted in the stimulation of these events, leading to the inhibition of Akt activation.

Conclusions: Together, these data provides evidence for a fundamental role of PECAM-1 in the inhibitory effects of statins on platelet activation, which may explain some of the pleiotropic actions of these drugs.

PA 4.02-4

Hydrophobic regions on protein surfaces, an ancient damage-associated molecular pattern, induce platelet activation

Kehrel BE[1], Bertling A[1], Jurk K[1], Heilmann C[2], Lahav J[3], Nofer J-R[4] and Brodde MF[1]

[1]University Hospital Muenster; [2]University Muenster, Muenster, Germany; [3]Rabin Medical Center, Beilinson Hospital, Petah Tikva, Israel; [4]Centre for Laboratory Medicine, University Hospital Muenster, Muenster, Germany

Background: Immune responses are initiated by pathogen-associated molecular patterns or by tissue-derived danger/alarm signals. Hydrophobic portions of proteins act, when exposed, as universal damage-associated molecular patterns, as shown by Matzinger. Herczenik et al. demonstrated that misfolded/partly unfolded proteins were able to activate platelets. Exposure of *hydrophobic* regions on its surface, the thermodynamic *hallmark* of a misfolded/partly *unfolded* protein, is recognized by the chaperone BiP/GRP78.

Aims: As platelet activation can be regarded as a response to injury, we studied the role of exposed hydrophobic areas in platelet activation by misfolded/partly unfolded proteins.

Methods: The effect of the completely different misfolded proteins on platelet adhesion, activation, secretion, aggregation, and thrombus formation was investigated by aggregometry, flow cytometry, thrombus formation in *in vitro* perfusion chambers, confocal laser scanning microscopy and plasmon resonance.

Results: The chaperones GRP78, and protein disulfide isomerase showed prominent, punctuate staining, with striking co-localization at the platelet surface. All tested misfolded proteins, HOCl oxidised Albumin, Eap from S. aureus, human neutrophil alpha defensin modified plasma proteins, thrombospondin-1 in its amyloid like state and von Willebrand factor under high shear conditions, induced platelet adhesion, GPIIb/IIIa activation, granule secretion, platelet aggregation and *in vitro* thrombus formation. All used agonistic proteins exposed aggregation-prone hydrophobic regions. Soluble BIP/GRP78 as well as soluble PDI, inhibitors of the PDI and the hydrophobic probe 4,4′-bis(1- anilinonaphthalene 8-sulfonate) (bis-ANS) inhibited platelet activation in a dose dependent manner.

Summary/Conclusion: Human platelets present the chaperone BIP/GRP78 on their surface. Platelet activation by misfolded proteins is inhibited by soluble chaperones that recognize exposure of hydrophobic regions on their surface, as well as by the hydrophobic probe bis-ANS. As hydrophobic regions on protein surfaces, an ancient damage-associated molecular pattern, induce platelet activation, platelet activation in thrombosis might be regarded as a mechanism to initiate repair, remodeling and defense against microorganisms, rather than inappropriate activation of haemostatic mechanisms. Future work in this filed might lead to an antithrombotic agent that will inhibit thrombosis, but spare haemostasis

PA 4.02-5

Amplification of platelet activation by surface pannexin-1 hemichannels

Taylor KA, Wright JR, Vial C, Evans RJ and Mahaut-Smith MP

University of Leicester, Leicester, UK

Background: Pannexin 1 (Panx1) forms an ion channel permeable to molecules up to 1000 Da and represents a non-lytic, non-vesicular ATP release pathway in erythrocytes, leukocytes and neurons. A role for related connexin gap junction proteins in haemostasis and thrombosis has recently been reported (Vaiyapuri et al. 2012, Circulation 125, 2479; Angelillo-Scherrer et al. 2012 Circulation 124, 930) whereas the expression and role of platelet pannexins remains unknown.

Aims: To determine the expression and functional role of pannexins in human platelets using a variety of molecular, cellular and functional techniques.
Methods: Washed suspensions of human platelets were isolated from informed consenting healthy donors with local ethical committee permission. Platelets were lysed in RIPA buffer for protein studies or fixed with paraformaldehyde for immunohistochemstry (IHC). mRNA from ultra-purified platelets was analysed by quantitative PCR. Aggregometry, ATP release, and calcium measurements were performed under conditions where P2X1 function was preserved (0.32 U/mL apyrase). Block of Panx1 was achieved with the two structurally unrelated and widely used inhibitors at concentrations that do not affect connexin channels; probenecid (Prb, 100 μM) and carbenoxolone (Cbx, 10 μM).
Results: Panx1, but not Panx2 or 3, was detected in platelet mRNA samples at a similar level to P2X1. Western blotting showed that Panx1 ran as a PNGaseF-sensitive glycosylated protein at 48 kDa. From biotinylation and IHC studies, Panx1 was found to be predominantly located on the surface membrane. Prb or Cbx inhibited Ca^{2+} influx to a range of agonists by up to 30%. Prb and Cbx also inhibited ATP secretion and aggregation, with the greatest effect (80% reduction in aggregation and 75% reduction in secretion) observed at low concentrations of collagen (0.5 μg/mL) where desensitisation of P2X1 receptors with α,β me-ATP had an equivalent effect to Panx1 blockade. Co-immunoprecipitation experiments with Panx1 and P2X1 demonstrated a weak association between these proteins.
Summary/Conclusions: Panx1 protein is present on the surface of platelets as the fully glycosylated species, which supports formation of ATP-permeable hemichannels but not gap junctions. The data suggest that Panx1 contributes to ATP release and secondary activation of platelets, particularly at low levels of collagen where aggregation depends upon secondary activation of P2X1 receptors. Panx1 may therefore have an amplifying role in arterial thrombosis.

PA 4.02-6
PKCd negatively regulates platelet function in response to thrombin via GPIba

Zaid Y[1], Hachem A[1], Yacoub D[2], Mourad W[2] and Merhi Y[1]
[1]*Montreal Heart Institute;* [2]*University of Montreal Hospital Center, Montreal, QC, Canada*

Background and Aims: The protein kinase C (PKC) family is essential for platelet function in response to various platelet agonists including thrombin. Thrombin signaling in platelets is mediated by a specialized family of G-protein-coupled receptors known as protease-activated receptors (PARs) and by GPIbα. Indeed, GPIbα, PAR1, and PAR4 are considered the high-, medium-, and low-affinity thrombin receptors in human platelets, respectively. It has been shown that PKC delta (PKCδ) negatively and positively influences platelet function in response to collagen and PAR stimulation, respectively. However, its importance in response to thrombin stimulation via the high-affinity GPIbα binding site is not known. This study was therefore designed to examine the role of GPIbα in platelet PKCδ signaling and function.
Methods and Results: We found that in human platelets, pre-treatment with a specific PKCδ membrane translocation inhibitor δ(V1-1)TAT significantly potentiated platelet aggregation and activation, as well as PKCδ phosphorylation on Tyr^{311}, in response to a priming concentration of thrombin. However, the responses to high concentrations of thrombin or to the PAR agonist peptides, TRAP1 and TRAP4, were not affected. This potentiation process is GPIbα-dependent, as specific inhibition of the high affinity thrombin-binding site on GPIbα reverses this effect. These results were reproduced using platelets from $PKC\delta^{-/-}$ mice and in platelets from WT mice pre-treated with δ(V1-1)TAT. Notably, tail bleeding times and blood platelet counts in $PKC\delta^{-/-}$ mice were significantly decreased following low thrombin injection as compared to WT mice, which is indicative of enhanced platelet activation. In addition, lung histological sections from $PKC\delta^{-/-}$ mice reveal exacerbated pulmonary thromboembolisms in response to a low-dose thrombin challenge. Importantly, $PKC\delta^{-/-}$ mice treated with a blocking anti-mouse GPIbα antibody were protected from these effects.
Conclusion: This study adds new insights into the role of PKCδ in platelet function downstream of GPIbα, where it negatively regulates platelet aggregation and activation in response to a priming concentration of thrombin. Thus, PKCδ may constitute a target in the management of thrombotic events.

PA4.03 – Platelets and Leukocytes

PA 4.03-1
Membrane fragments from dying platelets promote leukocyte aggregation and vascular obstruction during ischemia-reperfusion injury

Yuan Y, Kaplan Z, Ashworth K, Alwis I and Jackson SP
Monash University, Melbourne, Vic., Australia

Background: Ischemia-reperfusion (I/R) injury is a prominent feature of a wide range of human diseases, characterised by tissue damage initiated by vessel obstruction and exacerbated by blood reperfusion. I/R injury to the intestines can result in remote organ injury to the lung, leading to the acute respiratory distress syndrome, a condition associated with considerable morbidity and mortality. Both leukocytes and platelets are known to be important in this process however it is unclear how they promote remote organ injury.
Aim: We have examined the mechanism by which platelets in the ischemic mesenteric circulation promote leukocyte adhesion and infiltration into the lung parenchyma during mesenteric I/R injury.
Methods: A mouse mesenteric I/R injury model was utilised and the injury was induced by clamping the mouse superior mesenteric artery for 30, 60 or 90 min followed by blood flow restoration. The adhesive behaviour of leukocytes and platelets in the mesenteric circulation and in the lung was monitored by intravital microscopy and histology, respectively.
Results: Utilising a confocal imaging technique that enables detailed analysis of the entire mesenteric microvasculature during I/R injury we confirmed extensive leukocyte adhesion and rolling onto the surface of ischemic endothelial cells. Unexpectantly, we demonstrated that up to 50% of rolling leukocytes formed aggregates. These aggregates developed in the mesenteric venous circulation within minutes of blood reperfusion which increased as a function of ischemia time (30–90′). Anti-Gr1Ab staining revealed that neutrophils were the dominant leukocyte population forming aggregates, with aggregate size varying from 2 to > 10 cells. Co-staining platelets and neutrophils revealed the presence of both cell types in the aggregates and depletion of platelets from the circulation completely eliminated aggregate formation. Similarly, WT mice transplanted with bone marrow from P-selectin deficient mice revealed that platelet P-selectin ($P\text{-}sel^{PL}$) was critical for neutrophil aggregation. Greater than 80% of the platelets within the leukocyte aggregates expressed phosphatidylserine (PS^{+ve}) on the cell surface and analysis of leukocyte aggregate formation under shear conditions *in vitro* confirmed that PS^{+ve} platelets were both necessary and sufficient to induce leukocyte aggregate formation. PS^{+ve} platelets lose their cytoskeletal network and the membranes became fragile under shear, leading to the extrusion of long membrane strings and large cellular fragments. These strings/fragments were pulled from the surface of platelets by rolling leukocytes, forming a physical bridge between adjacent leukocytes. Injection of PS^{+ve} platelet fragments into the portal circulation during intestinal I/R injury greatly enhanced leukocyte aggregation in the portal vein and lung vasculature, leading to increased leukocyte infiltration and interstitial oedema.
Conclusion: These studies define a new proinflammatory function for dying platelets that involves the shear-dependent formation of membrane strings/fragments, capable of inducing leukocyte aggregation and vascular obstruction. PS^{+ve} fragments from dying platelets can

circulate from the portal circulation to the lung thereby promoting pulmonary leukocyte aggregation and remote organ injury.

PA 4.03-2

Platelets limit the histotoxic activities of infiltrating neutrophils and act as vascular healing patches in inflamed tissues

Ho Tin Noe B[1], Ollivier V[2], Lamrani L[2] and Jandrot-Perrus M[2]
[1]*Inserm UMR698;* [2]*Inserm, Paris, France*

Platelets are now recognized as major actors of innate and adaptive immune responses. In particular, it is well established that platelets support leukocyte infiltration into diseased tissues in various pathophysiological situations such as cancer, atherosclerosis, dermatitis, stroke, and acute lung injury. In addition to this leukocyte supporting action, platelets exert protective effects on vessels at sites of leukocyte infiltration, resulting in prevention of tissue hemorrhage. Thus, although platelets promote leukocyte infiltration through the activated endothelium, notably by loosening endothelial junctions and supporting endothelial activation, they also play a highly positive, vascular protective role in inflamed tissues. Here, using models of acute dermatitis, peritonitis, and pneumonitis, and *in vitro* experiments using isolated human platelets and neutrophils, antibody-induced profound thrombocytopenia and neutropenia in mice, we investigated the role of platelets in regulating the activation of infiltrating neutrophils. We show that GPVI-dependent early recruitment of platelets to the activated endothelium is required for prevention of neutrophil-induced bleeding in both immune-complexes-induced dermatitis and LPS-induced pneumonitis. We further show that although thrombocytopenic mice display reduced neutrophil infiltration in inflamed skin, lungs and peritoneal cavity, they are also characterized by an increased activation of infiltrating neutrophils, as indicated by the increased release of myeloperoxidase and elastase by their neutrophils, as compared to that of control mice. The ability of platelets to counter neutrophil-derived histotoxic activities was confirmed by co-incubating isolated human neutrophils and platelets, in the presence or absence of the pro-inflammatory cytokine TNF-alpha. Using pharmacological inhibitors of GPVI and ADP signalling, we found that this anti-neutrophil action of platelets was independent of GPVI but requires platelet activation. Together, our results indicate that although platelets favour neutrophil infiltration, they also limit the histotoxic activities of infiltrating neutrophils and act as vascular healing patches in inflamed tissues, thus limiting vascular injuries and bleeding.

Platelet thrombi utilize co-operative biochemical and biophysical mechanisms to induce excessive leukocyte accumulation to sites of endothelial injury

Alwis I[1], Kaplan Z[1], Ghasemzadeh M[1], Yuan Y[1], Bark D[1], Tovar-Lopez FJ[2], Nesbitt W[1] and Jackson SP[1]
[1]*Monash University;* [2]*RMIT University, Melbourne, Vic., Australia*

Background: Ischemia-reperfusion injury is associated with an intense inflammatory infiltrate that exacerbates tissue injury. It is generally considered that ischemic injury to the endothelium, leading to upregulated expression of adhesion molecules and proinflammatory cytokines, is the principal mechanism promoting leukocyte recruitment and inflammation. A growing body of evidence has suggested a potentially important role for the proinflammatory function of platelets in exacerbating leukocyte recruitment, inflammation and tissue damage following I/R injury, however the mechanisms responsible for this remain poorly defined.

Aim: To investigate the mechanisms by which platelets induce an exaggerated leukocyte recruitment response at sites of endothelial perturbation.

Methods: We established a murine model of intestinal I/R injury and used confocal intravital microscopy to analyse platelet and leukocyte adhesive responses in ischemic tissue. We subsequently developed a model of mechanical injury using micromanipulator needles in the mesenteric vasculature of mice to enable investigation of the mechanisms regulating platelet-leukocyte interactions. Particle image velocimtery (PIV) and computational fluid dynamics (CFD) were used to measure rheological parameters.

Results: Intravital confocal imaging of the murine intestinal microvasculature following I/R injury identified distinct patterns of leukocyte recruitment in the ischemic tissue, ranging from minimal stable adhesion to regions of extensive leukocyte accumulation and tissue infiltration. Significantly, the regions of exaggerated leukocyte adhesion correlated with the presence of platelet-rich thrombi, with leukocytes preferentially adhering to larger thrombi (surface area $> 0.5 \times 10^3$ mm^2). Leukocytes adherent to thrombi had a polarised, elongated morphology with enhanced motility, suggesting a potentially important role for thrombi in promoting localized infiltration of leukocytes into ischemic tissue. To identify the mechanisms by which platelet thrombi mediate efficient leukocyte recruitment *in vivo*, we developed a localised model of microvascular injury using microinjector needles. In this model we controlled the level of platelet activation by microinjecting platelet agonists and identified thrombin as the most potent inducer of leukocyte-thrombus interactions. There was a direct correlation between thrombus size and the efficiency of leukocyte recruitment and computational fluid dynamic analysis (CFD) revealed that the three-dimensional shape of the thrombus resulted in the formation of low shear pockets (< 100/s) where leukocyte accumulation preferentially occurred. Notably, large thrombi and potent platelet stimulation were not sufficient to induce efficient leukocyte recruitment in arteries. However, controlled manipulation of arterial flow rates demonstrated that the bulk flow rate had a profound impact on leukocyte-thrombus interactions, with an approximately 80% reduction in arterial flow leading to a > 50 fold increase in leukocyte recruitment.

Conclusion: These studies identify the key biochemical and biophysical factors which modulate leukocyte-thrombus interactions *in vivo*. Our results define the cooperative influences of both biochemical (platelet activation status and thrombin generation) and biophysical factors (loco-regional rheological effects imparted by thrombus size and prevailing bulk flow) in regulating leukocyte recruitment by microvascular thrombi. These findings may help explain the potent thromboinflammatory response that is characteristic of I/R injury, where excess thrombin generation and platelet activation, in combination with disturbed blood flow amplifies the thromboinflammatory response.

PA 4.03-4

Platelet FLow-Induced PRotrusions (FLIPRs): a landing strip for circulating monocytes

Tersteeg C[1], Heijnen HF[1], Pasterkamp G[1], Maas C[1], Urbanus RT[1], Hoefer I[1], Nieuwland R[2], Farndale RW[3], De Groot PG[1] and Roest M[1]
[1]*UMC Utrecht, Utrecht;* [2]*AMC Amsterdam, Amsterdam, The Netherlands;* [3]*University of Cambridge, Cambridge, UK*

Background: Platelets are the most important cells in the primary prevention of blood loss after injury. In addition, platelets provide a negatively charged phospholipid surface to support coagulation and are also involved in inflammatory responses through their interaction with leukocytes.

Methods: We perfused platelets over a fibrinogen surface and activated them with the GPVI agonist collagen related peptide (CRP). We

describe the formation of extremely long, negatively charged membrane strands that emerge from platelets adhered under flow conditions.

Results: FLow-Induced PRotrusions (FLIPRs) are formed downstream of adherent and activated platelets, and reach lengths up to 250 mm, which is 80-fold more than the size of and individual platelet. FLIPR formation occurs on 19.5 ± 4.1% of the platelets in a process that depends on the activation of calpain and is accompanied by a disassembly of the actin and microtubule organization. Due to shearing forces, FLIPRs severe/disintegrate leading to the generation of procoagulant microparticles. Furthermore our data reveal that FLIPRs may serve as a surface extension for tethering of monocytes required for monocyte accumulation at the vessel wall and subsequent recruitment of platelet-derived FLIPRs/microparticles from the surface. Monocyte binding to the membrane strands was dependent on the interaction between P-selectin -and PSGL-1.

Conclusion: Our study demonstrates that platelets have the capacity to create extremely long membrane extensions that may serve as capturing devices for circulating monocytes.

PA 4.03-5

Zebrafish as a model to investigate the effect of P2Y12 knockdown on leukocyte migration

Bright R, Storey R and Chico T

University of Sheffield, Sheffield, UK

Background: Activation of the platelet $P2Y_{12}$ receptor by ADP induces degranulation of α and dense granules from the platelet. α-granules release a myriad of different proteins including pro-inflammatory mediators that are involved in vascular inflammation as well as antimicrobial peptides. Clopidogrel and ticagrelor are $P2Y_{12}$ inhibitors that are used in the treatment and prevention of arterial thrombosis. Ticagrelor yields greater and more consistent $P2Y_{12}$ inhibition compared to clopidogrel. In the PLATO study, ticagrelor reduced mortality compared to clopidogrel in patients with acute coronary syndromes and post hoc analysis has suggested that partly this may be due to differential effects of the drugs on susceptibility to pulmonary infection and its complications. Zebrafish represent an ideal model to study inflammatory processes as transgenic zebrafish lines with fluorescently tagged macrophages and neutrophils enable excellent *in vivo* visualisation of migration. Temporary knockdown of gene function is achieved in the zebrafish by injection of morpholino antisense oligonucleotide.

Aims: To investigate the effect of $P2Y_{12}$ receptor knockdown on macrophage and neutrophil migration to injury.

Methods: The zebrafish transgenic *fmsgal4;UNM;mpoGFP* was utilised, in which mcherry red fluorescent protein is driven by the macrophage *fms* promoter, and Green Fluorescent Protein (GFP) is driven by the neutrophil specific myeloperoxidase (*mpo*) promoter. These double transgenics were injected at the 1 cell stage with 2.1 μg of either $P2Y_{12}$ or control morpholino antisense oligonucleotide. The effect of $P2Y_{12}$ knockdown was assessed by quantification of thrombus formation after laser-induced injury of the dorsal aorta. At 3 days post fertilisation (dpf) the ventral wall of the dorsal aorta was injured by laser, inducing thrombosis. The inflammatory response was induced by injury to the tail fin of 3 dpf larvae. Subsequent migration of macrophages and neutrophils were ascertained by counting number of macrophages or neutrophils present within the region between the tail injury site and loop of circulation 1, 4 and 8 h post injury.

Results: $P2Y_{12}$ receptor knockdown significantly reduced thrombus area in response to vessel injury ($2.26 \pm 0.4 \times 10^6$ pixels^2 control $0.12 \pm 0.01 \times 10^6$ pixels^2 $P2Y_{12}$ $P < 0.001$). The numbers of macrophages and neutrophils at the site of tail injury were determined for both the control and $P2Y_{12}$ knockdown groups. There was no significant difference between the groups in the numbers of macrophages or neutrophils at the site of injury.

Summary and Conclusion: $P2Y_{12}$ receptor knockdown significantly reduced thrombus area in response to vessel injury. However there was no significant effect on migration of macrophages and neutrophils to sites of injury. We therefore found no evidence that $P2Y_{12}$ plays a role in leukocyte migration in this model. Further work is required to explore potential mechanisms for differential effects of ticagrelor and clopidogrel on innate immunity.

PA 4.03-6

Cell-specific role of junctional adhesion molecule-A in flow-dependent atherosclerosis

Koenen R[1], Schmitt M[2], Megens RT[2], Zernecke A[3], Van Den Akker M[1], Rademakers T[1], Van Zandvoort MAMJ[1], Hackeng TM[1] and Weber C[2]

[1]Maastricht University, Maastricht, The Netherlands; [2]University Clinic of the LMU Munich; [3]Technical University Munich, Munich, Germany

Background: Leukocyte transendothelial migration is a crucial event in atherosclerotic lesion formation and is controlled by a multi modal cascade comprising adhesion molecules, integrins and cytokines. Junctional Adhesion Molecule- (JAM-) A, as a transmembrane protein mainly located in endothelial cell (EC) junctions and on leukocytes, displays a wide variety of functions in cell polarity, barrier function, leukocyte adhesion as well as stem cell adhesion and differentiation.

Aims: Little is known about the involvement of JAM-A from differing cellular origins to atherogenesis. As JAM-A from differing cellular origins display different or even contrary effects in a number of inflammatory disease models, we wanted to delineate the role of leukocytic, endothelial and somatic JAM-A on atherogenesis.

Methods: Besides common (immune-) histology for plaque assessment, molecular biological approaches for protein expression pattern recognition and functional assays for *in vitro* transendothelial migration, multi-photon laser scanning microscopy (MPLSM) was used to obtain crucial data e.g. *ex vivo* protein localization, *in vivo* transendothelial migration and *ex vivo* vessel permeability. Transgenic mice deficient for endothelial or leukocyte or both JAM-A origins with or without apolipoprotein ($Apoe^{-/-}$) deficiency were used.

Results: Deficiency of JAM-A expression in endothelial cells reduced atherosclerotic lesion and necrotic core formation and T- cell and macrophage content in $Apoe^{-/-}$ mice. In contrast, JAM-A deficiency in leukocytes increased lesion size, necrotic core and infiltration in chimeric $Apoe^{-/-}$ mice, amounting to indifferent effects in $Apoe^{-/-}$ mice with a somatic JAM-A deletion. In line with decreased macrophage transendothelial migration in plaques of mice lacking endothelial JAM-A, a reduced monocyte transendothelial migration could be demonstrated in *in vitro* assays and *in vivo* in mice deficient for endothelial JAM-A by high-resonance scanning MPLSM. Further, MPLSM of atherosclerotic carotid arteries *ex vivo* revealed a focal concentration and redistribution of endothelial JAM-A to the luminal surface in lesion-proneareas, which also could be validated in appropriate *in vitro* assays. Deletion of endothelial JAM-A had no direct influence on barrier function in contrast to deletion of leukocytic JAM-A, which showed an increase in vessel permeability.

Conclusion: Our data identify specific and targetable functions of endothelial JAM-A in atherosclerosis, which are mediated by its upregulation and redistribution under atherogenic conditions. Moreover, we were able to demonstrate contrary effects for JAM-A from differing origins in atherogenesis, emphasizing the importance of a comprehensive assessment of targets.

PA4.04 – Thrombocytopenia Models

PA 4.04-1

Only severe thrombocytopenia results in bleeding and defective thrombus formation in mice

Morowski M[1], Vögtle T[1], Kraft P[2], Kleinschnitz C[2], Stoll G[2] and Nieswandt B[1]

[1]*University Hospital Würzburg and Rudolf Virchow Center;* [2]*University of Würzburg, Würzburg, Germany*

Background: Platelets are essential players in thrombosis and haemostasis and their counts in peripheral blood average at 250 platelets/nL in humans. Thrombocytopenia is diagnosed if the platelet count is below 100 platelets/nL blood, but patients only have to undergo medical treatment to avoid excessive bleeding, if the platelet count is below 30 platelets/nL. On the other hand, it is not entirely clear how platelet counts affect the occurrence of acute ischaemic disease states, such as myocardial infarction or stroke.

Aims: Mice, which display a platelet count of 1000 platelets/nL blood, are an important model system to study haemostasis as well as the pathomechanisms underlying ischaemic diseases. To date, no systematic study has been reported that assessed the significance of platelet counts for normal haemostasis and experimental ischaemic diseases in mice.

Methods: To address the question to which extent the platelet count affects normal haemostasis and the occurrence of thrombotic events, we reduced platelet counts in mice to defined ranges between 0 and 1000 platelets/nL by platelet-depleting antibodies. Mice were then subjected to five different *in vivo* models to assess haemostatic and thrombotic function: tail bleeding time assay, thrombosis models in aorta, carotid artery and mesenteric arterioles as well as the transient middle cerebral artery occlusion (tMCAO) model of ischaemic stroke.

Results: We show that thrombotic occlusion of injured aortas and carotid arteries (large arteries) were partially impaired when the platelet count was reduced by 70% or 80%, respectively. In contrast, tail bleeding times and thrombus formation in small arterioles were largely unaffected by reductions of the platelet count up to 97.5%. Similarly, infarct growth and neurological deficits following tMCAO were unaffected by reductions of the platelet count up to 90% whereas a further reduction was protective.

Conclusion: These results reveal that arterial thrombosis, cerebral infarction and haemostasis in mice efficiently occur at unexpectedly low platelet counts which may have implications for humans at risk of thrombotic or hemorrhagic disease. Furthermore, our experimental thrombosis models indicate that occlusive thrombus formation in large vessels may be more sensitive to a reduced platelet count compared to small vessels.

PA 4.04-2

A novel non-antibody mediated model of thrombocytopenia allows efficient adoptive transfer of platelets and assessment of platelet function

Zhou CJ, Gangadharan B and Jobe SM

Emory University, Children's Healthcare of Atlanta, Atlanta, GA, USA

Background: Thrombocytopenic murine models have provided numerous insights into the role of platelets in normal physiology and disease. However, current methods of platelet depletion rely on either chemotherapeuticor antibody-based approaches. Off-target effects on the vasculature make interpretation of any results obtained using the chemotherapeutic approach problematic, while persistence of circulating antibody and rapid recovery of native platelets make adoptive transfer approaches technically challenging. Furthermore, antibody-mediated platelet opsonization and splenic clearance can induce immunoregulatory cytokine expression.

Aim: Develop a novel non-antibody mediated model of thrombocytopenia that will allow efficient adoptive transfer of platelets and assessment of platelet function

Methods and Results: Mice expressing simian diphtheria toxin receptor (DTR) on the megakaryocyte/platelet lineage (DTR^{PF4Cre}) were generated by crossing B6-iDTR mice (containing a simian DTR allele whose expression is blocked by an upstream *loxP*-flanked STOP sequence) with PF4-Cre mice. Since the cells of non-primate species lack the cell-surface receptor recognized by DT, mice are unaffected by injection of DT. Injection of 10 ng/g DT every third to DTR^{PF4Cre} mice resulted in complete platelet ablation (< 5%) of platelets by day 6 after injection, which was maintained through day 10. Depletion of megakaryocytes was confirmed by evaluation of bone marrow histology. Administration of an identical DT dose to control B6-iDTR mice (no DT expression) was without effect. Platelet-ablated mice were viable, and abnormal purpura was noted only with trauma.

To test the feasibility of adoptive transfer, donor platelets (DTR^{PF4Cre} negative) were transfused on day 1 after treatment with DT. 8×10^8 platelets injected by tail-vein or retro-orbital injection raised the circulating platelet count to approximately 3×10^5/mL in a 10–13 week old mouse. The function of the transferred platelets was assessed in a tail bleeding assay. Bleeding time in normal mice was 182 ± 73 s and platelet count was approximately 1000 K/μL. In platelet-depleted mice, bleeding did not cease prior to 600 s. Platelet repletion to 100–200 K/μL resulted in correction of the tail bleeding time to 340 ± 191 s. Bleeding time was normalized by platelet repletion to > 300 K/μL.

Conclusions: We have developed a novel non-antibody mediated method of platelet depletion that readily allows adoptive platelet transfer and assessment of platelet function. We expect that utilization of this model will allow the rapid assessment of platelet-specific roles in both genetic and acquired murine models of disease.

PA 4.04-3

Fucoidan improves adenovirus mediated thrombocytopenia and enhances viral liver transduction

Kaur H[1], Toukh M[1], Corscadden K[1], Parker AL[2] and Othman M[1]

[1]*Queen's University, Kingston, ON, Canada;* [2]*University of Glasgow, Glasgow, UK*

Background: Fucoidin is a known potent P-selectin antagonist and an inhibitor of platelet leukocyte- endothelial- interactions. Platelet P-selectin and Von Willebrand factor play a critical role in inducing thrombocytopenia following IV administration of adenovirus in mice. Adenovirus induces and potentiates ADP-induced platelet aggregation and results in rapid expression of P-selectin and the virus has been observed inside platelets. Adenovirus-platelet aggregates are taken up by macrophage and reduce liver transduction in mice; hindering the efficiency of adenovirus applications. Despite the documentation of CAR; the primary viral attachment receptor on human platelets, there are no reports proving this receptor on mice platelets. The direct effect of fucoidan on platelet functions is not fully understood and its effect on adenovirus mediated thrombocytopenia has not been investigated.

Aim: To study the effect of fucoidan on platelet- adenovirus interaction and platelet activation as well as the virus induced thrombocytopenia and viral liver transduction following intravenous administration of virus into mice.

Methods: Platelet adenovirus interaction was tested *in vitro* under the effect of fucoidan using Cy3 conjugated adenovirus by fluorescent microscopy. The presence of CAR on mice platelets was tested alongside with human platelets as positive control as well as CHO cells as negative control, by flow cytometry using mouse anti CAR and FITC-rabbit anti mouse as well as by RT-PCR. Mice were injected intrave-

nously with single dose of fucoidan 10 mg/kg 10 min before injection of Ad5 1 × 10 11 vp/mL and compared them to other mice injected with adenovirus only. Platelet count was examined 1 and 48 h following injection. Viral hepatic transduction was tested in mice receiving Ad5CTL (CAR binding) and Ad5KO1 (mutated to abate CAR interactions). *B*-gal expression was analysed visually and quantitatively using a *B*-gal ELISA.

Results: Fucoidan resulted in 3 -fold decrease in platelet P-selectin expression at 1 h after Ad administration to mice. Thrombocytopenia at 48 h was observed in both groups however; the reduction of platelet count was 46% in the group receiving fucoidan compared to 65% in the Ad only group. CAR was detected on mice platelets using flow cytometry (23 ± 0.04% $n = 3$). Fucoidan did not decrease Ad-platelet binding.

However, it increased liver transduction in mice receiving Ad5CTL (CAR binding) and Ad5KO1 (CAR mutated) compared to those not receiving fucoidan with significant increase in *B*-gal expression in mice injected with Ad5KO1.

Conclusions: Fucoidan inhibits P-selectin, improves thrombocytopenia following Ad administration, enhances liver transduction but does not abolish platelet Ad binding. Ablation of viral CAR interactions may have potential in improving safety and efficacy of adenovirus administration.

PA 4.04-4

Suspected clopidogrel induced thrombocytopenia – identifying the real culprit

Joseph JE[1], Aslam A[1], Markus R[1], Bougie D[2] and Aster R[2]

[1]St Vincent's Hospital, Sydney, NSW, Australia; [2]BloodCenter of Wisconsin, Milwaukee, WI, USA

Background: Drug induced thrombocytopenia (DIT) is an idiosyncratic immune-mediated reaction which most typically occurs 1–2 weeks after commencement of a new drug. A high index of suspicion is required when considering a drug-induced thrombocytopenia since testing for drug-dependent antibodies (apart from those due to heparin and quinine) is generally unavailable. The main differential diagnosis is primary immune thrombocytopenia.

Aims: A case of suspected clopidogrel induced thrombocytopenia is detailed in order to highlight the challenges in making such a diagnosis.

Methods: Serum samples were collected from the index case and referred to the BloodCenter of Wisconsin for testing. A NOD-SCID mouse which lacks xenoantibodies and therefore allows infused human platelets to circulate, was used to study drug-dependent clearance of platelets by drug-dependent antibodies *in vivo*. (methods as described previously in Bougie DW, et al Blood. 2010;116(16): 3033–3038)

Results: The index case was a female who developed a lacunar stroke. The patient was taking Aspirin, Rosuvastatin and Enalapril long term. Platelet count was normal at 171 × 10^9/L. Over the ensuing 3–4 weeks, a significant number of medication changes were made. Aspirin was ceased and the patient was placed on Clopidogrel. Enoxaparin was prescribed as venous thromboembolism prophylaxis. The platelet count remained normal during this time. Enoxaparin was ceased and the patient was commenced on Dantrolene, Duloxetine, Ciclesonide and then Escitalopram. Some 5 days later, the patient complained of bleeding gums and was found to have a platelet count of 4 × 10^9/L with no other abnormality on full blood count or blood film. All medications (apart from Rosuvastatin and Enalapril) were ceased and oral prednisone was commenced. A diagnosis of heparin induced thrombocytopenia was considered clinically unlikely and heparin antibody testing was negative. The platelet count began to increase within a few days of cessation of the suspected drugs and returned to normal within 1 week. Of the numerous medications the patient had been recently prescribed, Clopidogrel was considered the likely culprit. Patient serum was sent to the BloodCenter for further testing and was found to cause clearance of human platelets in mice injected (IP) with Clopidogrel. No effect was seen with patient serum alone or with normal serum given to mice challenged with Clopidogrel.

Summary/Conclusion: This case illustrates the potential difficulty in determining the cause of an acute, severe thrombocytopenia in a patient who has been commenced on several new medications. Clopidogrel was considered the most likely cause and specific testing confirmed this. As a result, the patient's ongoing anti-platelet therapy had to be altered accordingly.

PA 4.04-5

Megakaryocytes, not only victims, but also participants in ITP

Zhou Z[1], Ma L[2] and Yang R[2]

[1]The Second Hospital Affiliated to Kunming Medical University, Kunming, Yunnan Province; [2]State Key Laboratory of Experimental Hematology, Institute of Hematology and Blo, Tianjin, China

Background: Immune thrombocytopenia (ITP) is an autoimmune disease characterized by platelet destruction accelerated. Many abnormal immune responses are involved. Autoantibody secreted long-lived plasma cells in bone marrow may be a reason for incurable of ITP. The bone marrow microenvironmental niches are important for the generation and maintenance of these cells. Some studies had revealed that megakaryocytes can secret several cytokines, some of which are very important to plasma cell survival and antibodies release.

Aims: Based on the potency of megakaryocytes in the immune modulation, we studied the interactions of megakaryocytes and plasma cells in bone marrow from ITP patients *in vitro*. To clarify that whether megakaryocytes modulate the function and survival of platelets reactive plasma cells within bone marrow in ITP patients.

Methods: It was detected that megakaryocytic cell surface expression of the protein levels of APRIL and CD154 in ITP patients by flow cytometry. Megakaryocytes was co-cultured with isolated plasma cells and lymphocytes in the bone marrow of ITP patients *in vitro* and these were analysed that the survivion and activation of several T cells subtype and plasma cells.

Results: The surface APRIL ($P = 0.035$) and of CD154 ($P = 0.039$) expression levels of megakaryocytes in ITP patients were significantly increased. The megakaryocytes in the bone marrow of ITP patients plays a role in survivion of other immune cells. The megakaryocytes can promote surviving of CD4+ T cells, CD8+ T cells, CD27+ B cells and activation of CD4+, CD8+ T cells. HLA-DR expression was elevated in these immune cells when co-cultured with megakaryocytes. Moreover, we studied the role of APRIL and CD154 in the interreaction between megakaryocyte and immune cells in ITP. When the co-culture system was processed with anti-APRIL ($P = 0.038$), anti-CD154 ($P = 0.047$) antibody, the proliferation of plasma cells was weakened and platelet-specific autoantibody secretion was reduction. However, when TPO was added to the co-culture system, the number of CD138+ plasma cells was increase in the co-cultured system.

Conclusion: Our study for the first time suggested that megakaryocytes play an important active role in the modulation of activation and survival of bone marrow platelets-reactive plasma cells in ITP. Megakaryocytes are not only victims, but also participants of the pathologic immune reaction in ITP.

PA 4.04-6

Tissue plasminogen activator induced fibrinolyis on rotational thromboelastometry in chemotherapy-induced thrombocytopenia

Olde Engberink HG, Kuiper JAJM, Lancé MD, Henskens YMC and Beckers AM

Maastricht University Medical Center, Valkenswaard, The Netherlands

Background: Dropping platelet counts are a significant problem in patients with haematological malignancies treated with high dose chemotherapy. There is general consensus that platelet counts below 10×10^9/L are managed with prophylactic platelet transfusions. Nonetheless clinical significant bleedings may occur above this threshold and also, indeed, despite the prophylactic transfusion policy (Stanworth et al, 2012, ASH). Assessing the individual patient risk of serious bleeding complications is challenging and does not seem to depend solely on platelet counts. In absence of reliable platelet function tests in thrombocytopenic patients there is a clinical need for developing new haemostatic assays as predictors of bleeding.

Aims: In this study, the susceptibility to fibrinolysis, in thrombocytopenic individuals, was assessed by inducing tissue plasminogen activator (tPA)-mediated lysis in an adapted ROTEM test. The aim was to investigate whether any heterogeneity between healthy volunteers and thrombocytopenic patients might exist.

Methods: Ten healthy volunteers, with normal platelet counts and without any use of medication, were selected. Samples with different platelet counts (range 15–248 $\times 10^9$/L) were obtained by replacing platelet rich plasma (PRP) with platelet poor plasma (PPP) without changing the haematocrit or the fibrinogen concentration. Blood samples from 21 thrombocytopenic patients were not manipulated. Lysis speed (mm/minute) was calculated during three periods: maximal clot formation time (MCF-t) – lysis onset time (LOT) (100%-85%), MCF-t – lysis time (LT) (100%-10%) and LOT – LT (85%-10%).

Results: Fibrinolysis speed did not show any significant differences among different, manually diluted platelet counts (15–248 $\times 10^9$/L) with constant fibrinogen levels in healthy volunteers. Supraphysiological fibrinogen levels were found in a concentration-dependent manner when platelet counts decreased in chemotherapy induced thrombocytopenic patients. Fibrinogen levels in the lowest group of platelets (0–10×10^9/L) were significantly higher compared to the group just above the transfusion threshold (10–20 $\times 10^9$/L) (5.0 g/L vs. 4.1; $P = 0.005$). A decrease in platelet counts and subsequent higher fibrinogen levels resulted in a significantly lower lysis speed. This effect was observed both in physiologic conditions (i.e. without addition of tPA) as in tests where fibrinolysis was induced with a high concentration of tPA. One major bleeding (WHO grade 3) was reported in a patient with a platelet count of 16×10^9/L and a relatively low fibrinogen level (2.2 g/L) compared to other patients with platelet counts between 10 and 20 $\times 10^9$/L (median 4.1 g/L, interquartile range 3.4–4.3).

Conclusion: Supraphysiological fibrinogen levels were found, and might be associated with lower lysis speed, in patients with severe chemotherapy-induced thrombocytopenia. The preventative effect of higher fibrinogen levels might play a role in assessing the bleeding risks in these patients. Adjusted reference values for fibrinogen and other haemostatic proteins might be applicable during severe thrombocytopenia for establishing a more correct probability of bleeding tendencies. Our future investigations will focus on fibrinogen and other markers as possible predictors of bleeding in these patients.

Proteomic analysis of platelets from patients with X-linked thrombocytopenia with thalassemia (XLTT)

Bergemalm D[1], Ngoasong E[2], Kardeby C[2], Palmblad J[3] and Åström M[1]

[1]Örebro University Hospital; [2]Örebro University, Örebro; [3]Karolinska Institutet, Stockholm, Sweden

Background: X-linked thrombocytopenia with thalassemia (XLTT) is a rare inherited disorder resulting in problems of bleeding mainly in males. It is caused by the mutation 216R>Q in exon 4 of the *GATA-1* gene. The GATA-1 protein is a transcription factor involved in hematopoiesis. Clinical manifestations of XLTT include thrombocytopenia, altered platelet function and morphology, slight hemolysis and splenomegaly. We have recently reported that males also develop slight to moderate bone marrow fibrosis. In similarity to the disorder Gray platelet syndrome, large platelets deficient in alfa-granule are typical. Proteomics is a method used for analysis of the proteome, i.e. the translated set of proteins in a defined tissue, cell type or fluid. Extracted proteins can be separated by isoelectric point and molecular mass to produce high-resolution maps by two-dimensional electrophoresis (2-DE). This enables individual quantification and identification of proteins that are altered by disease.

Aims: The aim of this study is to increase the knowledge on XLTT pathogenesis by identifying specific protein alterations in platelets. Such a detection of protein alterations in XLTT platelets is also valuable for the general understanding of platelet function in health and disease.

Methods: Blood samples from four male XLTT patients from two recently reported Swedish families (one patient from family A, three patients from family B) were collected after informed consent and approval by the regional ethical review board in Uppsala, Sweden. Their platelet counts were 35, 50, 42 and 76 $\times 10^9$/L respectively. Whole blood was also collected from four age and sex-matched healthy volunteers. Platelets were isolated by differential centrifugations, using optimized conditions to keep them in an inactive state. The platelet pellet was gently washed to avoid plasma protein contamination. Platelet proteins were resolved in a highly denaturing solution containing urea and detergent and separated by 2-DE. By software evaluation, individual platelet proteins were quantified and compared between controls and XLTT. For statistical calculations, student's t-test and multivariate analysis (partial least squares) were used.

Results: On average, 850 individual protein spots were detected in each gel. With a chosen significance level of $P < 0.05$, about 60 protein spots were found altered in XLTT platelets. From quantitative 2-DE gels, 25 spots were chosen for initial identification. Preliminary mass-spectrometry analysis has so far identified nine of the differentially expressed proteins. Only one of these proteins, gamma-actin, was up-regulated (fold change 1.98). Of the eight downregulated proteins (fold changes 0.14–0–56), the majority are involved in modeling of actin and the cytoskeleton. Two downregulated proteins, regulator of G-protein signaling 10 (RGS10) and Acyl-protein thioesterase 1, both inhibit protease-activated receptor-1 (PAR-1) signaling dependent functions.

Conclusions: There is limited knowledge available on the pathogenic events caused by *GATA-1* mutations. XLTT is a non-progressive inherited disorder but shows similarities to the malignant disease primary myelofibrosis. XLTT might thus be a model for *GATA-1* related thrombopoietic changes contributing to myelofibrosis. By platelet proteomics, we have found altered protein expressions regarding the cytoskeleton and regulators of PAR-1 signaling pathways. Additional proteins with altered expressions are soon to be identified, and the consequences evaluated.

Inherited mild bleeding disorders (MBD) of undefined cause (BUC): platelets express decreased tissue factor-dependent FXa generation and low thrombin generation in platelet-rich plasma

Panes O, Zuniga P, Lopez A, Loncon G, Quiroga T, Pereira J and Mezzano D

Pontificia Universidad Catolica de Chile, Santiago, Chile

Background: Hereditary mild bleeding disorders (MBD), usually manifested with skin and mucous bleeding are of heterogeneous nature, involving different pathogenic mechanisms, including platelet function defects, decreased amount and function of plasma VWF, mild defects of clotting factors and also, increased fibrinolysis. However, up to 60% of all the patients with MBDs have abnormal bleeding of undefined cause (BUC). We previously showed that platelets contribute to the clotting system providing not only an anionic phospholipid-rich membrane, but also functional Tissue Factor (TF).

Aims: To revisit the old concept of Platelet Factor 3 (platelet procoagulant activity) now focusing our attention on platelet TF activity in patients with BUC.

Methods: TF-induced FXa generation was measured as described (Panes et al. Blood 2007;109:5242) in washed, resting and VWF-Ristocetin-stimulated platelets. Thrombin generation (TG) in PRP was performed by modified CAT method, with no TF and phospholipids added to the assay and assessed by the Velocity index (Vi, nM thrombin/min). Clot lysis time in PRP was measured as described (Panes et al. Platelets 2012;23:36). These measurements were compared in 72 Controls, 81 patients with BUC and 20 with type 1 VWD, of similar ages (21, 19 and 21, respectively). Anionic phospholipids exposure was assessed by annexin V binding (FC).

Results: Controls and patients with BUC had normal VWF:Ag, RCo and CBA, normal platelet aggregation-secretion and clotting screening tests. Clot lysis time, measured in PRP was similar in the three groups. Medians (ranges) of FXa generating potential (nM 10^{-7} platelets), expressed as the ratio of FXa generated by VWF-Ristocetin-stimulated platelets and resting platelets was lower in Controls than in BUC and VWD patients: 8.3 (3.4–30.1), 4.4 (1.2–10.9) and 9.8 (4.5–17.4), respectively ($P = 0.0042$). In TG assay, patients with BUC had lower Vi than Controls, either in non-stimulated (5.0 vs. 6.2) and VWF-Ristocetin (21.5 vs. 28) or TRAP-stimulated platelets (33.3 vs. 44) ($P < 0.05$–$P < 0.01$, Kruskall–Wallis with Dunn's multiple comparison test). Patients with VWD also had significantly decreased Vi in stimulated platelets. Annexin V binding was similar in Controls and BUC patients after stimulation with VWF-R (12% vs. 10.4% of labeled platelets) and TRAP (22.3% vs. 15%), respectively.

Conclusions: (i) FXa generation dependent on platelet Tissue Factor showed that platelets of patients with BUC generate less FXa than normal platelets. (ii) The velocity to generate thrombin in PRP in an assay with no added TF and phospholipids was significantly lower in platelets from patients with BUC than Controls. (iii) These results were unrelated to the ability of BUC platelets to expose anionic phospholipids, as shown by their normal annexin V binding. Up to 60% of patients with MBDs remain undiagnosed after a comprehensive laboratory work up. The decreased procoagulant activity of platelets observed in these patients probably constitutes a bleeding risk factor that may be pathogenically related to the symptoms in a proportion of these patients. This finding would represent a renewed version of the old-fashioned platelet factor 3. (Fondecyt 1110404 and 1130853).

A novel mutation in the dry motif of the P2Y12 receptor combined with a function-reducing polymorphism in PAR1 in a patient with a bleeding disorder

Austin S[1], Patel YM[2], Mitchell MJ[1], Lordkipanidze M[3], Lowe GC[3], Nisar SP[4], Garner K[4], Daly ME[5], Watson SP[3] and Mundell SJ[4]

[1]Guy's and St Thomas' Hospital NHS Foundation Trust; [2]Institute of Ophthalmology, London; [3]College of Medical and Dental Sciences, Birmingham; [4]University of Bristol, Bristol; [5]University of Sheffield, Sheffield, UK

Background: The study of patients with bleeding problems is a powerful approach in determining the function and regulation of important proteins in human platelets. As part of the Genotyping and Phenotyping of Platelets (GAPP) consortium we have identified a number of mutations in receptor genes that could contribute to bleeding tendency in patients, including mutations in the P2Y12 receptor (P2Y12R (1,2)). We have identified a patient, with a chronic bleeding disorder, expressing a homozygous mutation, predicting an arginine to a cysteine (R122C) substitution in their P2Y12R. Importantly this mutation is found within the DRY motif of this receptor which in other G protein-coupled receptors (GPCRs) plays a critical role in regulating conformational states.

Aims: To examine the consequences of this mutation upon P2Y12R function in the index and affected family members patient's platelets and cell lines.

Methods: Platelet function was assessed by measuring platelet aggregation responses in platelet rich plasma (PRP) whilst functional responses to the P2Y12R were assessed by measuring VASP phosphorylation. HA-tagged wild type (WT) or R122C-P2Y12R were expressed in 1321N1 astrocytoma cells and receptor function assessed as previously described (1).

Results: ADP-stimulated aggregation was significantly reduced as a result of a significant impairment of P2Y12R activity in the patient and family members. There was a significant reduction in R122C variant expression at the cell surface in both cell lines and in platelets as a consequence of increased agonist-independent internalization followed by subsequent receptor traffic to lysosomes. Strikingly, members of this family also showed a significant reduction in thrombin-induced platelet activation due to an intronic polymorphism in the PAR-1 gene shown to be associated with reduced PAR1 receptor expression (3).

Conclusions: We have identified a novel P2Y12R defect associated with patient bleeding and demonstrated that the DRY motif of the P2Y12R is critical in maintaining the receptor in a basal non-activated state. In addition our study is the first to demonstrate a deficit in two stimulatory GPCR pathways that regulate platelet activity further indicating that patient bleeding is a complex trait.

PTGS1 compound heterozygosity impairs gene expression and platelet aggregation and is associated with severe bleeding complications

Bugert P[1], Yagmur E[2], Weiskirchen R[3] and Schedel A[4]

[1]DRK-Blutspendedienst, Mannheim; [2]Laboratory Diagnostics Center, RWTH-University Hospital Aachen, Mönchengladbach; [3]Institute of Clinical Chemistry and Pathobiochemistry, RWTH-University Hospital, Aachen; [4]Institute of Transfusion Medicine and Immunology, Mannheim, Germany

Background: The prostaglandin endoperoxide synthase (PTGS1, COX1) catalyze the conversion of arachidonic acid (AA) into

prostaglandin H_2 intermediates and thromboxane A_2 (TxA_2). Polymorphisms of genes involved in AA metabolism are potential modifiers in platelet function. The Aspirin-like defect (ALD) is an inherited platelet function disorder that involves the AA pathway, however, the molecular basis remains unknown.

Aim: A patient without bleeding history prior surgical interventions but with postoperative recurrent disseminated bleeding showed strongly deminished platelet aggregation response on AA indicating an ALD. Our study describes the molecular genetic investigation of the AA metabolism genes in this patient.

Methods: Platelet function was analyzed by light transmission and whole blood impedance aggregometry using different agonists including ADP, AA and U46619. Molecular genetic investigation included exon re-sequencing of the *PTGS1, TBXAS1* and *TBXA2R* genes. In addition, gene transcripts were quantified in platelet RNA using real-time-PCR (qRT-PCR).

Results: AA-induced platelet aggregation response was significantly decreased, whereas platelet aggregation induced by U46619 as indicator for TxA_2-receptor function was unaffected. The *TBXAS1* and *TBXA2R* genes revealed regular DNA sequences, whereas, the coding region of the *PTGS1* gene of the patient was compound heterozygous (c.22C>T; c.50C>T). We found that *PTGS1* mRNA expression in the patient's platelets was significantly decreased compared to unaffected normal controls (5-fold) or single heterozygotes (2-fold).

Conclusions: Compound heterozygosity in the 5′ region of the *PTGS1* gene impairs transcription and is associated with a phenotype of severe bleeding complication. Therefore, surgeons and anaesthesiologists should be aware of risks which go with *PTGS1* polymorphisms prior elective surgery.

PA 4.05-5

Platelet defects in congenital variant of Rett syndrome patients with FOXG1 mutations or reduced expression due to a position effect at 14q12

Goubau C[1], Devriendt K[2], Van der Aa N[3], Wieczorek D[4], Kleefstra T[5], Rauch A[6], Tzschach A[7], Buyse G[2], Van Geet C[2] and Freson K[8]
[1]UZ Leuven; [2]University hospital Leuven, Leuven; [3]University Hospital of Antwerp, Antwerp, Belgium; [4]Universitätsklinikum Essen, Essen, Germany; [5]Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands; [6]University of Erlangen, Erlangen; [7]Max Planck Institute for Molecular Genetics, Berling, Germany; [8]KU Leuven, Leuven, Belgium

Background: The Forkhead box G1 (*FOXG1*) gene encodes a transcriptional repressor essential for early development of the telencephalon. Intragenic mutations and gene deletions leading to haploinsufficiency cause the congenital variant of Rett syndrome, a neurodevelopmental disorder characterized by microcephaly, hand stereotypies, severe intellectual disability, absent language, seizures, and corpus callosum hypoplasia. Recently, the presence of long-range regulatory elements for *FOXG1* expression in the region distal to *FOXG1* was hypothesized, based on descriptive studies in patients with a chromosome translocation breakpoint located distally to *FOXG1* or with 14q12 deletions that do not harbor the *FOXG1* gene.

Aims: Given that abnormal platelet morphology and function has been described in several other neuronal disorders, we have used platelets from Rett syndrome-like patients to study FOXG1 expression and platelet ultrastructure.

Methods: Platelet studies were performed in six patients, three of them carrying a balanced translocation with breakpoint in the chromosome 14q12 region, one patient having a 14q12 microdeletion excluding the *FOXG1* gene, and two previously described *FOXG1* mutation positive patients.

Results: The hypothesis of putative long-range FOXG1-regulatory elements was supported by our finding of reduced FOXG1 mRNA and protein levels in platelets and skin fibroblasts from these cases compared to normal controls. Electron microscopy of their platelets showed some enlarged, rounder platelets with often abnormal alpha and fewer dense granules. Platelet function studies were possible in one 14q12 translocation patient with a prolonged Ivy bleeding time and a patient with a heterozygous FOXG1 p.Tyr416X mutation. Both had a prolonged PFA100 occlusion time with collagen and epinephrine, and aggregations with low dose of ADP and epinephrine were also reduced while ATP secretion was normal.

Summary/Conclusions: Our study shows for the first time by using platelets functional evidence of *cis*-regulatory elements in the 14q12 region that result in reduced FOXG1 expression in patients having translocations or deletions in that region. The platelet functional abnormalities deserve further investigation regarding a non-transcriptional regulatory role for FOXG1 in these enucleated cells.

PA 4.05-6

Demonstration of novel gain-of-function mutations of aIIbβ3: association with macrothrombocytopenia and Glanzmann thrombasthenia-like phenotype

Kashiwagi H[1], Kunishima S[2], Kiyomizu K[3], Amano Y[4], Shimada H[5], Morishita M[6], Kanakura Y[3] and Tomiyama Y[7]
[1]Osaka University School of Medicine, Suita, Osaka; [2]National Hospital Organization Nagoya Medical Center, Nagoya; [3]Osaka University Graduate School of Medicine, Suita, Osaka; [4]Nagano Red Cross Hospital, Nagano, Nagano; [5]Keio University School of Medicine, Tokyo; [6]Tosei General Hospital, Seto; [7]Osaka University Hospital, Suita, Osaka, Japan

Background: Integrin αIIbβ3 is indispensable for normal hemostasis, but its role for thrombopoiesis is still controversial. Although platelet counts and morphology in Glanzmann thrombasthenia (GT), which is a congenital bleeding disorder due to qualitative or quantitative defects of αIIbβ3, are usually normal, several αIIb and β3 mutations have been identified in patients with congenital macrothrombocytopenia very recently.

Aims: To investigate genetic background and molecular mechanism of congenital macrothrombocytopenia associated with αIIbβ3 abnormalities.

Patients/Methods: We analyzed three unrelated Japanese families with congenital macrothrombocytopenia. Expression and activation state of αIIbβ3 in platelets was examined by flow cytometry and immunoblotting. Sequence of whole coding region and exon-intron boundaries of *ITGA2B* and *ITGB3* genes was performed. The effects of mutations on αIIbβ3 activation state and phosphorylation of FAK were analyzed in transfected cells.

Results: We newly identified three mutations; two mutations in highly conserved G^{991}FFKR sequence in juxtamembrane region of αIIb, p.G991C and p.F993del, and one donor site mutation of intron 13 of *ITGB3* leading to 40 amino acids deletion, p.D621_E660del, in the membrane proximal β-tail domain of β3. Case 1, whose platelets showed GT-like marked reduction in surface αIIbβ3 expression (3–11% of normal control) and macrothrombocytopenia with around $40 \times 10^3/\mu L$ of platelet counts, was a compound heterozygote with *ITGA2B* p.G991C and a novel nonsense mutation, *ITGA2B* p.R422*. Case 2 and Case 3 were heterozygotes of *ITGA2B* p.F993del and *ITGB3* p.D621_E660del, respectively, and their platelets showed moderate reduction of surface αIIbβ3 expression (60–70%) with 29–$113 \times 10^3/\mu L$ of platelet counts and increased platelet size. All three mutations, *ITGA2B* p.G991C, *ITGA2B* p.F993del and *ITGB3* p.D621_E660del, led to highly activated conformation of αIIbβ3 and spontaneous tyrosine phosphorylation of FAK in transfected cells.

Conclusion: These results suggest that spontaneous activation and aberrant outside-in signaling caused by mutations around membrane region of αIIbβ3 may lead to abnormal platelet number and morphology with impaired surface αIIbβ3 expression.

Anti-idiotypic DARPin molecules – potential new treatment tools for acquired thromobotic thrombocytopenic purpura (aTTP)?

Schaller M[1], Hiltbrunner S[1], Sulzer I[1], Vogel M[1], Kentouche K[2], Laemmle B[1] and Kremer Hovinga JA[1]

[1]University Hospital, Inselspital, Bern, Switzerland; [2]Friedrich Schiller University, Jena, Germany

Background: The hallmark of aTTP is a severe ADAMTS13 deficiency resulting from autoantibodies (Abs) neutralizing and/or accelerating ADAMTS13 clearance. Despite the success of plasma exchange the risk of relapse is approximately 40%. A therapy using small molecules capable to neutralize inhibitory anti-ADAMTS13 Abs and to eliminate anti-ADAMTS13 specific memory B- and plasma cells would be highly desirable.

Aim: In order to develop such a therapy we used previously generated spleen-derived inhibitory monoclonal anti-ADAMTS13 Abs, having in common one of four CDR3 motifs shared by two aTTP patients, to search for small anti-idiotypic molecules mimicking the conformational ADAMTS13 epitope and consequently thus specifically bind and neutralize inhibitory anti-ADAMTS13 Abs in aTTP patients when administered.

Method: As source of anti-idiotypic small molecules we choose a large combinatorial small protein library of Designed-Ankryin-Repeat-Proteins (DARPins, Molecular Partners AG, Switzerland) that are characterized by: (i) a high diversity through a library size of 10^{15-23}, allowing to find molecules to any target including conformational epitopes, by (ii) high stability once expressed, and by (iii) being immune tolerant when administered. Two DARPin libraries coding for either 2 (N2C-library) or 3 (N3C) randomized ankyrin repeat modules were screened against an equimolar pool of three inhibitory anti-ADAMTS13 antibodies using Ribosomal display. Selected anti-idiotypic single DARPin clones from the fourth panning round were purified, their DNA sequence analyzed and their expressed proteins tested for specificity and neutralization potential towards all inhibitory Abs ($n = 5$) holding the same CDR3 motif as the selecting Abs, by ELISA or FRETS assay. Furthermore the binding capacity of an equimolar pool of the selected DARPins towards anti-ADAMTS13 Abs in plasma of 37 different aTTP patients was tested by ELISA.

Results: Nine, as revealed by their DNA sequence, unique anti-idiotypic DARPins were highly specific for their targets. Preincubation with spleen-derived inhibitory anti-ADAMTS13 Abs (equimolar mAbs pool) with a 10-fold molar excess of four 4 anti-idiotypic DARPins restored ADAMTS13 activity in plasma in a dose-dependent manner as assessed by FRETS assay. Moreover, the four anti-idiotypic DARPins bound anti-ADAMTS13 antibodies from plasma of 27/37 (73%) randomly picked aTTP patients and reduced binding to immobilized recombinant ADAMTS13 by 70–95% when pre-incubated with five additional patient plasma.

Conclusions: Using spleen-derived inhibitory anti-ADAMTS13 Abs of one patient we were able to select four different highly specific anti-idiotypic DARPins that not only bind to anti-ADAMTS13 Abs being composed of a similar CDR3 motif than the selecting Abs, but also to a substantial proportion of anti-ADAMTS13 Abs in plasma of randomly selected aTTP patients. Our results are promising and hint at a limited number of different anti-idiotypic molecules necessary to neutralize inhibitory anti-ADAMTS13 Abs. Affinity and neutralizing capacities of all nine selected anti-idiotypic DARPins are underway.

PA 4.06-2

Identification of glycosylation sites in plasma derived ADAMTS13 employing tandem mass spectrometry

Sorvillo N[1], Kaijen P[1], Matsumoto M[2], Fujimura Y[2], Verbij FC[1], Van der Zwaan C[1], Fijnheer R[3], Voorberg J[1] and Meijer AB[1]

[1]Sanquin-AMC Landsteiner Laboratory, Amsterdam, The Netherlands; [2]Nara Medical University, Kashihara City Nara, Japan; [3]University Medical Center Utrecht, Utrecht, The Netherlands

Background: ADAMTS13 is a plasma metalloproteinase that regulates platelet adhesion and aggregation by its ability to process ultra-large von Willebrand factor (VWF) multimers on the surface of endothelial cells. Acquired deficiency of ADAMTS13 causes a rare and life-threatening disorder called thrombotic thrombocytopenic purpura (TTP). Several studies have shown that aberrant glycosylation can play an important role in the pathogenesis of autoimmune diseases. Aberrant glycosylation of antigens can not only create new ligands for different B cell epitopes but might also play a role in presentation of peptides to T cells. Several potential N or O-linked glycosylation sites have been predicted or identified in recombinant ADAMTS13. However, it is not known which of these sites are indeed glycosylated in plasma ADAMTS13.

Aim: In the study we analyzed the presence of N-linked or O-linked sugars on plasma derived ADAMTS13.

Methods: Plasma ADAMTS13 was purified using a monoclonal antibody directed against the disintegrin like domain. Sites of N-linked glycosylation were determined by the use of N-glycosidase-F, which removes the entire carbohydrate from the side chain of asparagines. In this process the asparagine residues are deaminated to aspartic acid, resulting in an increase of the peptide mass of 1 Da. Following trypsin or chymotrypsin digestion, deglycosylated peptides were identified by tandem MS.

Results: Nine of the predicted N-linked sites were identified in or near the metalloproteinase, spacer, thrombospondin type 1 repeat (TSR1) and theCUB domain of plasma ADAMTS13. Moreover, all seven predicted O-fucosylated sites were identified in the TSR1 domains of plasma ADMTS13 by performing searches of the MS/MS data for loss of glucose (hexose, 162 Da), fucose (deoxyhexose, 146 Da), or glucose-fucose (308 Da). Sequential loss of the glucose-fucose disaccharide gives a characteristic fragmentation pattern, allowing easy identification of modified peptides. With the use of electron transfer dissociation (ETD) we confirmed unambiguously the modified sites. ETD fragmentation produces ions that retain the post translation modification allowing a precise identification of the modified site.

In addition to N- and O-linked modifications, two C-mannosylation sites were identified within the TSR domains of ADAMTS13. Peptides with an increase of mass by 162 Da from the predicted tryptic fragments that contained a WXX_nW motif were subjected to MS/MS. C-mannosylation of Trp can be identified through the addition of 162 Da, but also by the loss of 120 Da in MS/MS spectra, a characteristic cross-ring fragmentation product of aromatic C-glycosides.

Summary/Conclusion: Taken together our data clearly identify different glycosylation sites on plasma ADAMTS13. Analysis of the glycosylation pattern gives novel information on the biochemical properties of plasma derived ADAMTS13 and might provide new insight in the initiation of autoimmune reactivity against ADAMTS13 in patients affected by acquired TTP.

Prophylactic and therapeutic efficacy of a recombinant ADAMTS13 in a mouse model of thrombotic thrombocytopenic purpura

Schiviz A, Verdino D, Resch M, Farnleitner E, Scheiflinger F, Schwarz HP, Muchitsch EM and Höllriegl W

Baxter Innovations GmbH, Vienna, Austria

Deficiency of ADAMTS13, a von Willebrand factor (VWF)-cleaving protease, is the key factor in the pathogenesis of thrombotic thrombocytopenic purpura (TTP), a life-threatening thrombotic microangiopathy. Baxter is developing a recombinant ADAMTS13 (rADAMTS13, a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13) product for the potential prophylaxis and treatment of TTP. A recently established disease model in ADAMTS13 ko mice (B6.129-ADAMTS13^{tm1Dgi}) was used to test the effectiveness of this drug candidate. In brief, animals are challenged with a high dose of human recombinant von Willebrand factor (rVWF) containing ultra-large VWF multimers to induce TTP-like symptoms.

In two studies, 10 ADAMTS13 ko mice per group received a single dose of 200 FRETS-U/kg rADAMTS13 5 min–120 h before or 15–180 min after challenge with rVWF. Buffer, administered either 5 min before or 15 min after challenge, was used as negative control. Efficacy was defined as the degree of prevention of platelet drop and increase in LDH. Schistocytosis and organ damage were also assessed.

All buffer-treated animals that received rVWF were severely thrombocytopenic and showed increased LDH levels, schistocytosis and organ damage. Efficacy of rADAMTS13 was treatment interval-dependent in both studies. Platelet count at termination of all rADAMTS13-treated animals was statistically superior to that of buffer-treated controls ($P \leq 0.0001$). However, clinically relevant protection was seen only for treatment intervals ≤ 72 h; animals that received prophylactic treatment 120 h before administration of rVWF showed severe thrombocytopenia. Treatment with rADAMTS13 stabilized the platelet count and prevented further development of thrombocytopenia. Serum LDH levels in rADAMTS13-treated animals were statistically significantly lower than in buffer-treated controls ($P \leq 0.0001$) in both the prophylactic and therapeutic setting. Other endpoints, such as schistocytosis and organ damage, confirmed the treatment interval-dependent efficacy for platelet count.

In conclusion, Baxter's rADAMTS13 was shown to be effective in an rVWF-induced animal model closely mimicking the situation in patients with hereditary TTP, and is thus a promising drug candidate for future clinical trials.

PA 4.06-4

Treatment of reperfusion injury with recombinant ADAMTS13 in a porcine model of acute myocardial infarction

Eerenberg ES[1], Teunissen PFA[2], Van Den Born BJ[1], Meijers JC[3], Hollander M[2], Aly M[2], Niessen HWM[2], Kamphuisen PW[4], Levi M[1] and Van Royen N[2]

[1]Academic Medical Center; [2]VU University Medical Center; [3]Academic Medical Center Amsterdam, Amsterdam; [4]University Medical Center Groningen, Groningen, The Netherlands

Background: No reflow and decreased microvascular perfusion after percutaneous coronary intervention increase morbidity and mortality in ST-elevation myocardial infarction (STEMI) patients. No reflow may be mediated by platelet vessel wall interaction that is governed by von Willebrand factor. ADAMTS13 is a metalloprotease that cleaves von Willebrand factor, thereby reducing its prohemostatic properties. There is considerable evidence that ADAMTS13 levels decrease and von Willebrand factor levels increase in STEMI patients. Recombinant ADAMTS13 has been effective in reducing cerebral infarct size in a murine model of stroke.

Aims: In this study recombinant ADAMTS13 was tested as a potential treatment of no reflow in a porcine model of cardiac ischemia and reperfusion.

Methods: In 23 female swine (median age 83 days, median weight 30 kg) a balloon was inflated in the circumflex coronary artery for 75 min. Fifteen minutes after reperfusion, an intracoronary bolus of either recombinant ADAMTS13 (400 U/kg, Baxter Innovations Vienna, Austria) or vehicle was given.

Results: ADAMTS13 activity significantly increased in treated pigs (from median 18%, IQR 14.5–24.0 to median 324%, IQR 117.0–384.0, $P = 0.003$) whereas no change was observed in the control group. Animals were sacrificed 7 days later for histopathology. There was no difference in the size of myocardial necrosis as assessed with plasma Troponin T measurements, continuous 12 leads ECG, macroscopical infarct analysis, and histopathology using phosphotungstic acid-hematoxylin staining. Microvascular obstruction as estimated by staining with anti-CD31/Hematoxylin and counting of vessels and microthrombi was similar for both groups.

Conclusions: Intracoronary treatment with recombinant ADAMTS13 did not prevent formation of microthrombi and did not decrease infarct size in this porcine coronary model of ischemia and reperfusion.

A rat model reveals feasibility of rADAMTS13 therapy in the presence of inhibitory antibodies

Schiviz A, Plaimauer B, Kaufmann S, Skalicky S, Höbarth G, Wolfsegger M, Muchitsch EM, Turecek PL, Scheiflinger F and Rottensteiner H

Baxter Innovations GmbH, Vienna, Austria

Anti-ADAMTS13 autoantibodies that either neutralise the activity of ADAMTS13 or enhance protein clearance are the major cause of severe ADAMTS13 deficiency in patients suffering from acquired TTP. Standard care treatment of these patients involves frequent plasma exchange with fresh frozen plasma. Although substitution therapy with recombinant (*r*) ADAMTS13 is considered preferable, the therapeutic efficacy is likely complicated by free circulating anti-ADAMTS13 autoantibodies that bind and neutralise infused rADAMTS13.

We addressed the feasibility of substitution therapy with rADAMTS13 in acquired TTP by simulating the dynamic *in vivo* situation in a rat model. Development of this model was based on our previous *in vitro* studies which demonstrated a clear linear correlation between inhibitor titer and the amount of rADAMTS13 required to overwhelm the antibodies and to normalise ADAMTS13 activity.

Defined quantities of a purified polyclonal goat anti-ADAMTS13 antibody were administered to normal rats, resulting in animals with a defined inhibitor titer of 12 BU/mL. These animals were then dosed with a single bolus of various concentrations of rADAMTS13. Citrated plasma was obtained at different time points (up to 336 h post-infusion) and levels of ADAMTS13 acitivity, free goat anti-ADAMTS13 inhibitor and anti-ADAMTS13 immune complexes were determined. Pharmacokinetic parameters including *in vivo* recovery and terminal half-life of rADAMTS13 were calculated based on the measured ADAMTS13 FRETS-VWF73 activities. Animals were monitored for clinical signs throughout the observation period. Kidneys were removed at the end of the observation period for histopathological analysis.

At a sufficient dose, rADAMTS13 was capable of building up ADAMTS13 activity in the presence of free inhibitors which became complexed and neutralised immediately upon infusion of rADAMTS13. The terminal half life of rADAMTS13 was calculated to be about 18 h, similar to that in the absence of inhibitors. The inhibitory antibodies remained bound in anti-ADAMTS13 immune complexes which

decreased over time. Even at the highest dose of rADAMTS13 tested, no clinical signs were observed and kidneys showed no abnormalities. The combined data therefore suggest that the immune complexes formed upon administration of rADAMTS13 were cleared over 48 h without causing any obvious adverse events.
Our findings support the concept of achieving therapeutic ADAMTS13 levels in the presence of neutralising anti-ADAMTS13 antibodies, and provide a rationale for rADAMTS13 dosing in patients with acquired TTP.

Background: von Willebrand factor (VWF) plays a pivotal role on physiologic hemostasis, mediating platelet aggregation under high shear stress conditions. However excessive functions of VWF could cause thrombotic occlusion of microvasculature such as arterial capillaries, where blood flow creates a typical high shear stress. The VWF-cleaving protease ADAMTS13 is therefore thought to down-regulate precisely the VWF function to maintain enriched microcirculation.
Aims: In this context, we hypothesized that this ADAMTS13 role might contribute to better donor cell homing and engraftment in various cell therapy approaches, in which fluent blood flow could be critical in the microcirculation system. To test this hypothesis, we studied the donor cell engraftment in the bone marrow transplantation (BMT) model in *Adamts13*−/− mice.
Methods: Irradiated recipient mice were received 2×10^6 GFP positive cells from the sex-matched GFP donor mice. All of irradiated recipient mice without receiving BMT died within 21 days. Although there is no difference between *Adamts13*−/− and wild-type mice in survival rate after 7 days of BMT, Kaplan-Meier analysis revealed that the percent ratio of survival rate starts significantly declining after 14 days of BMT in the group of *Adamts13*−/− mice. The successful cell engraftment in BMT was assessed by the number of GFP-positive neutrophils in peripheral blood at the several time points from BMT.
Results: The duration achieving the number of GFP-positive neutrophils over 500/μL was found to significantly delay in the *Adamts13*−/− mice, as compared with the wild-type mice (20.2 ± 3.8 vs. 14.4 ± 3.3 days). The delayed cell engraftment observed in the *Adamts13*−/− mice became normalized by the bolus administration of recombinant ADAMTS13 (10 μg/mouse) at the day 0 of BMT. Bone marrow analysis at the day 1 of BMT revealed that the number of GFP-positive blood cells in bone marrow was significantly reduced in the *Adamts13*−/− mice as compared with the wild-type mice, which could result in the delayed cell expansion at the day 7 and day14 of BMT in *Adamts13*−/− mice. The single bolus injection of recombinant ADAMTS13 was found to fully correct the delayed cell expansion in bone marrow in the *Adamts13*−/− mice.
Summary/Conclusion: Our results indicate that the regulation of VWF-mediated thrombotic or inflammatory responses by ADAMTS13 could contribute to better microcirculation which could be critical for efficient donor cell homing and engraftment in BMT, suggesting a therapeutic potential of ADAMTS13 in cell therapy approaches.

PA4.07 – Haemophilia A: Clinical – XIII

Relation between cut-off value of the Bethesda assay and the detection of low titre inhibitors in previously untreated children with severe haemophilia A

Platokouki H[1], Oldenburg J[2], Ljung R[3], Santagostino E[4] and Van Den Berg M[5]
[1]Haemophilia Centre and Haemostasis Unit, Aghia Sophia, Children's Hospital, Athens, Greece; [2]2Institute of Experimental Haematology and Transfusion Medicine University Clini, Bonn, Germany; [3]3Lund University, Department of Paediatrics, Skäne University Hospital, Malmö, Sweden; [4]4A. Bianchi Bonomi Haemophilia Centre, Ca Granda Foundation, Maggiore Hospital P, Milan, Italy; [5]5Julius Centre for Health Sciences and Primary Care, University Medical Centre, Utrecht, The Netherlands

Background: About one third of patients with severe haemophilia A (sHA) develop inhibitors towards infused FVIII. The inhibitor risk depends on genetic and non genetic factors. After the introduction of recombinant FVIII products the reported inhibitor incidences have increased. It is still unclear whether this is caused by higher intrinsic immunogenicity, by more frequent testing, higher awareness in reporting low titre inhibitors or higher sensitivity of the performed tests with a lower cut-off.
Aim: To describe the impact of the cut-off value of the Bethesda assay on the overall inhibitor outcome in previously untreated (PUPs) children with sHA.
Patients/Methods: The RODIN Study (Research of Determinants of Inhibitor development) included PUPs with sHA for the first 75 exposure days (E.D). Uniform prospective data and well-defined outcomes were collected from this patient cohort regularly tested for inhibitors in 29 haemophilia centres in Europe, Israel and Canada. The investigators are members of the European Paediatric Network for Haemophilia Management (PedNet) and/or the RODIN Study group. The centres, which all used the Nijmegen modification of the Bethesda assay, were asked to report on the cut-off value that was used during the study period (2000–2010) and also the frequency of testing during the first 20 E.D and between 20 and 75 E.D.
Results: Inhibitory antibodies were detected in 188 (30%) out of 621 eligible patients. Of all inhibitor patients, 124 (66%) developed a high-titre (> 5 BU) and 64 (34%) a low-titre. Patients developed inhibitors after a median of 15 E.D (inter-quartile range (IQR) 10–20 days), at a median age of 15.5 months (IQR 10.7–19.6 months). During the first 20 E.D, patients were tested every 3–5 E.D in 27 centres. After 20 E.D, the frequency of testing was unchanged in 6 centres and reduced (5–10 E.D to 3 months) in 15. There were 10 centres that used low cut-off values (0.3 and 0.4 BU/mL) and 19 using high cut-off values (0.5 and 0.6 BU/mL, the latter being the highest cut-off value for positivity). Centres that used the lowest cut-off values followed 203 PUPs (32.7%); centres that used the highest followed 418 (67.3%). The inhibitor incidence was 27.5% and 31.6%, respectively. In both groups, 66% of the inhibitors were diagnosed with a high and 34% with a low-titre.
Conclusion: A lower cut-off value did not influence the detection rate of inhibitors. Also the frequency of low vs. high titre inhibitor patients was similar for both cut-off values.
This abstract is submitted on behalf of the PedNet and RODIN Study Group.

Exp. Haematologie und Transfusionsmed, Bonn, Germany; [8]Barts and the London School of Medicine and Dentistry, London; [9]Department of Haematology, Addenbrookes Hospital, Cambridge, UK; [10]University of Pittsburgh and the Hemophilia Center of Western Pennsylvania, Pittsburgh, PA; [11]Indiana Thrombosis and Hemostasis Centre, Indianapolis, IN, USA; [12]Royal Prince Alfred Hospital, Camperdown, NSW, Australia; [13]Sahyadri Hospital, Mahara, India; [14]Biogen Idec; [15]Biogen Idec Hemophilia, Weston, MA, USA

Background: To improve the pharmacokinetics (PK) of factor VIII (FVIII), Fc technology was used to develop a monomeric recombinant FVIII Fc fusion protein (rFVIIIFc), with an extended half-life compared with currently available recombinant factor VIII (rFVIII) products. rFVIIIFc comprises a rFVIII molecule genetically linked to the Fc domain of immunoglobulin G_1, with no intervening sequence. The recently completed A-LONG phase 3 study evaluated safety, efficacy, and PK of rFVIIIFc for prophylaxis, treatment of acute bleeds, and perioperative control of bleeding in previously treated subjects with severe haemophilia A and demonstrated a 1.5-fold increase in half-life for rFVIIIFc vs. rFVIII (Advate®).

Aims: To evaluate the efficacy of rFVIIIFc for haemostatic control in the setting of major surgery.

Methods: Eligible male subjects ≥ 12 years old, with severe haemophilia A (< 1 IU/dL [1%] endogenous FVIII), a history of ≥ 150 prior exposure days (ED) to FVIII, and no current/prior FVIII inhibitors, received either individualised prophylaxis (25–65 IU/kg every 3–5 days; Arm 1), weekly prophylaxis (65 IU/kg; Arm 2), or episodic (on-demand; Arm 3) treatment. Subjects from each arm were eligible to enter the surgery subgroup for assessment of rFVIIIFc in perioperative management if they required major surgery, had ≥ 12 EDs to rFVIIIFc and negative inhibitor titres following this period and within 4 weeks prior to surgery. Dosing for subjects in this subgroup was determined by the investigator based on the subject's rFVIIIFc PK profile, dose regimen of FVIII generally required for the planned surgery, and bleeding status.

Results: Overall, nine major surgeries were performed in nine subjects (eight subjects from Arm; 1 subject from Arm 2), including knee arthroplasty ($n = 5$), laparoscopic inguinal hernia repair ($n = 2$), appendectomy ($n = 1$), and arthroscopy ($n = 1$). Haemostatic response with rFVIIIFc was rated by investigators/surgeons as excellent (8/9) or good (1/9) for all nine surgeries. Median (range) estimated blood loss, available for 7/9 surgeries, was 15.0 (0, 600) mL during surgery and 0.0 (0, 1100) mL post-operatively (post-surgical drainage). A single injection of rFVIIIFc was sufficient to maintain haemostasis to the end date/time of all major surgeries, at a median (range) dose of 51.4 (50, 77) IU/kg. Median (range) rFVIIIFc consumption (summarized over all injections during each referenced time period) was 80.6 (65.8, 115.4) IU/kg on the day of major surgery, 161.3 (45.8, 237.3) IU/kg for Days 1–3 days following surgery, and 387.1 (28.1, 728.8) IU/kg for Days 4–14 following surgery. No subjects reported a bleeding episode during the postoperative or rehabilitation periods. Overall, seven adverse events (AEs) were reported in 4 (44.4%) subjects in the surgery subgroup, of which six AEs were of mild or moderate severity, and one AE was considered severe. Two serious AEs (inguinal hernia and appendicitis) were reported in two subjects. All AEs during the perioperative period were assessed by the investigators as unrelated to rFVIIIFc treatment.

Summary/Conclusions: The results from this surgery study showed that rFVIIIFc effectively maintained haemostasis in all major surgeries, and suggest that perioperative haemostasis achieved after infusion of rFVIIIFc was comparable to that expected for similar surgeries in subjects without haemophilia.

PA 4.07-3

The importance of biomarkers of joint damage in monitoring the efficacy of different prophylaxis regimens for severe haemophilia A

Djunic I[1], Dopsaj V[2], Lesic A[3], Miljic P[1], Suvajdzic-Vukovic N[1], Tomin D[1], Novkovic A[4] and Elezovic I[1]

[1]Clinic for Hematology, Clinical Center of Serbia; [2]Institute for Medical Biochemistry, Pharmacy Faculty of Belgrade University; [3]Clinic for Orthopaedic Surgery and Traumatology, Clinical Center of Serbia; [4]Clinical Hospital "Zemun", Belgrade, Serbia

Background: Haemophilic arthropathy, with characteristic joint damage, is the main cause of morbidity in individuals with severe haemophilia A. The most important clinical strategy for management of these patients is treatment by continous prophylaxis with intravenously applied factor (F) VIII. Recently, it was shown that serum and/or urine biomarkers of cartilage turnover in joints reflected the degree of total joint degradation in haemophilia patients.

Aims: The aims of this study were to detect correlations between serum and urine concentrations of biomarkers of joint cartilage degradation and the radiological score for haemophilic arthropathy, as well as to estimate whether measurement of these biomarkers could be useful in monitoring the efficacy of different (secondary) prophylaxis regimens for severe haemophilia A.

Methods: This single-center study included 20 adult males with severe haemophilia A manifested by plasma FVIII < 1% of normal, without inhibitor. The first group involved five patients treated with full-dose prophylaxis: 20 U/kg three times per week. The second group included five patients given intermediate-dose prophylaxis: 10–15 U/kg three times per week. The third group consisted of 10 patients treated on demand (i.e. only in acute bleeding episodes). The following joint cartilage degradation products were measured: serum cartilage oligomeric matrix protein (COMP) and urinary C-terminal telopeptide of type II collagen (CTX-II). Blood and urine samples were collected initially, before the start of treatment (marked as COMP-1 and CTX-II-1) and after 3 months follow-up (marked as COMP-2 and CTX-II-2). Radiological evaluation of haemophilic arthropathy was estimated initially according to the Pettersson score. Approval from the local Ethics Committee and informed written consent were obtained from each subject.

Results: The mean age of the patients was 32 years (range 19–55). The results showed significant positive correlations between the number of points in the Pettersson score and both COMP level ($r = 0.602$, $P = 0.006$) and CTX-II level ($r = 0.580$, $P = 0.009$). In the group of patients given full-dose prophylaxis, the mean value for COMP-2 was significantly lower than that for COMP-1 ($P = 0.043$), while in the group of patients receiving intermediate-dose prophylaxis and in those treated on demand the mean values of COMP-2 were not significantly changed when compared to those for COMP-1. Likewise, in the group of patients treated with full-dose prophylaxis, the mean value for CTX-II-2 was significantly lower than that for CTX-II-1 ($P = 0.014$). Moreover, the mean value of CTX-II-2 was also significantly decreased compared to that for CTX-II-1 ($P = 0.028$) in the group

receiving intermediate-dose prophylaxis. The mean values of CTX-II in the group of patients treated on demand showed no change.
Conclusions: Joint cartilage degradation products, such as the biomarkers: serum COMP and urinary CTX-II, can provide an estimation of the amount of joint damage in patients with haemophilia A. Measurement of serum/urinary biomarker levels is useful for monitoring the efficacy of the applied doses of FVIII in different treatment approaches towards these patients.

PA 4.07-4

Factor VIII genotype and correlation with the hemophilia severity score

Dunn AL, Taylor F and Jobe SM

Emory University, Children's Healthcare of Atlanta, Atlanta, GA, USA

Background: Hemophilia A is classified into mild (> 5–40%), moderate (2–5%) and severe (≤ 1%) disease based upon plasma factor activity levels. Severity of bleeding is commensurate with the baseline factor levels in general; however heterogeneity of bleeding patterns in patients with severe disease is well described. The Hemophilia Severity Score (HSS) is a validated measure of phenotypic severity that takes into account the annual incidence of joint bleeds, the World Federation of Hemophilia Orthopedic joint score and annual factor consumption. The joint score and factor consumption are adjusted for age at the start of prophylaxis and body weight. Multiple factor VIII (F8) mutations have been described.
Aim: We examined the relationship between genotype and phenotypic severity in a cohort of patients with severe hemophilia A.
Methods: After informed consent was obtained, patients with severe hemophilia A (≤ 1%) were recruited from The Emory Hemophilia Treatment Center during routine clinic visits. Patients with concomitant bleeding disorders or thrombocytopenia (< 100,000/μL) were excluded. Each patient received a HSS score. In addition, genotype data was recorded if known or performed if unknown. Mutation analysis was performed by sequencing, multiplex ligation-dependent probe amplification, and polymerase chain reaction for inversions in F8 introns 22 and 1. The F8 genotype was classified as large deletions (single exon or multiple exons), nonsense mutations, intron 1 and 22 inversions, small deletions/insertions/combined deletions and insertions, missense mutations, frameshifts and splice sites. We considered severe molecular defects to include intron 1 and 22 inversions, nonsense mutations and large deletions, while less severe molecular gene defects included missense, splice site, small deletions and frameshift mutations. Associations between genotype and HSS phenotype were examined via one-way ANOVA. Association between severity of mutation and HSS phenotype was determined via t-test.
Results: To date, 71 patients with severe hemophilia A enrolled on the study. The patients ranged in age from 3 to 61 years. Full HSS and genetic data were available on 48 patients. Four (8%) patients manifested large deletions, 18 (38%) had inversion 22, 4 (8%) exhibited intron 1 inversion, 3 (6%) had nonsense mutations, 7 (15%) demonstrated frameshifts, 10 (21%) with missense mutations and 2 (4%) had splice site changes. The mean HSS differed significantly among the mutation types $P = 0.032$. The patients that manifested severe mutations had a significantly higher mean HSS (1.05 vs. 0.54) than those with less severe mutations, $P = 0.0045$.
Summary/Conclusion: We have demonstrated that bleeding severity as scored by the HSS correlates with the type and severity of genetic mutations. We surmise that patients with less severe mutations may produce small amounts of F8 and this may correlate with a less severe bleeding phenotype. These results suggest that assessment of F8 genotype, above and beyond F8 activity, may provide useful information regarding phenotypic severity in patients with severe hemophilia.

PA 4.07-5

A new treatment concept for haemophilia: safety, pharmacokinetics and pharmacodynamics of single i.v. and s.c. doses of a monoclonal anti-TFPI antibody in healthy males and haemophilia subjects

Chowdary P[1], Friedrich U[2], Lethagen S[2] and Angchaisuksiri P[3]

[1]Royal Free Hospital, London, UK; [2]Novo Nordisk A/S, Søborg, Denmark; [3]Ramathibodi Hospital, Bangkok, Thailand

Background: Regular prophylaxis with either factor VIII or IX is the current gold standard of care for patients with severe haemophilia to prevent joint damage. Frequency of the injections, poor venous access, cost, compliance and time commitment continue to be barriers for widespread use across the world. Novo Nordisk has developed a monoclonal antibody (mAb 2021) targeting tissue factor pathway inhibitor (TFPI). If successful, mAb 2021 has the potential to alter current concepts of prophylaxis in all types of haemophilia, including convenient subcutaneous (s.c.) administration with potential for improved compliance.
Aims: Safety was the primary objective. Secondary objectives were pharmacokinetics (PK) and pharmacodynamics (PD) of mAb 2021 after single i.v. and s.c. doses in healthy subjects (HS) and subjects with haemophilia A or B (patients).
Methods: This was a phase 1, multi-centre, placebo-controlled, double-blind trial. Escalating single i.v. and s.c. doses were administered to healthy subjects ($N = 28$) and patients with haemophilia ($N = 24$). Informed consent was obtained from all participating trial subjects. The trial was approved by the relevant ethical committees. I.v. dose cohorts for HS: 0.5, 5, 50 and 250 μg/kg; and for patients: 250, 1000, 3000 and 9000 μg/kg. S.c. dose cohorts for HS: 50, 250 and 1000 μg/kg; and for patients: 1000 and 3000 μg/kg. Four subjects were included in each dose cohort of which one received placebo.
We registered all Adverse Events (AEs), including Serious Adverse Events (SAEs), local tolerability, laboratory assessments, anti-drug antibodies, vital signs and ECG. A mAb 2021 ELISA was used for PK, and a residual TFPI functionality assay based on FXa generation for PD. An ELISA measured plasma TFPI.
Results: There were no SAEs and no anti-drug antibodies. Fifty-seven of 76 AEs were mild, 17 were moderate and two were graded as severe (one endodontic procedure, and one sciatica, both unlikely related to mAB 2021). Nineteen AEs occurred after placebo. Five AEs were judged by investigators as related, of which three occurred after administration of mAb 2021. Two of these were graded as mild and one as moderate severity, the latter a small superficial thrombophlebitis in a HS in the 1000 μg/kg s.c cohort, manifesting only as local skin tenderness and diagnosed with ultrasound. The symptom disappeared spontaneously, without treatment, the day after diagnosis. Injection site reactions were few, all mild except for one moderate.
There were no clinically relevant changes in Platelets, AT, APTT and PT. As expected a dose dependent procoagulant effect of mAb 2021 was seen as increased levels of D-dimers and prothrombin fragments 1 + 2.
Non-linear PK of mAb 2021 was observed due to target mediated clearance. A maximum AUC of 33.960.278 h*ng/mL and a maximum concentration of 247.104 ng/mL was measured at the highest dose, 9000 μg/kg i.v. Residual TFPI functionality and Total free plasma TFPI levels decreased in a mAb 2021 concentration dependent manner.
Conclusions: mAb 2021 was found to be safe after i.v. and s.c. administration. PK was influenced by target mediated clearance. A mAb 2021 concentration dependent effect was observed on plasma TFPI functionality and levels.

PA 4.07-6

Validation of the colorado adult joint assessment scale in patients with severe hemophilia A

Hong W[1], Raunig D[2] and Funk S[3]

[1]*Bayer HealthCare, Montville, NJ;* [2]*ICON Medical Imaging, Warrington, PA;* [3]*University of Colorado Denver, Aurora, CO, USA*

Background: Valid rating scales for the physical examination of joints are required for controlled studies of hemarthropathy in patients with hemophilia A. The Hemophilia Joint Health Score (HJHS) was previously validated in a pediatric population; a new joint rating scale for adults with hemophilia is also needed.

Aim: To demonstrate the validity of the Colorado Adult Joint Assessment Scale (CAJAS) for measuring joint status in adults with severe hemophilia A

Methods: Data for this validation study were obtained from a prospective, randomized, parallel-group study (SPINART; ClinicalTrials.gov identifier: NCT00623480), which compared routine prophylaxis vs. on-demand treatment with sucrose-formulated recombinant factor VIII in 84 male patients aged 15–50 years. Baseline CAJAS scores were evaluated for linearity (ie, distribution properties of baseline scores, range of observed values, floor and ceiling effects, correlation with bleeding episodes) and reproducibility (ie, variability among different raters, sites, and countries). Item analysis was conducted using multivariate analysis to evaluate item uniqueness, scoring difficulty, and discriminating properties (ie, ability to discriminate between healthy and unhealthy joints). Factor analysis was conducted using the maximum likelihood method to identify domains specific to the adult patient population.

Results: CAJAS scores moderately correlated with age ($r = 0.52$), similar to the expected correlation of joint health with total lifetime bleeding ($r = 0.43$–0.50) reported for older joint assessment scales and consistent with the expectation that all patients with hemophilia will experience joint bleeding episodes and that older patients will have accumulated more bleeding episodes than younger patients. The CAJAS demonstrated excellent reproducibility between countries despite widely varying degrees of joint damage and evaluator training. Few patients (3%) had CAJAS scores of 0, and no patient had a maximum score, demonstrating no adverse floor or ceiling effects. The CAJAS scores had excellent correlation with radiologic evaluations of joint damage ($r = 0.71$); this correlation is higher than the correlation of the physician joint health assessment to HJHS ($r = 0.42$) reported by Feldman et al. Items clustered by two important International Classification of Functioning, Disability, and Health factors that were likely related specifically to adult functions: Activity Functional Impairment and Structural Functional Impairment. Internal reliability was good, with an overall Cronbach's alpha of 0.68; this was lower than the Cronbach's alpha reported in the literature for the HJHS (alpha, 0.86). This result may have been due to the increased heterogeneity of disease severity in the SPINART population.

Conclusions: The CAJAS demonstrated good to excellent content validity and reliability for use in adults. Although the CAJAS is similar to previous scales, such as the HJHS, it also incorporates items consistent with adult joint health that were deleted from later versions of the HJHS. The items removed from HJHS were shown to be important and reliable items that increase the overall discriminant ability of the CAJAS.

PA4.08 – Heparin and Heparinoids – II

PA 4.08-1

Procoagulant red blood cells diminish the protective effect of prothrombinase on factor Xa inhibition by fondaparinux and low molecular weight heparin

Stevic I, Chan HW, Chander A, Berry LR and Chan AK

McMaster University, Hamilton, ON, Canada

Background: Numerous red blood cell (RBC) disorders have been linked with having procoagulant RBCs that over-express phosphatidylserine on their outer leaflets. We have previously demonstrated that prothrombinase (IIase) formed on procoagulant RBCs protects Xa from inhibition by antithrombin (AT) + unfractionated heparin, consistent with vesicles and platelet IIase systems. Others have also shown that IIase on vesicles and platelets also protects Xa from inhibition by fondaparinux and low molecular weight heparin (LMWH). However, inhibition of the RBC-IIase system by fondaparinux and LMWH has never been studied.

Aim: This study was performed to determine the inhibition of Xa within the IIase complex by AT+fondaparinux or AT + LMWH when the IIase forms on a procoagulant RBC surface.

Methods: Discontinuous second order rate constant assays were carried out to obtain k_2-values for inhibition of free or RBC-IIase-bound Xa by AT + fondaparinux or AT + LMWH. Freshly isolated RBCs were activated for 15 min with phosphatidic acid and calcium at room temperature prior to addition of Va, Xa, Ca^{2+} and pefabloc-TH in buffer. After an additional 3 min incubation, IIase was reacted with prothrombin (II), followed by addition of inhibitors (AT + fondaparinux or AT + LMWH) at specific time intervals. The reactions were neutralized by simultaneous addition of polybrene, Na_2EDTA and S-2222 in buffer. The remaining enzyme activity was obtained at 405 nm, and the k_2-values calculated from plots of lnVt/Vo vs. time.

Results: The k_2-values for inhibition of free Xa by AT+fondaparinux and AT+LMWH were $6.15 \pm 0.87 \times 10^6$/M/min and $1.35 \pm 0.36 \times 10^7$/M/min, respectively. However, incorporation of Xa in the RBC-IIase (without II) gave k_2-values that were slightly increased to $7.57 \pm 2.58 \times 10^6$/M/min for AT + fondaparinux and $1.73 \pm 0.43 \times 10^7$/M/min for AT+LMWH. Thus, protection of Xa by IIase appeared to be diminished on the surface of RBCs. When experiments were repeated with addition of II to the RBC-IIase system, there was a further slight increase in k_2-values to $8.38 \pm 2.58 \times 10^6$/M/min for AT+fondaparinux and $1.93 \pm 0.82 \times 10^7$/M/min for AT + LMWH. Since protection of Xa is not observed on RBCs, we performed additional experiments with synthetic phospholipid vesicles to confirm whether the protective effect was retained in that lipid system. We observed that, relative to free Xa, the k_2-values of the vesicle-IIase system (without II) were reduced to $2.33 \pm 0.83 \times 10^6$/M/min for AT + fondaparinux ($P < 0.001$) and $1.18 \pm 0.07 \times 10^7$/M/min for AT + LMWH ($P$ = ns), thus re-establishing the protective effect.

Summary/Conclusion: Inhibition rates from this study are one and two orders of magnitude lower for LMWH and fondaparinux, respectively, compared to previously reported rates for heparin. Moreover, IIase protection of Xa inhibition by AT + fondaparinux and AT + LMWH was not observed on procoagulant RBCs. In fact, incorporation of Xa within the RBC-IIase even trends slightly towards increased rate of inhibition, which is opposite to results previously reported for other cell surfaces. To ensure the functionality of our system, we repeated the experiments utilizing vesicles instead of RBCs, and demonstrated that Xa protection was restored to previously reported values for both inhibitors. Therefore, surface complexation of IIase on RBCs may provide suitable conditions for relative enhancement of Xa inhibition by fondaparinux and LMWH.

PA 4.08-2

Binding and inhibition of drug transport proteins by heparin – a significant role in modulation of multidrug resistance in human breast cancer cells

Chen Y[1], Scully M[1], Gloria P[2] and Ajay K[3]

[1]Thrombosis Research Institute; [2]Thrombosis Research Institute & University College London Hospitals; [3]Thrombosis Research Institute & University College London, London, UK

Background: A number of transmembrane drug transporter proteins, including the ATP-binding cassette (ABC) active transporters which require the energy of ATP hydrolysis as well as non-ABC transporters, are involved in multidrug resistance (MDR) to chemotherapeutic agents. In cancer patients undergoing chemotherapy, treatment with heparin has been shown to prolong survival compared to patients who have not received heparin treatment, yet the fundamental mechanisms underlying this survival benefit are largely unknown. We hypothesised that one of the possible mechanisms is that heparin treatment enhances the efficacy of chemotherapy.
Aims: To clarify whether heparin could act as aMDR modulator and thereby increase the potency of chemotherapeutic drugs in cancer patients.
Method: Four cancer cell lines, including a human enriched breast cancer stem cell (CSC) line, two of human breast cancer cell lines, MCF-7 and MDA-MB-231, and a human lung cancer cell line A549 were used. The ability of heparin to bind to individual drug transporter proteins was investigated by extraction on Heparin-agarose beads. The effect of heparin on the function of drug transporter proteins was investigated by measuring the rate of efflux of different drug transporter substrates from cancer cells in the presence of heparin using flow cytometry; Measurement of the effect of heparin on the ATPase activity of each of the ABC transporter proteins was carried out using individual ATPase kits (Solvo Biotechnology, Hungary). shRNA for *lung-resistance-protein* (LRP) – one of major non ABC transporters, was used to generate stable LRP knockdown cell lines. The sensitivity of chemotherapeutic drugs in treated cells was measured by cytotoxicity assay.
Results: Heparin was shown to bind to several of the drug transport proteins from ABC and non ABC transporter system. Among the ABC system, heparin binding caused a significant inhibition of the ATPase activity of ABCG2, and to a lesser extent of ABCC, and this was associated with significant inhibition of the efflux function observed as enhanced intracellular accumulation of substrates of the ABC transporter system in tumour cells. The cytotoxicity towards breast CSCs of each of a number of chemotherapeutic substrates of the ABC transporter system was increased when used in combination with heparin. As one of the major non-ABC transporter proteins, LRP was also confirmed to be a heparin binding protein. The expression of LRP was up or down regulated by 17β-estradiol treatment or shLRP transfection, respectively results which corresponded with the rate of intracellular accumulation and cytotoxicity of doxorubicin in MCF-7 cells.
Conclusion: Heparin acts as an inhibitor of a range of ABC and non-ABC transporter proteins, by blocking transporter protein activity and modulating drug metabolism and toxicity. It is proposed that these interactions are responsible, at least in part, for the increased survival of heparin treated cancer patients.

PA 4.08-3

Heparin induced apoptosis of breast cancer cells is associated with modulation of endogenous Protein Kinase C (PKC) activities

Chen Y[1], Scully M[1] and Ajay K[2]

[1]Thrombosis Research Institute; [2]Thrombosis Research Institute & University College London, London, UK

Background: Heparin exerts a pro-apoptotic effect on a variety of cells, but the fundamental basis of this action is little understood. It may well be due to its effect upon the primary signalling pathways regulating the cell cycle, such as the PKC system since previously heparin has been shown to antagonise serum or phorbol 12-myristate 13-acetate (PMA) induced PKC isoenzyme gene expression. These effects may arise from the ability of heparin to bind to and modulate the function of many of the growth factors and other agonists found in serum. Whether heparin is also able to affect PKC activity directly remains unclear.
Aims: The investigation of the principal interactions contributing to the pro-apoptotic effect of heparin on breast cancers cells.
Methods: Two human breast cancer cell lines (MCF-7 and MDA-MB-231) were cultured under serum-free conditions (in which cells are maintained by the activity of autocrine growth factors) in the presence of either unfractioned heparin (UFH) or a low molecular weight heparin (LWMH, Fragmin). Cell cycle and apoptosis assays were performed using flow cytometry. Based upon observations obtained by gene microarray analysis, the expression of a selection of pro-apoptotic proteins was analysed by Western blot. The level of phosphorylated protein kinases in signalling pathways involved in apoptosis was investigated in treated cells by Western blot and immunofluorescence assay.
Results: Cell cycle profiling of cell derivedDNA showed that MCF-7 cells were arrested in the G0-G1 phase when treated with each of the heparins. The percentage of apoptotic cells was also significantly increased by heparin treatment. Moreover, the percentage of apoptotic cells induced by treatment with heparin in combination with chemotherapeutic drug(s) was higher than in cells treated with drug or heparin alone. The level of phosphorylated protein kinases of signalling pathways involved in apoptosis was also modulated by heparin in both cell lines, including the reduction in the level of phosphorylation of members of the Raf/MEK/ERK pathway (p-ERK, p-Ref) and PI-3K/Akt pathway (p-Akt, p-PTEN)., The endogenous activity of each of a number of PKC isoenzymes, which are capable of triggering an apoptotic response, was also reduced by heparin treatment, including p-PKCα/βII, p-PKCδ, p-PKCθ, and p -PKD/PKCμ. In addition, the activity of p-PKCε, a transforming oncogene and possible tumour biomarker was reduced. The expression of a numbers of pro-apoptotic proteins was also regulated by heparin in both cell lines and was confirmed by RT-PCR and Western blot – these included TNFα, p-GSK3α/βII and active-caspase-3, and regulator proteins p21, p53 and Hsp90.
Conclusion: The pro-apoptotic action of heparin is associated with the modulation of the activity of a number of key signalling pathways, including endogenous PKC activity as well as increased expression of a number of pro-apoptotic proteins. This ability of heparin to promote apoptosis may contribute to the favourable effect of heparin treatment on cancer therapy.

PA 4.08-4

Protamine sulfate neutralization of anticoagulation by a potent antithrombin-heparin covalent complex

Atkinson M, Rubiano A, Berry LR and Chan AK

McMaster University, Hamilton, ON, Canada

Background: Heparin is a well-established anticoagulant for treatment of thromboembolic disease. Heparin catalyzes inhibition of several coagulation factors, including thrombin (IIa) and factor Xa (Xa), by enhancing the activity of antithrombin (AT). Despite development of low molecular weight heparins (LMWHs) and factor-specific direct anticoagulants, unfractionated heparin (UFH) remains the anticoagulant of choice in some clinical situations. Limitations of UFH include a short intravenous half-life, AT-dependence, and only one in three molecules have anticoagulant activity. We have developed a potent anticoagulant consisting of covalently linked AT and UFH (ATH). ATH has increased half-life, both AT-dependent and independent activities, faster reaction rates with coagulation factors, and 100% of its heparin chains are anticoagulant. Thus, ATH may be a more favourable anticoagulant than UFH for specific indications. When a patient receiving

heparin is experiencing acute bleeding or requires emergency surgery, anticoagulation is neutralized by administration of protamine sulfate. Protamine is also used to reverse heparin following cardiopulmonary bypass surgery (CPB). Protamine is a small charged protein which binds electrostatically to heparin forming an inactive complex. Protamine is less effective at inhibiting LMWHs, and factor-specific inhibitors currently do not have any known direct antidote. Thus far, ATH neutralization with protamine has not been studied.

Aim: To determine if protamine can neutralize the anticoagulant activity of ATH.

Methods: ATH or AT + UFH were exposed to various concentrations of protamine, before incubating with purified IIa or Xa. Residual enzyme activity against chromogenic substrates was monitored spectrophotometrically and expressed as a percentage of uninhibited enzyme activity in the presence of an equal amount of protamine. Additionally, normal human pooled plasma mixed with 0.2 U/mL ATH or UFH was treated with protamine, followed by initiation of clotting with calcium and dilute tissue factor. Time to clot was monitored turbidimetrically and defined as the time to reach half maximal turbidity.

Results: Inhibition of IIa by ATH or AT + UFH was fully reversed with protamine, both requiring the same molar ratio of protamine: anticoagulant. A 4:1 molar ratio of protamine:UFH recovered 88.7 ± 2.2% of uninhibited Xa activity, whereas the maximum recovery of Xa activity in the presence of ATH was 78.4 ± 1.6%. Increasing amounts of protamine gave no further reversal. In plasma, 0.2 U/mL ATH and UFH extended the time to clot from 3.2 ± 0.1 to 13.6 ± 0.6 and 18.7 ± 1.3 min, respectively. Protamine, at 1 μg/mL, reduced the time to clot for both ATH and UFH to 3.8 ± 0.1 min, although it had a slight anticoagulant effect (4.6 ± 0.1 min) in plasma on its own.

Conclusions: IIa inhibition by ATH or AT + UFH was completely abolished by protamine in a purified system. Interestingly, in similar experiments with Xa, protamine did not entirely reverse the inhibitory effects of ATH, or even those of AT + UFH. However, protamine fully neutralized ATH and UFH anticoagulation when determined by clot formation in plasma. Further experiments studying protamine efficacy against ATH *in vivo* are warranted. These results contribute significantly to the development of ATH as a clinical therapeutic option.

PA 4.08-5

In vitro immunogenicity assessment of branded enoxaparin and a US generic version of enoxaparin

Walenga JM, Prechel M, Escalante V, Jeske W, Hoppensteadt D, Chaudhry T and Bakhos M

Loyola University Medical Center, Maywood, IL, USA

Background: With the approval of generic enoxaparin for clinical use in the US, and the fact that that low molecular weight heparins (LMWHs) are not immunogenically inert, it is of interest to understand if the immunogenic response of the generic enoxaparin is equivalent to that of branded enoxaparin (Lovenox®).

Aims: The focus of these *in vitro* studies was on heparin-induced thrombocytopenia (HIT) where cross-reactivity of generic enoxaparin to HIT antibodies was compared to the reactivity of branded enoxaparin.

Methods: Five batches each of branded (Sanofi-aventis; Bridgewater, NJ) and generic (Sandoz US; Princeton, NJ) enoxaparin were studied. Drugs were purchased through hospital pharmacies as pre-filled syringes containing 40 mg drug. HIT antibodies from multiple patients (minimum $n = 9$ sera strongly ELISA and SRA positive) and platelets (pre-screened for platelet assay reactivity) from different donors were employed to assure the robustness of the data. Platelet activation by HIT antibodies was determined by the clinical ^{14}C-serotonin release assay (SRA; using washed platelets) and the heparin-induced platelet aggregation assay (using platelet rich plasma). The metabolic capacity of platelets after incubation with HIT antibodies and LMWH was determined by our MPA colorimetric assay (*Platelets* 2012;23:69) using the AQ_{ueous} One Solution (Promega; Madison, WI) indicator dye to detect mitochondrial activity. PF4 displacement by LMWH was determined using the PF4-Enhanced ELISA (GTI; Waukesha, WI) and detecting HIT antibody binding.

Results: Over multiple runs mean values did not reveal significant differences between the generic in comparison to the branded enoxaparin for PF4 affinity or effect on platelet function (activation, aggregation, metabolic potential) due to cross-reactivity with various HIT antibodies. However, what was revealed were variable responses between the tested batches of generic enoxaparin. This batch-to-batch variation was not observed with the branded enoxaparin that gave a more consistent response. This signal would have been masked if individual data were not evaluated and the data was only analyzed as an average.

Conclusion: This was a comprehensive evaluation of the immunogenic potential of generic enoxaparin compared to branded enoxaparin using multiple sources of HIT antibodies as well as several different assay systems. While no obvious difference between drugs in these *in vitro* assays was observed in a general sense, the significant finding was a higher batch-to-batch variation for the generic enoxaparin. This finding is of importance since an enhanced immunogenic response of even some batches of generic enoxaparin make the branded and generic materials non-equivalent. It also would raise concern for clinicians of true interchangeability between branded and generic products. It is thus of clinical interest to include investigations into the immunogenic response of complex biological drugs, such as generic LMWHs, for regulatory recommendations.

Non-anticoagulant heparin analogue protects against ConA-induced acute hepatitis and sepsis

Wildhagen CAA[1], Garcia de Frutos P[2], Soehnlein O[3], Hemker CH[4], Schrijver R[1], Deckers N[1], Reutelingsperger C[1] and Nicolaes GAF[1]

[1]Maastricht University, Maastricht, The Netherlands; [2]Institute of Biomedical Research of Barcelona, Barcelona, Spain; [3]Ludwig-Maximilians-University Munich, Munich, Germany; [4]Synapse b.v., Maastricht, The Netherlands

Sepsis is a worldwide healthcare problem for which adequate therapy is currently not available and severe sepsis is associated with a mortality rate of up to 50%. Recent findings have identified extracellular histones as major mediators of hyperinflammation in sepsis. Histones are major protein components of neutrophil extracellular traps that are formed in response to infection. Consequently histones were identified as interesting therapeutic targets for the treatment of hyperinflammation and sepsis.

Unfractionated heparin (UFH) has the highest negative charge density of all known biological molecules and is a good candidate to bind positively charged extracellular histones to potentially neutralize them. The disadvantage of heparins for clinical use is the associated risk for bleeding complications. To this end, we prepared a heparin-analogue, HA, that has only marginal anticoagulant effects.

The *in vitro* and *in vivo* effects of UFH and HA were tested and we demonstrate that both UFH and HA dose-dependently inhibit the cytotoxic effects of histones on endothelial cells. In a ConA-triggered mouse model for fatal liver injury and in a CLP model, HA administration could increase survival from 40% in the untreated group till 90–100% in the treated groups, with no signs of bleeding in the treated groups.

We show that HA can be used as a safe and effective means of protection against histone-mediated death *in vivo* and conclude that HA has a strong therapeutic potential to treat hyperinflammatory responses in humans, such as occur during sepsis.

Disclosure of Interest: The author declares no conflict of interest.

Acquired von willebrand factor deficiency and bleeding risk in a rabbit model of aortic stenosis

Rauch A[1], Banfi C[2], Jean Pierre E[3], Rousse N[4], Ung A[4], Godier A[5], Caron C[3], Elkalioubie A[4], Van Belle E[2] and Susen S[6]

[1]University Lille Nord de France; [2]CHRU, Pôle de Chirurgie Cardiovasculaire et de Cardiologie; [3]Haematology Transfusion Department; [4]Univ Lille Nord de France, UDSL, IFR114, EA2693, Faculté de Médecine, Lille; [5]Anesthesia and Critical Care, Hotel-Dieu and Cochin Hospitals, Paris Descartes, Paris; [6]Haematology Transfusion Department and Univ Lille Nord de France, UDSL, IFR114, Lille, France

Background: Acquired deficiency of von Willebrand factor (VWF) is characterized by the loss of high molecular weight (HMW) multimers. HMW multimers have been reported in association with high shear-cardiovascular disorders, mainly in aortic valve stenosis. Although it has been shown that acquired deficiency of VWF is improved after correction of the pathological condition, the causal evidence of a pathological shear condition on HMW multimers changes has not been established in an experimental model *in vivo*. Moreover the involvement of these selective HMW multimers in the bleeding risk is not demonstrated.

Aims: Our aim was to provide an *in vivo* causal evidence between loss of HMW multimers and aortic stenosis in an animal model and to evaluate the bleeding risk induced by the stenosis.

Methods: We developed a rabbit model of calibrated supra aortic stenosis. All experiments were conducted in syngeneic male New Zealand rabbits (2.7–3 kg) in accordance to the declaration of Helsinki. The ascending aorta was surgically exposed after a median sternotomy under general sedation. A severe stenosis > 75% was performed using a vascular silicone occluder placed on the ascending aorta. The occluder was inflated with a device allowing a reproducible stenosis. Blood was sampled at baseline (T0) and at 30 min (T30) after stenosis for VWF antigen and multimeric profile assessment in 17 animals. The multimeric structure of plasma VWF was analyzed as previously described in humans and the revelation was adapted for rabbits. The percentage of the highest molecular weight multimers (more than 15 mers) was determined using densitometric scanning. Results were expressed as a ratio vs. baseline value.

In this model, a hepatosplenic surgical cut was performed in 20 rabbits randomly allocated to two groups (stenosis/sham, $n = 10$ each) to evaluate blood loss. Blood was collected through four gauze compresses previously disposed around the liver and the spleen. Hepatosplenic blood loss was considered as the weight of compresses after procedure. Potential confounding variables (pH, platelet count, HCO3, PCO2, body temperature) were monitored throughout procedure, body temperature was maintained using a heating blanket.

Results: A significant decrease of HMW multimers was observed (ratio 0.77 ± 0.07; $P < 0.0001$) after the induction of the stenosis when compared to baseline values. HMW multimers remained unchanged in sham group (1.03 ± 0.07;ns). VWF:Ag remained unchanged in the both groups during the whole procedure.

A trend for an increase in blood loss was observed in the aortic stenosis group ($11.8\ g \pm 5.6$) when compared to the sham group ($7.1\ g \pm 2.1$; $P = 0.06$). No significant changes were observed in confounding variables.

Summary/Conclusions: We provide the first *in vivo* causal evidence of HMW multimers loss associated with aortic stenosis. This selective loss of HMW multimers was associated with a moderate increase in bleeding risk.

PA 4.09-2

Loss of either Fut1 or Fut2 fucosyltransferase is associated with significantly elevated von Willebrand Factor (Vwf) levels in mice

Johnsen JM, Yohannes E and Walsh TW

Puget Sound Blood Center, Seattle, WA, USA

Background: von Willebrand Factor (VWF) is a critical coagulation glycoprotein which stabilizes Factor VIII, adheres at sites of vascular injury, and binds platelets. VWF is synthesized in megakaryocytes and vascular endothelium, where it undergoes complex post-translational processing, including extensive glycosylation, prior to secretion. VWF levels vary widely in humans, and the carbohydrate blood group, ABO, is a well-known genetic modifier of VWF. 'H' glycan is the precursor structure for ABO, and thus is also a candidate to influence VWF. H glycan is generated by two alpha-1,2-fucosyltransferase genes, *FUT1* and *FUT2*. In humans (but not mice), *FUT1* is expressed in erythrocytes and vascular endothelium. In both humans and mice, *FUT2* (and to a lesser extent, *FUT1*) is expressed in mucosa. Human homozygotes for *FUT1* nonsense mutations ('Bombay' blood type) are very rare and exhibit low VWF levels, likely due to the absence of H (and therefore ABO) on endothelial-cell derived VWF. On the other hand, individuals homozygous for *FUT2* nonsense mutations ('non-Secretor') are common and have been reported to have slightly higher VWF levels, but the literature is conflicted. To investigate the hypothesis that mucosal H glycan expression influences VWF, we examined Vwf levels in *Fut1* and *Fut2* knock-out mice.

Methods: *Fut1* and *Fut2* knock-out animals (backcrossed > 20 generations to C57BL6/J prior to analysis) were obtained from the Jackson Laboratory. Heterozygous F1 animals were intercrossed to generate F2 offspring. Littermate controls were generated for each knock-out mouse line separately. Male mice aged 8–12 weeks were studied to avoid the effects of estrous and aging. Twenty-six individuals were analyzed per group except for *Fut1*−/− ($n = 25$). Platelet-poor plasma was assayed for Vwf antigen (Vwf:Ag) in duplicate by sandwich ELISA [rabbit anti-human VWF (Dako); sheep anti-rabbit VWF (Abcam)] using a pooled C57BL6/J reference standard (100 arbitrary Units/uL).

Results: *Fut2*−/− animals exhibited significantly higher (> 2-fold) Vwf:Ag levels compared to their wild-type littermates (*Fut2*−/− = 217.9 ± 75.3 U/uL; *Fut2*+/+ = 106.7 ± 31.7 U/uL; $P = 5.7 \times 10^{-8}$). Interestingly, *Fut2*+/− animals (heterozygotes) had an intermediate elevation in Vwf:Ag levels (*Fut2*+/− = 155.4 ± 59.7 U/uL; $P = 5.9 \times 10^{-4}$), consistent with an allele dose effect. *Fut1*−/−animals also exhibited Vwf:Ag levels nearly double that of their wild-type littermates (*Fut1*−/− = 186.1 ± 70.8 U/uL; *Fut1*+//+ = 97.9 ± 28.9 U/uL; $P = 2.2 \times 10^{-6}$).

Conclusions: Loss of either *Fut1* or *Fut2* expression is associated with significantly higher Vwf:Ag in mice. This supports previous human studies which found modestly increased VWF levels in non-Secretors. We speculate that the large effect size of *Fut1* and *Fut2* on Vwf levels observed in mice is due to the absence of the confounding effects of endothelial H expression which occurs in humans. Although the mechanism by which mucosal H expression influences circulating Vwf is not yet known, it must be distinct from the classical model of VWF glycosylation in the Golgi of endothelial cells as the tissue-specific expression patterns of *Vwf* and the *Fut* genes do not overlap in mice. We conclude glycosylation variants may influence VWF by more complex mechanisms than previously suspected.

Incorporation of von Willebrand Factor into a fibrin network induces activation of von Willebrand Factor enabling binding of GPIb

Miszta A[1], Pelkmans L[2], Ruggeri ZM[3], Al Dieri R[1], Du V[4], De Groot PH[4], Hermens W[2], Hemker CH[1], Kelchtermans H[1] and De Laat B[5]

[1]Synapse BV, Cardiovascular Research Institute Maastricht, Maastricht University; [2]Cardiovascular Research Institute Maastricht, Maastricht University, Maastricht, The Netherlands; [3]The Scripps Research Institute, La Jolla, CA, USA; [4]Clinical Chemistry and Hematology, University Medical Center Utrecht, Utrecht; [5]Department of Biochemistry, Cardiovascular Research Institute Maastricht, Maastricht, The Netherlands

Background: Attachments of platelets from the circulation onto a growing thrombus is a complicated process involving several receptors on the platelet and components in the thrombus. Platelet binding to a thrombus under arterial flow indicates a role for Von Willebrand Factor (VWF) and Glycoprotein Ib (GPIb).

Aim: We investigated a possible interaction between Von Willebrand Factor and fibrin(ogen).

Methods: We measured the interactions of von Willebrand Factor with fibrin(ogen) using different enzymes in a purified system and plasma based system. The following enzymes were used: (i) Plasma purified thrombin cleaves fibrinopepties A (FpA) and B (FpB) and interacts with fibrinogen; (ii) Plasma purified γ-thrombin cleaves FpA and FpB but does not interact with fibrinogen due to not active exosite I; (iii) Arvin only cleaves FpA but not FpB; (iv) The venoms from snakes Agkistrodon contortix contortix and Contralux atrox cleave FpB and the first 42 amino acids (where FpB is located), respectively. To study binding kinetics between fibrin, VWF and Glycoprotein Ib we used ellipsometry and surface plasmon resonance. To visualise the effect of VWF on fibrin structures Scanning Electron Microscopy was introduced.

Results: Applying ellipsometry and surface plasmon resonance we observed that VWF does not bind to either fibrinogen nor to polymerized fibrin. Interestingly, we did establish binding of VWF to fibrin monomers during the process of fibrinogen-to-fibrin conversion in the presence of thrombin. This indicates that VWF is incorporated into the fibrin mesh and that the incorporation more probable occurs in the E domain where FpA and/or FpB are situated. Furthermore, using either γ-thrombin, Arvin, Agkistrodon contortix contortix or Contralux atrox we were able show that VWF was incorporated into the fibrin mesh indicating that cleaving of either FpA or FpB is sufficient. To identify the binding place of VWF to fibrin monomers we tested mutant RGGS-VWF in our system. The lack of incorporation of mutant RGGS-VWF into fibrin indicates that VWF most probably binds to fibrin via its RGD sequence located in the C-terminal part of VWF. Moreover, using truncated GPIb proteins we demonstrated that the incorporated VWF into the thrombus is able to bind GPIb. Furthermore, we have accomplished incorporation of VWF into a developing fibrin mesh under conditions of flow in a purified system. Using Scanning Electron Microscopy we have observed that increasing concentrations of VWF in plasma result in a denser fibrin mesh with significantly thinner fibres.

Summary/Conclusion: We have shown that the C-terminal part of VWF and the E-domain of fibrin monomers are involved in the incorporation of VWF into a fibrin mesh. This interaction explains the incorporation of platelets into a growing thrombus under conditions of arterial shear.

PA 4.09-4

Von willebrand factor acts as a novel antagonist for nitric oxide synthase to promote insulin resistance in hypoxia

Khan GA, Singh B, Biswas I and Garg I

Defence Institute of Physiology and Allied Sciences, New Delhi, India

Background: Insulin resistance (IR) and impaired nitric oxide (NO) availability is reported in respiratory diseases such as chronic obstructive pulmonary disease (COPD), obstructive sleep apnoea (OSA) and high altitude (HA) induced cardio respiratory diseases (CRDs). NO plays an important role in preventing vascular diseases through regulation of vascular tone and endothelial functions. High plama level of vWF has been reported in all above mentioned diseases due to endothelial dysfunction. However, the molecular mechanism responsible for impaired NO production and IR in hypoxia remain unknown.

Aim: In this study, we investigated the possible mechanism of impaired NO production and IR during hypoxia in a mice model.

Methods: Mice (Swiss albino, 25–30 g, male, $n = 6$/group) were subjected to HAH (in an environmental chamber) equivalent to the prevailing atmospheric conditions at an altitude of 7628 m (282 mm Hg barometric pressure) having O_2 content approximately 8.5%, humidity $55 \pm 5\%$ and temperature 25 ± 2 °C for 0–24 h. Age and sex matched control mice (not exposed to HAH) were maintained in 21% O_2 with same environmental conditions. Blood was drawn though retro-orbital method and different assays were performed. The expression of vWF was analyzed by ELISA and SDS-immunobloting. The NO assay was done by oxyhaemoglobin methods. The IR resistance parameters were evaluated by glucose tolerance test (GTT), insulin tolerance test, D-[U-^{14}C] – glucose uptake and HOMA-IR. The interaction between vWF and nitric oxide synthase were studied by far-western blotting, coimmunoprecipitation and plasma surface resonance spectroscopy. *In vivo* inhibition of vWF was performed by tail vein injection of anti-vWF neutralizing antibody 2 h before HAH exposure.

Results: Exposure to hypoxia showed a time dependent increase of IR (GTT, ITT & HOMA-IR) as well as multimeric form of vWF and subsequent decrease of NO production. Pre-incubation of time dependent hypoxia exposed animal plasma or recombinant human-vWF dose dependently inhibited insulin (0.24 μM) induced NO production and higher dose of insulin (1.2 μM) reverses the effect. In contrary, pre-incubation of immunodepleted (vWF) plasma failed to inhibit insulin induced NO production, whereas vWF immunoneutralization attenuated hypoxia induced IR and D-[U-^{14}C] – glucose uptake. Furthermore, the interaction between vWF and nitric oxide synthase (NOS) were studied by Far-western blotting, coimmunoprecipitation, surface plasma resonance spectroscopy. The kinetic analysis showed that the dissociation constant (K_D), inhibitory constant (K_i) and IC_{50} are 1.79×10^{-8} M, 250 and 18.31 pM respectively suggesting vWF binds to NOS with higher affinity having greater efficacy for the activator (insulin) inhibition.

Conclusion: These results demonstrated that vWF acts an antagonist for NOS, inhibits insulin induced NO production and exerts IR. These data may have important implications in understanding the pathophysiology of hypoxia induced cardiopulmonary and other metabolic diseases.

PA 4.09-5

Vimentin is a ligand for von Willebrand factor: the role of this interaction in platelet adhesion

Cruz MA, Vijayan V, Brown R and Correa J

Baylor College of Medicine, Houston, TX, USA

Background: Platelet adhesion to ruptured atherosclerotic plaque or exposed subendothelial matrix is critical to both pathological thrombosis and normal hemostasis, respectively. In this context, the participation of Von Willebrand factor (VWF) under high hydrodynamic force is well documented. The binding of the GPIba from the glycoprotein (GP)Ib/IX/V complex to the A1 domain of VWF is considered as a key step to recruit the rapidly flowing platelets. This interaction enables the platelets to 'roll' over the VWF surface and allows them to firmly adhere to the exposed plaque or extracellular matrix through other platelet receptors. While studying the platelet adhesive/activation properties of two recombinant VWF fragments, the isolated A1 domain and a fragment encompassing the A1A2A3 domains that lacks the binding site for integrin aIIbb3, we obtained intriguing results. First, platelets rolled more slowly on a surface coated with A1A2A3 protein than on an A1-coated surface under arterial shear stress. Second, in sharp contrast to the A1 protein, the A1A2A3 protein activated platelets in a manner similar to the activation induced by full-length VWF under high shear stress.

Aims: This result suggested that the triple A domain protein provides an additional adhesive contact point on platelets. We proposed the existence of another receptor on platelets that binds to the A1A2A3 domains. We considered vimentin since it was identified as a binding protein to the isolated A2 domain of VWF in another ongoing project from our laboratory and vimentin can be detected on the surface of platelets.

Methods: We examined the effect of anti-vimentin antibodies on blocking the interaction of platelets with VWF using parallel flow chamber and flow cytometry. Purified plasma VWF and recombinant proteins were utilized to perform protein-protein binding analyses. Finally, transgenic mice models were used to investigate vimentin as a potential receptor for VWF.

Results: Purified plasma VWF and wild type (WT) A1A2A3 protein bound to vimentin in a ristocetin-dependent manner, whereas an A1A2A3 mutant expressing increased GPIba-binding activity bound without the need of ristocetin. Vimentin was detected on the surface of platelets by flow cytometry. The binding of the A1A2A3 mutant to vimentin on platelets, and the binding of isolated A2 domain to purified vimentin were inhibited with anti-vimentin antibody, V9. Platelet adhesion to WT A1A2A3 protein, and collagen fibrils were inhibited (40–75%) by anti-vimentin antibody under high shear stress. To test whether the interaction of GPIba with A1 domain directly regulates the exposure of vimentin on platelets, we used V9 as a probe of vimentin expression. We perfused blood over a surface coated with a mixture of A1 domain and V9 or A1 and mouse IgG. Platelets rolled and did not attach stably on the A1/IgG surface, but many of them firmly bound to the A1/V9 surface. Lastly, vimentin-deficient mice had an increased tail bleeding times, and the isolated platelets from these mice exhibited reduced adhesion to VWF at high shear stress compared to wild type mice.

Conclusion: We have demonstrated a previously unknown function of vimentin in platelet adhesion to VWF under high shear stress.

PA 4.09-6

Conformation and N-linked glycan determinants within the A1A2A3 domains play critical roles in modulating human von Willebrand factor interaction with macrophages

Chan Kwo Chion A[1], Bergsson G[1], O'Sullivan J[1], Rawley O[1], Keyes S[1], Jenkins V[1], McKinnon T[2], Laffan MA[2], Brophy TM[1] and O'Donnell JS[1]

[1]Trinity College, Dublin, Ireland; [2]Imperial College London, London, UK

Background: Recent studies have shown that hepatic Kupffer cells play a key role in modulating *in vivo* clearance of von Willebrand Factor (VWF). However the molecular mechanisms through which macrophages interact with VWF remain poorly understood.

Aims: In this study, we have utilised a novel Hi-Content-Analysis methodology to characterize the role of VWF domains and glycans in regulating macrophage binding.

Methods: Plasma-derived human VWF was purified using cryoprecipitation and 2BCl gel filtration. Recombinant full length VWF and VWF fragment VWFA1A2A3 were expressed in HEK23T cells, and purified by Nickel-affinity chromatography. VWF point mutations of interest (N1515Q; N1574Q; N1515Q/R1450E and R1450E) were introduced using site-directed mutagenesis. Finally, macrophage-VWF binding was analysed using PMA-differentiated THP-1 cells. VWF binding was quantified using FITC-labelled polyclonal VWF and Hi-Content-Analysis.

Results: In the presence of divalent cations, plasma-derived VWF (pdVWF) and full length recombinant VWF (rVWF) bound to differentiated THP-1 cells in a time- and dose-dependent manner. Binding of pdVWF was markedly attenuated ($P = 0.003$) following pre-treatment with PNGase F, suggesting a critical role for VWF N-linked glycans in modulating macrophage binding. Moreover, pdVWF binding to THP-1 was also significantly inhibited in the presence of either 10 mM mannose or 10 mM galactose respectively. In contrast, pdVWF-macrophage interaction was markedly enhanced in the presence of ristocetin. Similarly, introduction of the VWD Type 2B mutation R1450E also resulted in a striking increase (13-fold; $P < 0.001$) in macrophage-binding. In the presence of ristocetin, VWF R1450E macrophage binding was also increased, but to a lesser degree than the effect observed with wild-type rVWF. Cumulatively these data suggest that VWF confirmation also plays a critical role in regulating macrophage interaction. In view of the major effects of ristocetin and R1450E in regulating the interaction of full length VWF with macrophages, we further investigated the specific contribution of the VWF A1A2A3 domains. Recombinant VWF A1A2A3 also bound macrophages in a dose-dependent manner. Moreover, A1A2A3 binding was significantly enhanced in the presence of ristocetin, and/or following introduction of the R1450E substitution. PNGase-digestion significantly attenuated A1A2A3 binding, suggesting that local N-linked glycans may be specifically important. In keeping with this hypothesis, macrophage-binding was reduced by 50% following introduction of the point mutation N1515Q. In contrast however, VWF A1A2A3 N1574Q binding was unaffected. Loss of the N1515 sugar chain could inhibit macrophage binding by reducing a specific lectin-glycan interaction, or through a secondary local conformational effect. In support of the latter hypothesis, we observed that the inhibitory effect of N1515Q was lost in the double mutant VWF N1515Q/R1450E, which displayed enhanced macrophage-binding in keeping with that of the single mutant VWF R1450E.

Summary/Conclusions: These novel data clearly demonstrate that the conformation and N-linked glycan determinants within the A1A2A3 domains play critical roles in modulating human VWF interaction with macrophages. Further studies will be required in order to further localize VWF binding motifs, and to identify the specific macrophage receptors involved in the physiological clearance of human VWF.

Real-world management, clinical outcome and predictors of thromboembolism during a 1-year follow-up in patients with atrial fibrillation: results from the ATA-AF study

Gussoni G[1], Maggioni AP[2], Vescovo G[3], Fabbri G[2], Baldo C[1], Lucci D[2], Nozzoli C[4], Zoni Berisso M[5], Mathieu G[6] and Di Pasquale G[7]

[1]FADOI Foundation, Milan; [2]ANMCO Research Centre, Firenze; [3]Hospital San Bortolo, Vicenza; [4]Azienda Ospedaliera Careggi, Firenze; [5]Padre Antero Micone Hospital, Genova-Sestri Ponente; [6]Hospital of Pinerolo, Pinerolo; [7]Maggiore Hospital, Bologna, Italy

Background: Prevention of thromboembolism (TE) is a cornerstone in the management of atrial fibrillation (AF). Oral anticoagulants (OAC) offer the best prevention; however, vitamin K antagonists (VKA) are cumbersome to use, their prescription is generally far from evidence-based recommendations, and some grey zones exist even in recent guidelines as for the optimal treatment of AF patients. Finally, real-world data on long-term management of AF are limited and therefore needed, since they could provide interesting information on the present attitudes and related outcomes, and be an useful benchmarking for the future scenario of treatment with new OAC.

Aims: Aim of the present study was to evaluate real-world management, clinical outcome and predictors of TE in patients with AF and followed-up for 1 year.

Methods: Data were collected from May 2010 to July 2011 in the context of the observational ATA-AF study endorsed by the Italian Scientific Societies of Hospital Internists (FADOI) and Cardiologists (ANMCO). The survey prospectively enrolled, in Internal Medicine and Cardiology settings, patients with current or previous diagnosis of AF, who were followed-up for 12 months. The association with TE was evaluated for a number of potential predictors: age ≥ 75, $CHADS_2$ score ≥ 2, modified HASBLED (without 'labile INR') ≥ 3, previous TE, recent major bleeding, paroxysmal AF, valvular AF, cognitive/functional dysfunction. A P value < 0.05 was considered statistically significant.

Results: A total of 1368 patients were evaluated, with median age 76 years. At baseline, 21.4% of patients had diagnosis of paroxysmal AF, and 27.7% valvular disease. $CHADS_2$ score was ≥ 2 in 62.1% of patients, while 23.0% of patients could be considered at high hemorrhagic risk (modified HASBLED ≥ 3). Percentages of use of VKA or other antithrombotic therapy were 65.7% and 27.1% at study enrollment, and 65.4% and 27.2% among patients who completed the one-year follow-up. Discontinuation of VKA occurred in 116 patients, mainly due to physician's decision; 31 patients started OAC treatment during the follow-up. One-year all-cause mortality was 10.3%, and 22.2% of patients had hospitalization within this time period. Thromboembolism or major bleeding occurred in 2.9% and 1.6% of patients, respectively. $CHADS_2$ score ≥ 2 ($P < 0.05$), modified HASBLED ≥ 3 ($P < 0.05$), previous TE ($P < 0.01$) and cognitive/functional dysfunction ($P < 0.01$) appeared significantly related to the occurrence of thromboembolic events.

Summary/Conclusions: Long-term prevention of TE is challenging in patients with AF, since they frequently have concomitant high thrombotic and hemorrhagic risk. In our survey, the percentage of use of VKA was high if compared to previous studies; in the next years we will evaluate if new OAC might overcome restrictions and disadvantages of VKA and extend OAC therapy. According to our study, occurrence of TE is more frequent than major hemorrhages, and this could suggest the opportunity of further efforts to optimize prevention of TE. This attitude could be particularly stringent in patients who appeared at increased risk of TE in our analysis (those with positive history or present high thrombotic risk, and patients generally receiving suboptimal prevention due to hemorrhagic risk or poor compliance).

PA 4.10-2

Warfarin monitoring with the Fiix-prothrombin time (Fiix-INR) increases time within target range and reduces dose adjustment need compared to standard monitoring using INR

Onundarson PT[1], O Arnar D[1], Bjornsson E[1], Magnusson MK[1], Indridason S[1], Einarsdottir KA[1], Magnusdottir G[1], Vidarsson B[1], Francis CW[2] and Gudmundsdottir BR[1]

[1]Landspitali University Hospital and University of Iceland, Reykjavik, Iceland; [2]University of Rochester Medical Center, Rochester, New York, NY, USA

Background: The quality of vitamin K antagonist (VKA) management has major impact on the efficacy and safety of the anticoagulation, ie the thromboembolic and major bleeding rate. Thus, poor clinical outcome is more frequent among poorly managed patients with a low time within target range (TTR). A low TTR is commonly due to a fluctuating PT-INR. Since PT-INR fluctuation is partly caused by rapid changes in factor VII concentrations that experiments suggest have only minor influence on thrombin generation *in vivo*, we invented a new prothrombin time, Fiix-PT, that is sensitive to the more stable factors II and X only.

Aims: We hypothesized that dosing VKA based on the Fiix-PT (Fiix-INR) could lead to a more stable anticoagulant effect and subsequently better anticoagulation outcome than dosing based on PT-INR monitoring.

Methods: In the single center clinical Fiix study, patients on warfarin with INR target range 2–3 are randomized into two arms, ie. dosing based on Fiix-INR or based on PT-INR (standard control) aiming for at least 1200 patient year observation time. The study is patient, dose-manager and assessor blinded. Fiix-INR and PT-INR values are reported by the laboratory in a blinded manner as 'INR'. Software assisted dosing is managed by specially trained staff using the DAWN® anticoagulation software. Clinical events and surrogate parameters are continously monitored. Surrogate parameter results based on the first nine study months are presented here as per protocol analysis, ie periods of initiation and temporary discontinuation of warfarin are excluded. Numerical and categorical data were analyzed with the Mann-Whitney and Chi square tests respectively.

Results: After 9 months the observation time was on average 5.5 months for each patient, i.e. 224 patient years in 484 patients in the Fiix group and 222 years in 488 patients in the PT group. There were 6.3% fewer monitoring tests in the Fiix group. The median INR was 2.5 in the Fiix group vs. 2.4 ($P = 0.0003$) in controls. Extreme high and low INR′s were less common in the Fiix group. The proportion of tests within target range was 5.2% higher in the Fiix INR group, 71.7% vs. 68.1% ($P < 0.001$). The center TTR was also higher (82.7% vs. 79.4% respectively, $P < 0.0001$). The median individual TTR was 87.2% vs. 81.7% ($P = 0.0007$). The mean (median) interval between monitoring tests was longer or 23.2(21) in the Fiix group vs. 21.9(20) days in controls, $P < 0.01$. The mean dose adjustment frequency was reduced by 11.2% in the Fiix group, from 44.6% to 39.6% ($P < 0.0001$). When only patients observed for 7–9 months were analyzed the dose adjustment frequency was reduced further (13.4%, $P < 0.0001$).

Conclusions: These first surrogate parameter results of the Fiix study show that within 6 months of randomization, the Fiix-INR has led to increased anticoagulation stability and reduced dose adjustment frequency. The improvement has occurred despite a high TTR in the standard monitoring control group. Although preliminary, the results suggest that monitoring VKA therapy with the Fiix-INR instead of

the PT-INR may hold a potential to increase both safety and efficacy of VKA therapy.

PA 4.10-3

Efficacy and safety of weight-adjusted heparin prophylaxis for the prevention of acute venous thromboembolism among obese patients undergoing bariatric surgery: a systematic review and meta-analysis

Ikesaka T, Le Gal G and Carrier M
The Ottawa Hospital, Ottawa, ON, Canada

Background: Obesity is a growing global problem putting people at risk for VTE. Obese patients are often excluded from clinical trials or are not recruited in sufficient number to assess safety and efficacy of LMWH in this population. The bariatric surgical population is a particularly high risk population for VTE. It is unclear if standard (i.e. non-adjusted) thromboprophylaxis doses of low-molecular weight heparin (LMWH) provide adequate protection for obese patients undergoing bariatric surgery, or if higher doses are required.
Aims: To determine whether a weight based thromboprophylactic dosing regimen is safe and effective in the post-operative period for obese patients undergoing bariatric surgery.
Methods: A systematic literature search was performed using MEDLINE and EMBASE. The primary outcome measures were VTE and major bleeding events. Venous thromboembolism was defined as symptomatic proximal lower limbs (popliteal vein or more proximal) deep vein thrombosis or pulmonary embolism. Weight-adjusted thromboprophylactic LMWH dosing was defined as the use of a higher than standard recommended dose. Major bleeding was defined as per the ISTH definition. Pooled proportions for the different outcomes during hospitalization were calculated.
Results: A total of seven studies (one randomized controlled trial and six cohort studies) containing 2396 patients met the inclusion criteria and were included in the analysis. Post bariatric surgery patients receiving weight-adjusted prophylactic doses of LMWH, had an in hospital rate of VTE of 0.54% (95% CI: 0.2–1.0%) compared to 2.0% (95% CI: 0.1–6.4%) for those that did not weight adjust doses. Rates of major bleeding were for both groups: 1.6% (95% CI: 0.6–3.0%) for patients receiving weight-adjusted dosing compared to 2.3% (95% CI: 1.1–3.9%) for those receiving standard doses of LMWH.
Summary/Conclusions: Adjusting the dose of LMWH for thromboprophylaxis post-bariatric surgery seems to be associated with a lower rate of VTE compared to a strategy of not adjusting the dose. This practice does not lead to an increase in adverse major bleeding events. Future studies assessing the efficacy and safety of weight adjusted dosing of bariatric surgical patients are needed to confirm these findings.

PA 4.10-4

A 7-year outcome study on the effect of warfarin and co-morbidities in critically injured patients. Has the outcome improved?

Omar MH, Bouarmra O, Jenks T, Edwards A, Lecky FE and Evans PA
ABMU, University Hospital, Haemostasis Biomedical Research Morriston Swansea UK, Swansea, UK

Aim: To establish whether warfarinised trauma patient with injury score of ISS 9 and above and in comparison to controlled group of similar characteristics who non-warfarinsed patients in the UK.
Patients and Methods: We conducted first multi-centred retrospective study in UK, Europe and Australia by analysing all patients who were entered onto a large national database, (Trauma Audit and Research Network) TARN, for data collected on both groups simultaneously between 2005 and 2012.
Results: A total of 101,794 adult trauma patients dating from November 2005 to July 2012 were retrospectively analysed. Out of these, 445 patients were taking warfarin at the time of trauma. These cohorts were compared with a controlled group. Significant differences were found in age, ISS, GCS, (median age 74.8 vs. 52.6), ISS (median 16 vs. 9), and had significantly increased mortality rate at 30 days post injury (76/445 = 17.1% vs. 6816/101,794 = 6.7%; $P < 0.0024$; odds ratio (OR) 2.45; 95% confidence interval (CI) 71.7–84.2) (Table 1).
Further analysis of sub-grouping to modulated variability of age, ISS and GCS also further revealed that the warfarinised trauma patients had a statistically significant higher mortality rate than age and ISS matched control group (54/155 = 34.8% vs. 2782/11,561 = 24.1%; $P \geq 0.001$; OR 1.72; 95% CI [1.3–2.3] Table 2).
Table 1. Baseline clinical characteristics of study patients.
PMC, per existing medical condition.
Table 2. Baseline and clinical characteristics of patients study.
Conclusion: This largest UK study showed the trend of mortality rate has not changed since 1994[1]. The outcome has not altered despite trauma guidelines and trauma centred[2]. Within the trauma study group warfarinised patients had the highest mortality rate compared with controlled group. There are no specific guidelines in the management of these subgroup trauma patients, which is further complicated with co-morbidities.

The effect of rivaroxaban and dabigatran on the surface architecture of clots formed from plasma enriched with different levels of autologous platelets

Chan HW[1], Gantioqui J[1], Stevic I[1], Kim PY[2], Lau K[1] and Chan AK[1]
[1]McMaster University; [2]Thrombosis and Atherosclerosis Research Institute, Hamilton, ON, Canada

Background: Current guidelines for treating patients with thromboembolism and concomitant thrombocytopenia are based on anecdotal data. We have developed an *in vitro* assay using thromboelastography (TEG) to describe the effects of several anticoagulants on plasma clot formation in the presence of autologous platelets at levels below 150×10^9/L. We observed that clotting of plasma containing predefined platelet counts is less compromised by the presence of factor-specific oral anticoagulants than with heparinoids. As fibrin and platelets are two key determinants for those TEG parameters showing pronounced differences, we further characterized the fibrin clot structure to investigate how the structures of theses clots were altered by the presence of (a) platelets at varying concentrations, and (b) different anticoagulants.
Aim: To determine the effects of various anticoagulants on the surface architecture of clots formed from plasmas enriched with different levels of autologous platelets.
Methods: Fresh human platelet-rich plasma and platelet-poor plasma (PPP) were obtained from each donor and subsequently mixed to produce plasma samples with varying platelet counts. Plasma containing platelets < 10 (PPP), 30, or 150×10^9/L, was mixed with 30 μg/mL corn trypsin inhibitor, and one of the following anticoagulants at therapeutic concentration: 0.3 IU/mL UFH, 1.0 IU/mL dalteparin, 1.0 IU/mL fondaparinux, 150 ng/mL rivaroxaban and 180 ng/mL dabigatran. Clotting was initiated by addition of 10 mM $CaCl_2$ and monitored with TEG for a maximum of 180 min. After completion of clot formation, the clots were fixed with 2% v/v glutaraldehyde in

0.1 M phosphate buffer (pH = 7.4), washed, and then stained with 1% osmium tetroxide in 0.1 M sodium cacodylate buffer. The clots were dehydrated with gradient ethanol series, dried, mounted onto stubs, and gold sputter-coated for scanning electronic microscopy examination at 20,000× magnification. The diameter and instances of fibers and the porosity of the fibrin clots were quantitated. The fibrin fibers composed of single strand were defined as minor fibers whereas those with ≥ 2 visible strands in a bundle formation were defined as major fibers.

Results: Without anticoagulant, clots formed in low-platelet-count plasma had less minor fibers and increased porosity. For clots that contained the same platelet count, dabigatran or rivaroxaban reduced the number of minor fibers compared with control clots without anticoagulants ($P < 0.05$). Although there was no significant change in the number of major fibers, these fibers were thicker in the presence of dabigatran or rivaroxaban ($P < 0.05$). Clots containing dabigatran were more porous than controls and those with rivaroxaban ($P < 0.05$). None of the samples containing heparinoids clotted, thus their structures could not be studied.

Summary/Conclusion: Our study demonstrates the differences in the plasma clot structure affected by the presence of various anticoagulants and/or platelets levels. Heparinoids have more prominent anticoagulant effects on platelet-enriched plasma as compared with rivaroxaban and dabigatran. As the platelet counts decrease, plasma clots contain less minor fibers, which consequently lead to thicker major fibers and increase porosity. These changes are exacerbated by the presence of new factor-specific oral anticoagulants, in particular for dabigatran.

PA 4.10-6

Determinants for anticoagulant use in patients with first-time venous thromboembolism: VTE Epidemiology Group (VEG) Study

Martinez C[1], Cohen A[2] and Rietbrock S[3]

[1]Consultant Epidemiologist, Frankfurt, Germany; [2]King's College Hospital, London, UK; [3]Consultant Statistician/Data Analyst, Frankfurt, Germany

Background: The benefits and limitations of vitamin K antagonists and low molecular weight heparins in the management of venous thromboembolism (VTE) are well documented. Initiation of anticoagulant therapy is necessary to avoid recurrent events and other potentially fatal complications. Therefore, the factors resulting in the decision to initiate anticoagulation therapy need to be studied.

Aims: To assess determinants of the initiation of anticoagulation use in a cohort of patients without active cancer and with first-time VTE.

Methods: Patient data were retrieved from the subset of general practices in England contributing to the Clinical Practice Research Database (CPRD) linked to data from the Hospital Episodes Statistics (HES) and the Office for National Statistics (ONS). From January 2001 to October 2011, all VTE cases in the CPRD were verified with an algorithm based on a review of clinical notes, hospital diagnoses, cause of death and anticoagulation therapy. Patients were excluded if they survived < 7 days, had a history of active cancer or had previous use of anticoagulants. We conducted a nested case–control study defining all patients who received anticoagulant treatment in the following 90 days as cases, and those without anticoagulant treatment as controls. Patients who developed recurrent VTE during the observational period were censored. Adjusted odds ratios (OR) with 95% confidence intervals (CI) were derived from multivariate logistic regression models to estimate the association between the determinant of interest and anticoagulant use.

Results: The cohort comprised 20,995 anticoagulant-naïve, non-cancer VTE patients. The mean age was 62.7 years; 45.5% were male. There were 17,503 cases (83.4% of the VTE cohort), of whom 6196 (35.4%) had provoked VTE and 11,307 (64.6%) had unprovoked VTE. There were 3492 controls (16.6% of the VTE cohort).

Type of VTE was the strongest predictor for anticoagulant use: OR = 2.06 (95% CI 1.89–2.25) for pulmonary embolism (PE) and OR = 2.93 (95% CI 2.37–3.63) for PE with deep vein thrombosis (DVT) compared with DVT alone. Male patients and those aged 60–79 years at the time of first VTE were most likely to receive anticoagulants. Other determinants for anticoagulant use were unprovoked VTE (OR = 1.53; 95% CI 1.41–1.66), body mass index ≥ 30 kg/m^2 (OR = 1.12; 95% CI 1.02–1.24), rheumatologic conditions (OR = 1.71; 95% CI 1.36–2.14) and history of asthma (OR = 1.63; 95% CI 1.16–2.29). The following factors were determinants of non-initiation of anticoagulant treatment: age < 50 and > 80 years, current and ex-smokers, lowest socioeconomic status (OR = 0.80; 95% CI 0.68–0.94), diabetes (OR = 0.79; 95% CI 0.69–0.91), history of varicose veins (OR = 0.54; 95% CI 0.43–0.67), peripheral vascular disease (OR = 0.79; 95% CI 0.66–0.93) and major bleeding in the previous year (OR = 0.52; 95% CI 0.35–0.77). Previous antiplatelet therapy was not significantly associated with anticoagulation initiation.

Summary/Conclusions: Real-life data from the UK setting show that at least 83.4% of patients with a first VTE receive anticoagulation treatment. Further studies confirming our findings, and strategies to increase anticoagulation initiation where it may be beneficial should be considered.

PA4.11 – Blood Coagulation Tests – XIV

PA 4.11-1

Increase of INR above 2–2.5 and within therapeutic range does not change the thrombin generation capacity of patients on warfarin

Adamidou D[1], Riddell A[2], Aghishi S[2], Mohadam L[2], Priest P[2] and Chowdary P[2]

[1]Ippokratio Hospital, Thessaloniki, Greece; [2]Katharine Dormandy Haemophilia Centre and Thrombosis Unit, Royal Free Hospital, London, UK

Background: In clinical practice conventional monitoring of vitamin K antagonists with INR does not always predict the bleeding or thrombotic risk. Thrombin generation test (TGT) in plasma rich (PRP) or poor (PPP) in platelets is a promising tool for assessing haemostasis.

Aim: We investigated all thrombin generation parameters in patients on warfarin and their relation to INR.

Methods: Fifty six patients (27 male/29 female) with a median age of 66 (18–89) years were enrolled in the study. They were anticoagulated with warfarin for a median period of 3 (0.5–16) years with an INR of 2.5(1.5–4.0).Twenty nine received warfarin as primary prophylaxis (22 atrial fibrillation-7 valve replacement) and 27 for secondary prevention (thrombotic events). All patients were in steady state at the time of sampling and on no other medication affecting haemostasis. Thrombin generation was measured in CAT (Calibrated Automated Thrombinoscope).Citrated PRP with CTI was triggered with 0.5 pM TF whereas PPP analysis was run in non-CTI samples triggered with phospholipids and TF (5 pM). We assessed all time (lagtime and ttpeak) and amount parameters (ETP, Peak) from the TG curve. Plasma levels of clotting factors (F) FII, FVII, FX, FIX were measured. Patients were analysed in five groups based on INR (1.5–1.9/2–2.4/2.5–2.9/3–3.4/3.5–4).

Results: We found strong positive correlation between INR and time parameters (r 0.9) and negative correlation between INR and amount parameters (r 0.85) and factors levels (r 0.8) in both PRP and PPP TGT ($P < 0.001$).However when we analyse patients by INR group we find significant differences in all TG parameters only between group 1 and 2. Patients in group 2 and 3 differed significantly only when PPP was used. Interestingly despite the strong negative correlation between INR and all factors measured, FIX showed the modest decrease keeping almost haemostatic levels (37%) even in the group with the highest INR.

Conclusions: Based on our results, TGT identifies as critical point an INR value of 2(PRP) or 2.5(PPP).It also highlights that further increase within the usual therapeutic range (2.5–4.0) does not offer significant reduction in thrombin generation which might be due to the relatively high levels of factor FIX. Our findings in clinical terms could raise dual interpretation. First that patients are deeper anticoagulated only when they reach an INR > 2(PRP) or 2.5(PPP) and secondly that further INR increase within the therapeutic range (2.5–4) does not necessarily add significantly either in anticoagulation or in bleeding risk. Prospective trials with clinical endpoints concerning antithrombotic efficacy and bleeding risk are needed before implementing TGT information into clinical practice.

PA 4.11-2

The SAW-CT assay: a point-of-care clotting assay based on surface acoustic waves (SAWs) to monitor anticoagulant pharmacotherapy

Meyer dos Santos S

University Hospital Frankfurt, Frankfurt, Germany

Aim: A microfluidic and scaleable μ-fluidic coagulation assay that can be used bed-side.

Methods: We describe a new microfluidic coagulation assay in that SAWs rapidly mix and recaclify citrated blood. Coagulation kinetics were quantified by automatic image processing methods and compared with standard methods: used in clinical routine laboratories.

Results: Human whole blood (citrated) was spiked with a range anticoagulants in clinical use, such as the direct thrombin inhibitor argatroban (0–4000 ng/mL), unfractionated heparin (0–1.0 IU/mL), the platelet integrin inhibitor abciximab (0 vs. 4 μg/mL) and the new anticoagulants dabigatran (0–1000 ng/mL) and rivaroxaban (0–500 ng/mL). The SAW-CT was prolonged in dose-linear fashion and this was highly correlated with custom methods e.g. aPTT, PT or Ecarin Time. These results prove the suitability of our SAW-CT method to monitor anticoagulant therapy of clinically relevant doses of currently used anticoagulants. A series of clinical samples of patients under dabigatran also showed excellent correlation with their aPTT. Pretreatment *in vivo* with aspirin did not affect alter SAW-CT in 125 ng/mL dabigatran treated blood (351 ± 13 s before vs. 373 ± 49 s after aspirin), in 250 ng/mL rivaroxaban treated blood (521 ± 58 s before vs. 528 ± 28 s after aspirin) and untreated blood (204 ± 25 s before vs. 240 ± 25 s after aspirin). Also, treatment with clopidogrel alone or with aspirin showed no influence on SAW-CT.

Conclusion: Our method can be downscaled to a fully automatic, small hand held device and did not require trained personnel to operate. This might be an advantage in situations where the coagulation status needs a quick answer, e.g. in emergency settings and unconscious patients.

PA 4.11-3

Protein C and factor VII concentrations can predict outcomes of surgical intensive care unit patients

Tang N and Pan Y

Tongji hospital, Huazhong University of Science and Technology, Wuhan, China

Background: In surgical intensive care unit (SICU), most of the patients suffered major surgery or serious trauma, coagulopathy always happened and correlated with outcomes of these patients.

Aims: Characterizing the evolution of coagulation/anticoagulation markers' concentrations in SICU patients, and finding out the valuable markers which may help in predicting mortality risk and identifying potential therapeutic targets.

Methods: One hundred and fifty-two patients entering our hospital's surgical ICU were investigated, the soluble P -selection, factor VII, protein C, antithrombin, fibrinogen and d-dimer levels on the first week of admission were detected daily, and deaths during the first month were registered.

Results: Among all the coagulation tests, protein C and factor VII levels of the first day were lower ($P < 0.05$) in non-survivors ($n = 31$, 20.4%), irrespective of the presence of sepsis, type of admission and type of surgery. In a multivariable analysis with SICU mortality as the dependent variable, the initial protein C concentration < 49.5% and factor VII concentration < 51.0% were independent risk factor for SICU death. In survivors, both of protein C and factor VII levels increased gradually and got higher concentrations in the seventh day than those in the first day ($P < 0.05$); in non-survivors, comparing with the first day, only factor VII levels decreased to a lower concentrations in the seventh day ($P < 0.05$).

Conclusion: In SICU patients, initial protein C and factor VII concentrations were generally low and independently associated with a higher risk of mortality; the factor VII level seemed to be a better initial therapeutic target than protein C for patients.

PA 4.11-4

Changes in hemostasis during the perioperative period of orthopedic surgery

Oberweis B, Nardi MA, Cuff G, Rosenberg A, Pardo L, Guo Y, Marshall M, Steiger D, Stuchin S and Berger JS

New York University Medical Center, New York, NY, USA

Background: Thrombosis and major bleeding are significant, albeit poorly understood, concerns during the perioperative period. Several hemostatic parameters are known to influence the hemostatic system and may contribute to the delicate balance between thrombosis and bleeding.

Aim: We sought to better understand the mechanism of perioperative hemostasis by investigating the changes in coagulation factors during the perioperative period.

Methods: We performed a prospective cohort analysis of 70 subjects undergoing non-emergent orthopedic surgery of the knee ($n = 28$), hip ($n = 35$), or spine ($n = 7$) between August 2011 and November 2011. Plasma was collected preoperatively (T1), 1-h into the operation (T2), 1-h (T3), 24-h (T4) and 48-h postoperatively (T5). Coagulation assays were performed for factor VII, factor VIII, von Willebrand Factor (vWF), and fibrinogen. Mean curve profiles were compared using linear mixed models with time and main effect terms of interest.

Results: Of the 70 subjects, mean age was 64.1 + 9.8 years, 61% were female, and 74% were Caucasian. Coagulation assays changed significantly throughout the perioperative period. Factor VIII (T1 – 148.3% [standard error, 8.0], T2 – 129.1% [8.1], T3 – 130% [8.9], T4 – 140% [8.3], T5 – 175.8% [9.6], $P < 0.0001$), vWF (T1 – 171.3% [8.9], T2 – 139.8% [7.9], T3 – 149% [8.0], T4 – 216.9% [15.4], T5 – 298.9% [14.8], $P < 0.0001$) and fibrinogen (T1 – 488.7 mg/dL [15.7], T2 – 428.4 mg/dL [14.7], T3 – 421.4 mg/dL [15.8], T4 – 560.9 mg/dL [18.5], T5 – 885.1 mg/dL [28.1], $P < 0.0001$) significantly increased, while factor VII (T1 – 131.9% [9.6], T2 – 115.2% [10.3], T3 – 112.1% [9.1], T4 – 65.1% [4.3], T5 – 52.7% [2.2], $P < 0.0001$) significantly decreased during the perioperative period. Overall, factor VIII increased by 18.5%, vWF by 74.5%, and fibrinogen by 81.1%, while factor VII decreased by 60.0%. The change in hemostasis was independent of age, sex and race.

Conclusions: Among subjects undergoing non-emergent orthopedic surgery, factor VIII, vWF and fibrinogen increased, while factor VII decreased during the perioperative period. Understanding differences in hemostatic markers may better explain the pathophysiology of the heightened risk of thrombotic and bleeding events during the perioperative period.

PA 4.11-5

External quality assessment of platelet function by the PFA-100: an update from the RCPAQAP Haematology

Bonar RA[1] and Favaloro EJ[2]

[1]RCPA Quality Assurance Programs, St Leonards, NSW; [2]ICPMR, Westmead Hospital, Westmead, NSW, Australia

Background: The PFA-100 is commonly used in Haemostasis laboratories for screening and monitoring of both von Willebrand disease (VWD) and platelet function. Testing by PFA-100 requires fresh whole blood, so External Quality Assessment (EQA) of PFA-100 test practice requires an innovative approach.
Aims: The RCPAQAP Haematology, an international EQA provider, established a formal PFA-100 program in 2010 with 50 participants currently enrolled. Our objective is to provide test challenges encompassing 'normal' and 'variable case-dysfunctional' samples for participants.
Methods: A novel approach was developed whereby a range of formulated test tubes are distributed to EQA participants to which citrated normal whole blood collected on site is added, thereby creating test material that can be locally evaluated. Several surveys have been conducted over the past few years (total of 12 challenges), with most designed to mimic a mild or severe primary haemostasis defect, or an aspirin-like effect.
Results: Numerical results for PFA-100 closure times (CTs) and interpretive comments provided by participants analysed over the past few years have consistently yielded results within expectations, with good reproducibility evidenced by repeated challenges. For example, coefficients of variation (CVs) generated for two cartridge types (C/ADP and C/Epi) for 2012 challenges [median (range): 14.8 (0.0–29.5) and 10.9 (4.4–17.3)] were similar to those for native whole blood [15.0 (14.2–15.7) and 14.7 (14.3–15.0)]. The median (range) CTs for each challenge, as obtained by participants, was within the regions of expectations according to sample challenge details. For example, PF12-08b yielded maximally prolonged (i.e. > 250s) median (range) CTs for both C/ADP 301s (147–301s) and C/Epi 301s (211–301s) for over 90% of the results returned. Interpretations were, in general, also consistent with expectations and test data provided by laboratories.
Conclusions: An EQA process for the PFA-100 has been successfully introduced that includes very reproducible data, thus providing a valuable mechanism for monitoring and improving laboratory test performance. Future goals include an expansion in challenge material to help assess performance with newer anti-platelet agents.

PA 4.11-6

Thrombin generation assay (TGA) is not able to predict hemostatic efficacy of by-passing agents in patients with hemophilia and inhibitors: results from *in vivo* studies

Mancuso ME, Santagostino E, Chantarangkul V, Clerici M, Fasulo MR and Tripodi A

Fondazione IRCCS Ca' Granda, Ospedale Maggiore Policlinico, Milan, Italy

Background: Therapy with by-passing agents (BPA) in patients with hemophilia and inhibitors still lacks a laboratory test able to assess the hemostatic response that may help clinicians in therapeutic choices. Thrombin generation assay (TGA) has been used at this aim by spiking *in vitro* haemophilic plasma with BPA, however *in vivo* evidence remains limited.
Aim: The aim of this study was to evaluate whether or not TGA is able to predict the response to the administration of either rFVIIa or aPCC at different doses in patients with hemophilia and inhibitors.
Methods: In this study, thrombin generation was assessed *in vivo* in platelet-rich (PRP) and platelet-poor (PPP) plasma with the addition of corn trypsin inhibitor in 15 patients with hemophilia A and high-responding inhibitors (median age: 34 years). Four parameters of the TGA curve were evaluated: lagtime, endogenous thrombin potential (ETP), peak and time-to-peak. TGA was assessed in 11 patients prior, 30 min and 3 (rFVIIa 120 and/or 270 μg/kg) or 6 (aPCC 80 IU/kg) h after drug injection in a non-bleeding state and a minimum wash-out period of 48 h from the last injection. It was also assessed once daily prior and 30 min after BPA administration in nine patients undergoing orthopaedic surgery. Haemostatic treatment to cover surgical procedures and post-operative period was established irrespective of TGA measurements.
Results: In the group of 11 patients who received BPA in a non-bleeding state, the baseline values of the TGA curve were highly variable between patients as well as in the same patient both in PRP and in PPP (ANOVA $P = 0.01$). Overall, ETP increased after drug administration in all cases, with similar results obtained in PRP (median ETP increase: 585 nM × min, IQR: 226–997) and PPP (median increase: 552 nM × min, IQR: 415–1013) and no difference observed with respect to product type and/or doses used. In all patients who underwent surgery, the TGA curve was evaluated over a 7-days post-operative period and a lack of response was observed over time in all patients irrespective of type and/or intensity of treatment with BPA. Five post-operative bleeding complications were observed (four major and one minor), however the TGA curve was not able to discriminate between patients who bled and those who did not bleed. For patients who underwent TGA measurement both in a non-bleeding state and during surgery, there was no correlation between the values obtained in the two different settings.
Conclusions: Our data show that *in vivo* TGA values are highly variable between different subjects as well as in the same subject; TGA is not able to discriminate the type and the dose of drug used and during post-operative period a 'lack of response' was observed irrespective of the therapeutic regimen adopted.

Isolated decrease of factor v in children treated by 6-mercaptopurine for acute lymphoblastic leukemia

Filhon B[1], Dumesnil C[1], Van Dreden P[2], Compagnon P[1], Adam M[2], Schneider P[1], Vasse M[3] and Vannier JP[1]

[1]Rouen University Hospital, Rouen; [2]Diagnostica Stago, Gennevilliers; [3]EA4531, Châtenay-Malabry, France

Background: Maintenance therapy for acute lymphoblastic leukemia (ALL) aims to eradicate leukemic cells persisting after remission and after intensive chemotherapy. It is based on oral daily 6-mercaptopurine (6-MP) and oral weekly methotrexate (MTX). Side effects of 6-MP (hepatotoxicity, myelotoxicity) are correlated with concentrations of its various metabolites, and depend on genetic polymorphisms of enzymes involved in its metabolism.
Aims: Among 62 children treated for ALL in the Pediatric Hematology and Oncology Department of the University Hospital of Rouen, between 1 January 2007 and 31 December 2011, four patients developed an unexplained decrease of Prothrombin Time (PT) during maintenance therapy despite the absence of any hepatic injury.
Methods: Factor V activity (FV:Act) was quantified by a one-stage clotting assay, FV antigen (FV:Ag) was measured by enzyme-linked immunosorbent assay (ELISA)
Results: The decrease in prothrombin time seen in the four patients was observed after a mean time of 6 months (range: 1–17 months) of maintenance therapy. Of all the prothrombin complex factors, FV:Act was the lowest (mean: 30%, range: 20–54), whereas vitamin K dependent factors were in the normal range. FV:Act decrease was unrelated to hepatic cytolysis. Disseminated intravascular coagulation and acquired inhibitors to FV were ruled out, as well as toxicity to MTX. High concentrations of methylated metabolites of 6-MP (6-MMPN, mean 17,620 pmol/8.10^8 erythrocytes, range: 10,456–27,184 pmol/

8.10^8 erythrocytes) were observed at the same time (levels of 6-MMPN superior to 5000 pmol/8.10^8 erythrocytes are considered hepatotoxic). Drug imputability (Naranjo probability scale) in FV decrease shows a definite reaction to 6-MP in three cases and a probable reaction in one case. In two patients, FV:Ag was in the same range as the FV:Act. Patients were asymptomatic. The deficiency was reversible upon discontinuation or dose reduction of 6-MP.

Summary/Conclusion: Seven cases of a FV decrease have previously been described in the literature during 6-MP or azathioprine treatment for ALL or inflammatory bowel disease. These case reports have not described either a correlation with high levels of 6-MMPN or an association with FV levels (activity and antigen). The mechanism of action of 6-MP toxicity on FV levels remains unknown. The correlation between FV:Ag and FV:Act suggest either a direct effect on FV transcription or a lack of post-translational modifications of FV (phosphorylation, sulfatation or glycosylation) induced by a metabolite of 6-MP, which could prevent FV production or secretion. As patients were asymptomatic, the interest to maintain or reduce 6-MP treatment remains to be defined in such circumstances.

PA 4.12-2
Cleavage at Arg1018 is not required for factor V activation

Na M[1], Wiencek JR[1], Hirbawi J[2] and Kalafatis M[1]
[1]Cleveland State University; [2]Cleveland Clinic, Cleveland, OH, USA

Background: The coagulation cascade is initiated following vascular injury which results in the exposure of endothelial tissue factor to the blood flow and that in turn results in robust thrombin generation. The proteolytic conversion of prothrombin (Pro) to thrombin is catalyzed by the prothrombinase complex. This enzymatic complex is composed of the cofactor factor Va (fVa), the enzyme factor Xa (fXa) associated on a procoagulant membrane surface in the presence of divalent metal ions. Factor V (fV) circulates as a single chain inactive precursor consisting of three domains A1-A2-B-A3-C1-C2. The molecule must be activated by thrombin following three sequential cleavages at Arg^{709}, Arg^{1018}, and Arg^{1545} to generate the active cofactor (fVa) composed of heavy and light chain. It was previously reported that cleavage at Arg^{1545} by thrombin requires prior cleavage at Arg^{1018}.

Aim: To determine the role of cleavage at Arg^{1018} during activation of fV.

Methods: We used site directed mutagenesis to create several recombinant fV molecules with the activation sites mutated to Glutamine (R to Q). We have also used a recombinant mutant factor V molecule with the region 1000–1008 from the B region deleted ($fV^{\Delta B9}$). We have created recombinant fV molecules as follows: fV^{WT} (wild type), fV^{QQR} (only cleavage at Arg^{1545} is available), fV^{RQQ} (only cleavage at Arg^{709} available), fV^{QRQ}, (only cleavage at Arg1018 available), fV^{RQR} (cleavages at Arg^{709} and Arg^{1545} available), fV^{QQQ} (no cleavage available), $fV^{\Delta B9/RQR}$ and $fV^{\Delta B9/QRQ}$. The recombinant molecules were expressed in COS-7 cells, purified to homogeneity and assayed for clotting activity as well as in prothrombinase assays using purified reagents. Western blotting followed by staining with specific monoclonal antibodies to the heavy and light chain of the cofactor was used to evaluate the integrity of the recombinant fV/fVa molecules.

Results: Two-stage clotting assays revealed that the clotting activities of fVa^{QQR}, fVa^{RQQ}, and fVa^{QRQ} were reduced while fV^{QQQ} was devoid of clotting activity. In addition, fVa^{RQR} and $fVa^{\Delta B9/RQR}$ have similar clotting activities as fVa^{WT}. In contrast, fVa^{QRQ}, and $fVa^{\Delta B9/QRQ}$ are impaired in their clotting activities and have clotting activities similar to the activity expressed by fV^{QQQ}. Kinetic analyses demonstrated that fVa^{RQR} and $fVa^{\Delta B9/RQR}$ have similar affinities for fXa, while fVa^{QRQ}, and $fVa^{\Delta B9/QRQ}$ were impaired in their interaction with fXa. The k_{cat} values for prothrombinase assembled with fVa^{RQR} and $fVa^{\Delta B9/RQR}$ were similar to the k_{cat} obtained with prothrombinase assembled with fVa^{WT}, while prothrombinase assembled with fVa^{QRQ} and $fVa^{\Delta B9/QRQ}$ had 2- and 7-fold reduced catalytic efficiency respectively, when compared to the k_{cat} values obtained with prothrombinase assembled with fVa^{WT}. Finally, the k_{cat} value for prothrombinase assembled with fVa^{QQR} was approximately 50% lower than the k_{cat} obtained with prothrombinase assembled with fVa^{WT}.

Conclusion: Our data demonstrates that cleavage at Arg^{1018} is neither essential nor required for activation of factor V. These data further promote our understanding of the mechanisms regulating blood coagulation and the assembly of prothrombinase.

PA 4.12-3
Galectin-8 does not function as a factor V receptor on the surface of CMK cells and *ex vivo*-derived megakaryocytes

Gertz JM, Pineault KM and Bouchard BA
University of Vermont, Burlington, VT, USA

Background: Plasma-derived factor V is endocytosed by megakaryocytes and is subsequently modified to form the unique platelet-derived cofactor molecule. Factor V endocytosis is mediated by a two receptor system including an uncharacterized, specific factor V receptor and low density lipoprotein receptor related protein-1 (LRP-1), a ubiquitous endocytic receptor. Studies are currently underway to identify the unknown factor V receptor. A recent study by Zappelli and colleagues suggested that galectin-8, an intracellular galactoside-binding protein, is expressed on the cell surface of DAMI cells, and may function as the unknown, specific factor V receptor [J Biol Chem. 2012; 287(11): 8327–35].

Aims: In the current study, a role for galectin-8 in factor V endocytosis was further characterized using the megakaryocyte-like cell line, CMK, a well-characterized model of factor V endocytosis, as well as *ex vivo*- derived megakaryocytes.

Methods: CD34+ cells were isolated from umbilical cord blood and induced to differentiate *ex vivo* into megakaryocytes for 10 days. Galectin-8 cell surface expression was determined by flow cytometry using a specific, inhibitory monoclonal antibody directed against the N-terminus of galectin-8. The role of galectin-8 in factor V endocytosis was also assessed using inhibitors of galectin-8 ligand binding.

Results: *Ex vivo*-derived megakaryocytes were identified by their forward and side scatter, as well as expression of the megakaryocyte/platelet-specific marker CD41. Flow cytometric analyses of these cells under non-permeabilizing and permeabilizing conditions demonstrated intracellular but not extracellular expression of galectin-8. This observation is consistent with data from Rowley et al. showing galectin-8 mRNA in human platelets [Blood. 2011; 118(14):e101–11] as well as its known intracellular roles in cellular differentiation, growth regulation, and apoptosis. Cell surface and intracellular galectin-8 expression were also assessed in CMK cells. Under conditions where endocytosis of fluorescently-labeled factor V (30 nM) was observed, galectin-8 expression was only detected following cell permeabilization. Endocytosis assays were performed in the presence of lactose, a β-galactoside known to block carbohydrate-dependent binding of galectins to their ligands, as well as an inhibitory antigalectin-8 antibody to assess the role of galectin-8 in factor V binding and endocytosis. Preincubation of the cells with lactose and mannose had no effect on endocytosis of fluorescently-labeled factor V or 125I-labeled factor V (30 nM) by *ex vivo*-derived megakaryocytes or CMK cells. Mannose was used as a negative control as its structure is similar to lactose, but it does not interfere with galectin ligand binding. Consistent with this observation, the presence of the inhibitory anti-galectin-8 antibody had no affect on factor V endocytosis by either of these cell types.

Conclusions: These combined observations suggest that, while galectin-8 may be involved in factor V endocytosis in DAMI cells, its role in factor V endocytosis by other megakaryocyte model systems including megakaryocytes derived *ex vivo* from human cord blood, remains unclear.

PA 4.12-4

Molecular characterization of FV deficiency in a large cohort of Italian patients

Paraboschi EM[1], Guella I[1], Peyvandi F[2], Duga S[1] and Asselta R[1]
[1]*University of Milan;* [2]*Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, University of Milan, Milan, Italy*

Background: Factor V (FV) deficiency is a rare coagulation disorder characterized by low or unmeasurable plasma levels of functional and immunoreactive FV and associated with a hemorrhagic phenotype of variable severity. It is transmitted as an autosomal recessive trait (OMIM +227,400) with a prevalence of about one in 1 million and, among rare inherited coagulopathies, is the least characterized from the molecular point of view.
Aims: To investigate the molecular basis of the disease in 24 Italian FV-deficient patients, nine of whom affected by a severe form and 15 with mild deficiency.
Methods: Mutational screening was performed by direct sequencing of PCR products covering all FV gene (*F5*) exons and a region of *F5* promoter. Missense mutations were investigated by *in-vitro* expression of mutant FV in COS-1 cells, followed by SDS-PAGE of immunoprecipitated proteins, as well as by enzyme immuno assays on cell lysates and conditioned media.
Results: DNA sequencing disclosed 22 mutations, ten of which (three nonsense, one splicing, five missense, and one frameshift) were hitherto unknown. Moreover, five individuals were found to carry the HR2 haplotype, a *F5* allele responsible for a mild form of FV deficiency. Whilst the identified nonsense and frameshift mutations (W1797X, S1849X, L1908X, V381QfsX1) introduce premature stop codons, thus likely resulting in unstable transcripts and eventually in low protein synthesis, the pathogenic role of missense and splicing mutations was experimentally verified. All analyzed missense mutations (N409D, D1669G, G1867R, C2033Y, C2038Y) were shown to impair FV secretion, leading to a concomitant reduction of functional and immunologic FV levels. The role of the splicing mutation (c.5879-11_-12delinsAA) is currently being investigated by producing the mutant transcript in HeLa cells. Bioinformatics analyses suggest that the mutation, interrupting the polypyrimidine tract, might cause the skipping of exon 20. Interestingly, four mutations (R1133X, Y1702C, c.248+1G>A, and G1902D), already described in the literature, were each identified in two unrelated patients of our cohort, suggesting that these variants may be recurrent in the Italian population.
Conclusions: This work reports the identification and the functional characterization of 10 novel genetic defects responsible for FV deficiency in the Italian population.

PA 4.12-5

Factor V is endocytosed and trafficked to proplatelet extensions by megakaryocytes derived *ex vivo* from human umbilical cord blood

Gertz JM, McLean K and Bouchard BA
University of Vermont, Burlington, VT, USA

Background: Platelet- and plasma-derived factor Va are absolutely essential for thrombin generation catalyzed by the prothrombinase complex. The platelet-derived form represents only approximately 20–25% of the total factor V pool; however, several observations suggest that it is physically and functionally distinct and plays a more relevant role in clot formation. Thus, any alterations in this pool may have a profound effect on the maintenance of normal hemostasis.
Aim: The mechanism by which platelets acquire, modify, and store factor V is being investigated. In the current study, megakaryocytes differentiated *ex vivo* from umbilical cord blood or bone marrow-derived $CD34^+$ cells were examined as potential models to study the formation of the distinct platelet-derived factor V pool.
Methods: $CD34^+$ cells were isolated from human umbilical cord blood or bone marrow and induced to differentiate into megakaryocytes by culture in the presence of stem cell factor, thrombopoietin, and/or interleukin-3. Endocytosis of AlexaFluor488-labeled factor V (30 nM) was assessed by flow cytometry or confocal microscopy and correlated with expression of megakaryocyte-specific markers. DNA content was assessed by propidium iodide staining followed by flow cytometry.
Results: *Ex vivo*-derived megakaryocytes were identified by their forward and side scatter and expression of megakaryocyte/platelet-specific markers by flow cyytometry. Expression of these markers by bone marrow-derived megakaryocytes increased over time of culture. Of the cells capable of factor V endocytosis, $19.1 \pm 6.3\%$ are positive for CD41 on day 3. This increases over time to $98.2 \pm 4.1\%$ by day 10. Similar observations were made for CD61, von willebrand factor, and P-selectin. Additionally, cells with up to 16N DNA content could be visualized. However, these cells do not appear to produce platelets *ex vivo* suggesting that they may not be suitable to study the entire factor V trafficking pathway. Umbilical cord blood is often used as an alternative source of $CD34^+$ cells for *ex vivo* differentiation into megakaryocytes. In addition, these cells exhibit higher proliferation and are able to generate proplatelets, possibly making them a more suitable model system. Thus, their use for this study was also assessed. Factor V endocytosis by cord-blood derived megakaryocytes was observed on days 5–13 of culture, consistent with what was observed in the bone marrow-derived cells. Expression of CD41 increased from 32.4% on day 5 to $55 \pm 8.1\%$ on day 12 of culture. Additionally, cells that endocytose factor V and are also CD41 positive follow a similar trend, increasing from 25.1% on day 5 to $60.3 \pm 0.35\%$ on day 12. Day 13 cells were incubated with fluorescently-labeled factor V for 8 h just prior to culture on fibrinogen-coated slides to induce proplatelet formation. Following its endocytosis, factor V was observed in the proplatelet extensions by confocal microscopy.
Conclusions: Cord blood-derived megakaryocytes endocytose factor V in a manner similar to bone marrow-derived cells and traffic it to proplatelet extensions. These observations suggest that cord blood-derived megakaryocytes may be a suitable model to study the formation of the distinct platelet-derived factor V pool.

PA 4.12.6

A new regulatory function of activated factor V: inhibition of the activation by tissue factor/factor VII (a) of factor X

Al Dieri R, Bloemen S, Kelchtermans H, Wagenvoord R, De Laat B and Hemker CH
Maastricht University, Maastricht, The Netherlands

Background: We observed that minute amounts of thrombin or the enzyme Russell's viper venom activating factor V (RVV-V), added to plasma strongly diminish the potential of that plasma to generate thrombin after being triggered by tissue factor.
Aim: To find the mechanism behind this phenomenon.
Methods: Calibrated automated thrombin generation (CAT) was measured in platelet poor plasma using different triggers (tissue factor, kaolin, factor IXa or direct activation of factor X) in the absence and presence of factor V(a). The effect of FV(a) on the activation of factor X by tissue factor (TF) and factor VII(a) was determined in a purified system.
Results: Thrombin generation (TG) initiated by tissue factor is strongly and dose-dependently inhibited by addition of activated factor V (FVa) or by addition of a factor V activator (thrombin or RVV-V). The two forms of activated factor V (FVa_1 and FVa_2) diminished thrombin generation similarly while FV_1 and FV_2 showed no effect. No inhibition by FVa is seen when TG is triggered via the intrinsic pathway or by direct activation of factor X. The effect is independent of proteins C and S and tissue factor pathway inhibitor (TFPI). The inhibiting action is also observed in hemophilia A and B samples. In

factor VII -deficient plasma the effect is seen when it is spiked with recombinant factor VII (FVII) and to a much lesser extent when spiked with recombinant FVIIa. In a purified system, FVa also dose-dependently inhibits the activation of FX by TF/FVII(a). The inhibitory effect is neutralized by antibodies against the light chain of FVa but not by antibodies against the heavy chain.

Conclusions: We report a new regulatory function of factor Va where it inhibits the activation of factor X. This observation can be explained by assuming that factor Va, via its light chain, binds to the complex TF/FVII(a) and prevents it from activating factor X. We assume that this mechanism reduces the possibility that thrombin and factor Xa escaping from a wound area into the circulation, together with blood-borne tissue factor, would trigger intravascular coagulation.

Assessment of structural comparability between rFVIIIFc and unmodified B domain-deleted FVIII by complementary biophysical methods

John K[1], Tsutakawa S[2], Bou-Assaf G[3], Chiu P-L[4], Liu ZL[1], Goodman A[1], Arndt J[3], Whitlow M[5], Mezo A[1], Tainer J[6], Stephen B[3], Laura S[3], Elizabeth C[1], Haiyan J[1], Light D[1], Walz T[7] and Robert P[1]

[1]Biogen Idec Hemophilia, Waltham, MA; [2]Lawrence Berkeley National Laboratory, Berkeley, CA; [3]Biogen Idec, Cambridge, MA; [4]Harvard Medical School, Boston, MA; [5]Colabrativ Inc., El Sobrante, CA; [6]The Scripps Research Institute, La Jolla, CA; [7]Department of Cell Biology, Harvard Medical School, Boston, MA, USA

Background: Recombinant Factor VIIIFc (rFVIIIFc) is a long-lasting FVIII molecule developed to reduce dosing frequency and increase protection for patients with severe hemophilia A. rFVIIIFc is a fully recombinant protein consisting of a single molecule of B domain-deleted (BDD) human coagulation factor VIII (FVIII) covalently linked to the dimeric Fc domain of human immunoglobulin G1 (IgG1) with no intervening sequence. The specific activity of rFVIIIFc, on molar basis, and its affinity for von Willebrand factor (VWF) are comparable to those of commercially available BDD rFVIII and full-length rFVIII products, indicating that the Fc moiety does not impair the association of rFVIIIFc with other elements of the Xase complex or with VWF.

Aims: This study was undertaken to assess the structural comparability between the BDD-FVIII and Fc constituents of rFVIIIFc and their respective free counterparts, and to evaluate the relative orientation and conformational dynamics of the FVIII and Fc elements within the rFVIIIFc molecule.

Methods: The following methods were employed to evaluate the structural comparability of rFVIIIFc and rFVIII, as well as the conformational dynamics of rFVIIIFc: (i) hydrogen-deuterium exchange (H/DX) mass spectrometry (MS), (ii) multiplexed surface plasmon resonance (SPR) affinity analysis with a panel of anti-FVIII antibodies, (iii) Small-angle X-ray scattering (SAXS), (iv) X-ray crystallography, and (v) negative stain electron microscopy (EM).

Results: H/DX-MS analysis was performed on rFVIIIFc and its recombinant FVIII and Fc constituents with a sequence coverage of 94% for FVIII (416 peptides) and 87% for Fc (50 peptides). Over a time course of 4 h, no statistically significant differences in deuterium exchange rates were observed for any peptide pairs, indicating a high degree of structural comparability between the BDD-FVIII and Fc constituents of rFVIIIFc and their respective free counterparts. Consistent with these findings, members of a panel of 23 anti-FVIII monoclonal antibodies, which recognize epitopes distributed among the different domains of FVIII, bound to both rFVIII and rFVIIIFc with comparable affinities as determined by SPR array analysis. SAXS analysis combined with molecular dynamics simulation enabled derivation of a minimal ensemble of structures for rFVIIIFc in which the Fc domain is extended away from, and does not interact with, the FVIII component. The X-ray crystallographic structure of rFVIIIFc, determined at low resolution (approximately 5 Å) was comparable to published FVIII atomic coordinates 2R7E and 3CDZ. Electron density for the Fc domain was not observed, indicating that the tethered Fc domain experiences conformational freedom in relation to the FVIII component. Negative stain EM analysis of 5853 particle pairs (60°/0°) showed that 3184 rFVIIIFc particles adopted the same conformation (six out of 10 classes). In the resulting 3D reconstruction at 27 Å resolution, the Fc domain projects maximally away from the FVIII component.

Conclusions: The results from these complementary biophysical approaches are in agreement with respect to the structure of rFVIIIFc. The linkage of Fc to FVIII does not alter the conformation of either component. The rFVIIIFc linkage permits conformational flexibility between the two components, with the appended Fc domain extending away from the FVIII component.

PA 4.13-2

Structure of membrane-bound porcine factor VIII

Stoilova-McPhie S, Dalm D, Grushin K and Miller JL

University of Texas Medical Branch, Galveston, TX, USA

Factor VIII (FVIII) is a multidomain blood plasma glycoprotein, when defective or deficient causes for hemophilia A, a severe hereditary bleeding disorder. Upon initiation of coagulation FVIII is cleaved by Thormbin and the active form FVIIIa, acts as co-factor to the serine protease Factor IXa (FIXa) within the membrane-bound tenase complex. Human FVIII (hFVIII) is a large glycoprotein of approximately 280 kDa Molecular weight, composed of six domains: A1-A2-B-A3-C1-C2. *In vitro*, FVIII exists as a mixture of heterodimers of a variable length heavy chain (HC) of the A1-A2 domains with different length of the B domain, and a constant length light chain (LC) of the A3-C1- C2 domains. The LC holds the FVIII membrane-binding sites. The HC holds the main FIXa interaction sites. The LC and HC are non-covalently linked via divalent metal cations. Recombinant FVIII concentrate is the most effective drug against hemophilia A and commercially available FVIII is expressed as full-length (FVIII-FL) or B-domain deleted (FVIII-BDD). Porcine (p) FVIII-BDD shares 84% amino acid sequence identity with hFVIII-BDD, has 10–14 fold higher expressions and is used as replacement therapy in patients who develop inhibitory antibodies against the human form, as it forms functional complexes with human FIXa.

The focus of this work is to achieve a high resolution structure of membrane-bound pFVIII-BDD close to physiological conditions, by combining cryo-EM and structure analysis. For this purpose we have expressed, purified and organized helically pFVIII-BDD onto single bilayer lipid nanotubes (LNT) containing phsophatidylserine in a 20 mM HEPES buffer, pH 7.4, containing 150 mM NaCl and 5 mM $CaCl_2$. The calculated cryo-EM structure for membrane-bound pFVIII-BDD at subnanometer resolution was further refined by fitting the existing hFVIII-BDD crystal structure within the density map. A pFVIII-BDD homology structure was further generated with the fitted hFVIII-BDD structure as a template.

The presented membrane-bound pFVIII-BDD structure further confirms the previously refined 3D structure for helically organized hFVIII-LC on LNT and that the FVIII membrane-bound organization differs from that of the FVIII organized in 3D crystals in solution. Fitting the FVIII domains from the hFVIII-BDD crystal structures within the density map resolved by cryo-EM shows that the C2 domain is the main FVIII membrane interaction site. The C1 does not interact directly with the membrane interface when the pFVIII-BDD molecules are helically organized onto the LNT surface. A new

interface is formed between the C1 and the A1 and A3 domains, creating a platform for the A2 domain holding the main FIXa interaction site. This organization of the FVIII-LC domains has been previously observed for plasma derived hFVIII in membrane-bound 2D crystals and hFVIII-LC helically organized onto LNT.
Comparing the membrane-bound organization for both human and porcine FVIII-BDD as resolved by cryo-EM will provide a structural basis for comparing the activity of mutations, complementing the existing homology models. Understanding the differences between the organization of porcine and human FVIII-BDD bound to LNT will provide a structural scaffold for mapping the functionally important FVIII interaction sites and improve drug design based on recombinant FVIII.

Dose response relationship and duration of effect of a PEGylated recombinant FVIII conjugate, N8-GP, in a new tail vein transection bleeding model in anaesthetized FVIII k/o mice

Johansen PB, Tranholm M, Kjalke M, Haaning JT and Knudsen T
Novo Nordisk A/S, Måløv, Denmark

Background: Turoctocog alfa is a new serum-free B-domain truncated recombinant FVIII for treatment and prevention of bleeding in patients with haemophilia A. N8-GP is turoctocog alfa with a 40 kDa PEG conjugated to the O-glycan in the 21 amino acid B-domain. The potency of Advate®, turoctocog alfa and N8-GP are similar in the standard mouse tail transection model, while the half-life and duration of effect is longer for N8-GP. We now report on a sensitive tail vein transection bleeding model in anaesthetized FVIII k/o mice, where clinically relevant FVIII doses are effective. The new model was used to investigate the dose response relationship of N8-GP and the duration of effect of N8-GP and turoctocog alfa on bleeding time and blood loss.
Methods: FVIII k/o (exon 16 disrupted) male mice on a mixed background, C57Bl6/129, were dosed with N8-GP, turoctocog alfa, or vehicle in the right lateral tail vein 24 or 48 h before injury. The bleeding challenge comprised a template-guided transection of the left lateral tail vein at a tail diameter of 2.7 mm in isoflurane anaesthetized mice. The tail was immersed in saline (37 °C) allowing visual recording of the bleeding for 60 min, whereafter the blood loss was determined by measuring the haemoglobin concentration. Data are reported as means ± SEM. One-way ANOVA with post test for linear trend or Bonferroni's adjustment for multiple comparisons was applied for analysis of data.
Results: The haemophilic phenotype was verified in all animals as: (i) intact primary haemostasis with a primary bleeding lasting ≤ 3 min after injury and (ii) subsequent re-bleeding episodes depending on the actual treatment. Dose response relationships were demonstrated for total bleeding time and blood loss when tail vein transection was made 24 h after administration of N8-GP. Mice dosed at 20, 10, 5, 2.5, 1.25, or 0 U/kg had total bleeding times of 7.0 ± 1.0, 11.8 ± 2.2, 25.3 ± 4.7, 25.1 ± 4.5, 36.1 ± 3.5, and 46.0 ± 1.4 min, respectively ($P < 0.0001$). The corresponding blood losses were 1372 ± 359, 2286 ± 592, 4659 ± 993, 5679 ± 1108, 7120 ± 533, and 7382 ± 714 nmol haemoglobin, respectively ($P < 0.0001$). A study comparing N8-GP 10 U/kg, turoctocog alfa 10 IU/kg, and vehicle dosed 48 h before tail vein transection had total bleeding times of 18.6 ± 3.1, 34.3 ± 4.6, and 36.5 ± 3.0 min with corresponding blood losses of 2832 ± 829, 6325 ± 782, and 6117 ± 498 nmol haemoglobin, confirming the prolonged duration of effect of N8-GP when compared to turoctocog alfa ($P < 0.05$ for total bleeding time and $P < 0.01$ for blood loss).
Conclusion: Dose response relationship was demonstrated at 24 h for N8-GP when applied in clinically relevant doses using a new tail vein transection bleeding model in anaesthetized FVIII k/o mice. Furthermore, the prolonged duration of effect of N8-GP was confirmed.

PA 4.13-4

Impact of factor VIII A2 domain stabilization on activated factor X generation

Leong L[1], Thompson T[1], Tran K[1], Ramsey PH[1], Wakabayashi H[2], Fay PHJ[2], Kretschmer P[1], Patel C[1], Murphy JE[1] and Laux V[1]
[1]Bayer HealthCare Pharmaceuticals, US Innovation Center, San Francisco, CA; [2]University of Rochester Medical Center, Rochester, NY, USA

Background: An important negative regulator of activated factor VIII (FVIIIa) cofactor activity is subunit dissociation. Factor VIII (FVIII) molecules with stabilized activity have been generated by elimination of charged residues at the A1-A2 and A2-A3 interfaces. These molecules exhibited reduced decay rates as part of the factor Xase complex (FXase) and retained their activities under thermal and chemical denaturing conditions (Wakabayashi H, et al. *J Thromb Haemost*. 2009;7 (3):438–44).
Aim: The goal of this study was to determine the relationship between FVIII A2 subunit stabilization and its cofactor activity.
Methods: We established the A2 stabilization of two molecules 'D519VE665V and D519VE665VE1984A' and performed extended kinetic characterization of these mutants to select a candidate for further testing in animal models. These mutants differed by their FVIII and FVIIIa stability as assessed by FXase decay.
Results: Biacore studies with FVIII immobilized on an A2 subunit-specific antibody indicated comparable molecular integrity (90%) for both D519VE665V and D519VE665VE1984A after thrombin activation and 30 min of buffer wash. In contrast, only approximately 25% of B-domain' deleted FVIII (BDD) remained intact under the same conditions. Coatest assay (Chromogenix) results show D519VE665V had twice the specific activity of D519VE665VE1984A, which had comparable activity to BDD. The difference in chromogenic specific activity does not correlate with FXase decay data and raises the possibility that mutations conferring A2 subunit stability affect FVIIIa interactions with other components of the FXase complex, activated factor IX (FIXa) and factor X (FX). A kinetic assay indicated a 2-fold increase in apparent FIXa affinity for D519VE665V vs. BDD, regardless of whether FVIIIa or FIXa were varied in the assays. In contrast, D519VE665VE1984A affinity was comparable to BDD. Finally, an FXase kinetic assay with 100-pM FIXa and 10-nM FVIIIa concentrations indicated similar FX activation kinetics for all variants and BDD.
Conclusion: Taken together, our results indicate that mutations in FVIII that stabilize A2 subunit association can also affect FVIIIa interactions with its FXase partners, which raises the possibility that there may be an optimum balance between increasing A2 stability and cofactor activity.

Increased mortality risk in US Hemophilia A inhibitor patients

Walsh C[1], Miller CH[2] and Soucie M[2]
[1]Mount Sinai School of Medicine, New York City, NY; [2]Centers for Disease Control and Prevention, Atlanta, GA, USA

Published mortality studies are limited in hemophilia inhibitor populations but indicate that there is no increased risk of mortality in FVIII inhibitor patients. In an updated assessment of the mortality of Hemophilia A patients with inhibitors in the US, we analyzed retrospective data on 7605 males with severe hemophilia A over a 12 year period (1998–2011) using the CDC UDC database. Inhibitor cases were participants who had either an elevated inhibitor titer, were on immune tolerance or who had failed ITI according to data from their most recent UDC visit. There were a total of 641 cases and the remaining 6964 participants served as controls. Information from mortality data

forms was used to determine date and cause of death for all study subjects. During the study period, 48 of the 435 participants who died had an inhibitor. Demographic characteristics most strongly associated with death were increased age and Medicare health insurance. Among clinical characteristics increased number of reported bleeds, signs of liver disease and infection with either HIV or HCV were all strongly associated with increased odds of death. After adjustment for all other causes of death, the odds of death were 70% higher (odds ratio = 1.7; 95% confidence interval 1.2–2.4) among inhibitor cases than non-inhibitor subjects ($P < 0.01$). Over 40% of deaths in inhibitor cases were due to bleeding, especially intracranial hemorrhage, compared to 12% of deaths in non-inhibitor patients ($P < 0.001$). Of the 48 inhibitor cases who died, 31 (65%) had used one or more bypassing agents in the year prior to the last UDC visit. The data suggest that people with Hemophilia A and an inhibitor may be at higher risk of death.

PA 4.13-6

VWF affects the clearance and biodistribution of recombinant factor VIII Fc fusion (rFVIIIFc)

Van Der Flier A, Tan S, Liu Z, Chen K, Liu T, Patarroyo-White S, Light D and Jiang H

Biogen Idec, Waltham, MA, USA

Background: rFVIIIFc is a fully recombinant fusion protein consisting of a single B domain deleted human FVIII covalently attached to the dimeric Fc domain of human IgG1. rFVIIIFc was shown to have a 1.5–fold extended half-life and decreased clearance compared to rFVIII in patients with hemophilia A in clinical studies. The Fc region of rFVIIIFc binds to the neonatal Fc receptor (FcRn), which is part of a naturally occurring pathway that cycles IgG back into circulation, delaying lysosomal degradation. Clearance studies in FcRn knock-out mice indicated a similar role for FcRn in the prolonged half-life of rFVIIIFc and studies with FcRn–chimeric mice show that the decreased clearance of rFVIIIFc is mediated by FcRn expressed in somatic cells and not hematopoietic cells.

Biodistribution studies with ^{125}I–rFVIIIFc identify liver as the dominant clearance organ and primary liver cell co-culture indicated uptake of rFVIIIFc by somatic liver sinusoidal endothelial cells (LSEC), rather than Kupffer cells (KC) or hepatocytes (HC). However, in blood, 95% of FVIII circulates as a non-covalent complex bound to von Willebrand Factor (VWF) suggesting that VWF binding may also play an important role in the clearance of rFVIIIFc.

Aims: Investigate the contribution of VWF binding to the clearance and biodistribution of rFVIIIFc compared to rFVIII in order to understand the mechanism leading to the long-lasting half–life of rFVIIIFc.

Methods: Pharmacokinetic studies compared rFVIII and rFVIIIFc in VWF-KO and FVIII/VWF–KO double knockout (DKO) mice. Biodistribution studies compared ^{125}I–rFVIII and ^{125}I–rFVIIIFc in DKO and HemA mice by quantitative whole body autoradiography and quantitating the radioactivity remaining in perfused organs.

Results: VWF stabilizes rFVIIIFc in the blood and extends rFVIIIFc half-life in HemA mice ($t_{½}$ = 13.7 h) in contrast to VWF-KO ($t_{½}$ = 2.5 h) or DKO mice ($t_{½}$ = 1.6 h). Thus rFVIIIFc is cleared rapidly in VWF-KO mice, but even more rapidly in mice lacking both VWF and endogenous murine FVIII. Biodistribution studies show that the liver is the predominant clearance organ for both rFVIIIFc and rFVIII. For both molecules, over 10% of the initial dose is found in liver within the first 15 min after injection in HemA mice. In contrast, 30% of the initial dose of rFVIIIFc is found in the liver of DKO mice showing that VWF delays liver uptake and improves rFVIIIFc half–life in mice with circulating VWF. In addition, RT-PCR confirms that all three primary liver cell types (LSEC, KC and HC) express FcRn.

Summary/Conclusions: Together with our previous observation that the FcRn from LSEC is primarily responsible for extended half-life of rFVIIIFc, our results support the following conclusions:

1 Similar to FVIII, the majority of rFVIIIFc circulates as a complex with VWF and this interaction strongly influences the clearance of both FVIII and rFVIIIFc.
2 Free rFVIIIFc is taken up by LSEC, and cycled back into circulation by an FcRn–dependent mechanism.

Effects of VWF on the clearance of rFVIIIFc using both *in vitro* cell uptake and *in vivo* immunohistochemistry studies are ongoing.

PA 4.14-1

Mechanism by which platelet-bound Prothrombinase maximizes platelet procoagulant activity

Todd BL, Silveira JR and Tracy PB

University of Vermont, Burlington, VT, USA

Background: The generation of physiologically relevant concentrations of thrombin, effected by Prothrombinase, a Ca^{2+}-dependent, stoichiometric (1:1) complex composed of factors Va and Xa assembled on an appropriate membrane, is absolutely essential for an appropriate hemostatic response. Physiologically, activated platelets provide this surface and in so doing promote prothrombin cleavage initially at Arg271 and subsequently at Arg320 to form thrombin. Cleavage at Arg271 generates the inactive intermediate prethrombin-2. In contrast, when Prothrombinase is assembled on the surface of phospholipid vesicles of defined content (PCPS vesicles), initial cleavage at Arg320 is preferred, generating the enzymatically-active intermediate meizothrombin, which expresses substantial anticoagulant activity.

Aim: Our aim is to define the unique functional and structural attributes of the platelet-bound complex that dictate initial cleavage at Arg271. Studies from other laboratories indicate that the prothrombinase complex is capable of binding two conformationally distinct forms of prothrombin, a 'proteinase-like' state optimally positioned for cleavage at Arg271, and a 'zymogen-like' state, optimally positioned for cleavage at Arg320. We hypothesized that platelet-bound Prothrombinase binds its substrate in a 'proteinase-like' state.

Method: Two experimental approaches were developed to address the following questions. Does platelet-bound Prothrombinase bind prothrombin in a 'proteinase-like' state that allows the irreversible incorporation of Phe-Pro-Arg-chloromethyl ketone (FPR-CK) into a pseudo-active site, whereas vesicle-bound Prothrombinase, which binds prothrombin in a 'zymogen-like' state, does not? Secondly, would increasing concentrations of dansylarginine N-(3-ethyl-1,5-pentanediyl)amide (DAPA), a reversible, active-site inhibitor of thrombin, force prothrombin into a 'proteinase-like' state and promote cleavage at Arg271 by vesicle-bound Prothrombinase?

Results: We observed that increasing the concentrations of DAPA in prothrombin activation reactions containing vesicle-bound Prothrombinase resulted in increased utilization of the prethrombin-2 pathway, suggesting that as the DAPA concentrations increased, so did the concentrations of prothrombin in a 'proteinase-like' state. When an identical experiment was performed with platelet-bound Prothrombinase as the enzyme, increasing the concentrations of DAPA increased the rate of prethrombin-2 formation, again suggesting that DAPA interactions with prothrombin forced the substrate into a more 'proteinase-like' state, making it a better substrate for platelet-bound Prothrombinase. The ability of platelet-bound Prothrombinase to bind and configure prothrombin in a 'proteinase-like' state was confirmed in experiments in which inactive platelet-bound Prothrombinase effected the incorporation of FPR-CK into prothrombin. The formation of FPR-prothrombin was verified by demonstration that the thrombin formed subsequent to its cleavage had no enzymatic

activity. In contrast, FPR-CK was not incorporated into prothrombin when inactive vesicle-bound Prothrombinase was used under similar conditions.

Summary/Conclusions: Our data support the concept that platelet-bound Prothrombinase orients prothrombin into a 'proteinase-like' state to promote the rapid generation of thrombin at a site of vascular injury, thus optimizing the procoagulant response by preventing the generation of the anticoagulant intermediate, meizothrombin. We speculate that the activated platelet membrane supports the binding of the Prothrombinase constituents in a manner that dictates prothrombin cleavage at Arg271 and the preferential use of the prethrombin-2 pathway of activation.

PA 4.14-2

Differential effects on TFPI levels upon exposure of human endothelial cells and cynomolgus monkey vascular beds to TFPI KPI-2 antibody mAb 2021 and TFPI KPI-3 antibody mAb 0001

Augustsson C, Loftager M, Hansen L, Petersen LC, Hilden I and Petersen H

Novo Nordisk A/S, Bagsvaerd, Denmark

Background: Tissue factor pathway inhibitor (TFPI) is synthesized by endothelial cells as two isoforms. It is stored intracellularly in a full-length form (TFPI α) and present on the cell membrane mainly as the GPI-anchored TFPI β form. Heparin induces synthesis and secretion of TFPI from endothelial cells *in vitro* and increases the TFPI plasma level *in vivo* by an unknown mechanism. A recent publication describes the haemostatic effect of monoclonal antibody mAb 2021 that binds to the Kunitz proteinase inhibitor (KPI) 2 domain of TFPI. Here, we compare the *in vitro* and *in vivo* effects of mAb 2021 on TFPI secretion to the effects of heparin and an antibody binding to the KPI-3 of TFPI (mAb 0001).

Aims: To evaluate the effect of mAb 2021 and mAb 0001 on TFPI secretion from endothelial cell culture and on TFPI levels shortly (0.5–2 h) after administration to cynomolgus monkeys.

Methods: Endothelial-like cells ECV304 were treated with 5 U/mL heparin or 10 nM of mAb 2021 or mAb 0001 for 24 h in serum-free medium with 0.5% BSA. Cynomolgus monkeys were dosed intravenously with mAb 2021 or mAb 0001 (20 mg/kg) and TFPI levels were followed by measuring total-TFPI (the sum of free TFPI and TFPI in complex with antibody) and free-TFPI in plasma samples. The different TFPI levels were quantified by specific sandwich ELISAs.

Results: *In vitro*, treatment with heparin caused a 4-fold increase in TFPI levels in the supernatants from endothelial cell cultures compared to non-treated controls. Similarly, a 3-fold increase could be measured after treatment with 10 nM of mAb 0001, whereas 10 nM of mAb 2021 had no measurable effect on the TFPI levels. *In vivo,* dosing cynomolgus monkeys with mAb 0001 caused a steep increase in the total TFPI plasma level within 30 min. At 2 h the increase had continued, but at a much slower rate. The rate of accumulation of total-TFPI after mAb 2021 treatment was much slower and largely linear over the observation period. In both studies, the free TFPI levels were reduced after mAb administration.

Conclusions: TFPI KPI-3 mAb 0001 demonstrated a strong stimulatory effect on the secretion of TFPI from endothelial cells, comparable to the effect of heparin. In contrast, TFPI KPI-2 mAb 2021 had no effect on TFPI secretion. Data from cynomolgus monkeys demonstrated a rapid increase of total-TFPI in animals treated with mAb 0001. This increase is most probably due to both an accumulation of total-TFPI but also a secretion of TFPI as seen by endothelial cells *in vitro*. Animals treated with mAb 2021 showed a slow and linear increase in total-TFPI level, most likely caused only by an accumulation of total-TFPI and no secretion. The results demonstrate that the biological effects of the two antibodies are distinctly different. Only the KPI-3 antibody seems to affect the endothelial secretion of TFPI and may work by the same mechanism as heparin. However, further studies are needed to fully elucidate the mechanism of action.

PA 4.14-3

Increased expression of TFPI by NaBut is due to changes in the acetylation pattern of the TFPI promoter

Skretting G[1], Myklebust CF[1], Dørum E[1], Stavik B[1], Iversen N[2] and Sandset PM[3]

[1]Oslo University Hospital Rikshospitalet; [2]Oslo University Hospital Ullevål; [3]Oslo University Hospital Rikshospitalet/ University of Oslo, Oslo, Norway

Background: Tissue factor pathway inhibitor (TFPI) is the physiological inhibitor of tissue factor (TF) induced coagulation. Increased levels of TFPI are correlated with antithrombotic and anticancer effects. Sodium butyrate (NaBut) is a histone deacetylase inhibitor that is used in treatment of cancer, and it is able to modulate gene transcription and apoptosis. In another study, we found that NaBut was able to increase the expression of TFPI in HEK293 cells, and we have previously reported that the transcriptional activity of the promoter was mediated by the −287T/C promoter SNP where the presence of the C allele resulted in higher promoter activity compared to the T allele.

Aim: The aim of the present study was to acquire information on whether the effect of NaBut on TFPI expression involved the TFPI promoter; specifically the potential role of the −287T/C SNP in this context, and also to identify nuclear factors that bind this SNP.

Methods: The TFPI promoter was studied in HEK293 cells using a reporter gene approach by measuring the luciferase activity after transient transfections with the various promoter constructs and subsequent treatment of the cells with ± 1 mM NaBut. Binding studies of nuclear proteins to the −287T/C SNP were performed using EMSA. Identification of binding factors was done with EMSA and immunoprecipitation, and the histone acetylation pattern of the promoter was studied using ChIP.

Results: Treatment of transfected cells with NaBut resulted in increased luciferase activity compared to the corresponding activity in untreated cells. This increase was dependent on the region surrounding the −287 SNP and was highest when the −287T wild type (wt) was present. EMSA studies with a probe containing either the −287T wt or the C variant allele revealed DNA binding activity of nuclear proteins from the HEK293 cells to both SNP variants; the activity was most prominent for the C allele. Treatment with the transfected cells with NaBut did not change the DNA binding activity to the SNP. The transcription factor FOXP3 was identified to bind to the T allele. Since NaBut is a histone deacetylase inhibitor, we analysed the effect on histone proteins H3 and H4. The global acetylation pattern revealed increased acetylation of both histones. Preliminary results indicate changes also in the acetylation pattern of the histone proteins H3 and H4 in the TFPI promoter after NaBut treatment. It is recognized that also non-histone proteins can be acetylated and studies are in progress to examine whether treatment with NaBut also affects the acetylation of FOXP3.

Conclusions: We conclude that NaBut affects the TFPI expression by a mechanism that involves the TFPI promoter region directly. A role of the −287T/C SNP is indicated together with changes in the acetylation pattern of the histone proteins H3 and H4 in the promoter region of TFPI. We have identified that the transcription factor FOXP3 binds specifically to the −287T allele and we hypothesize that NaBut affects the acetylation pattern of the factor. The findings may in part explain the anti-cancer effect of NaBut.

PA 4.14-4

Sodium butyrate induces TFPI-mediated apoptosis through the AKT/mTOR pathway

Cui XY[1], Stavik B[1], Myklebust CF[1], Andresen M[1], Dørum E[1], Iversen N[2], Sandset PM[1,3] and Skretting G[1]

[1]Department of Haematology and Research Institute of Internal Medicine, Oslo University Hospital, Rikshospitalet; [2]Department of Medical Genetics, Oslo University Hospital and University of Oslo; [3]Institute of Clinical Medicine, University of Oslo, Oslo, Norway

Background: Sodium butyrate (NaBut) is a histone deacetylase inhibitor that has been shown to regulate gene expression and induce apoptosis in cancer cells. Tissue factor (TF) pathway inhibitor (TFPI), which regulates the TF-dependent pathway of blood coagulation, can also induce apoptosis and inhibit cell proliferation in cancer cells. In the present study we have found that NaBut elevates the endogenous expression of TFPI and induces apoptosis in HEK293 cells.
Aims: Our aim has been to further investigate the NaBut induced increase in TFPI expression and apoptosis and to explore the potential signaling pathways underlying the involvement of TFPI.
Methods: HEK293 cells were treated ± 1 mM NaBut, and The Cell Death Detection ELISA^{PLUS} kit and flow cytometry were used to assess the apoptotic activity of the cells. TFPI expression was determined using qRT-PCR and ELISA. TFPI and AKT knock down was performed with the siRNA approach. The PI3K/AKT/mTOR signaling pathway was examined by Western blot with antibodies against AKT, Phospho-Akt, mTOR and Phospho-mTOR. The activation of AKT was also determined using ELISA. Together with the knock down of AKT, the PI3K inhibitor LY294002 was used to study the involvement of AKT in NaBut induced TFPI expression and apoptosis.
Results: NaBut treatment of HEK293 cells resulted in an increased apoptotic activity accompanied by increased TFPI expression. TFPI expression increased in a time- and dose-dependent manner. When TFPI was knocked down, the apoptotic activity of the cells was impaired. NaBut treatment of the cells resulted in elevated phosphorylation of AKT and mTOR. Preliminary results indicate that inhibition of AKT phosphorylation or knock down of AKT by siRNA technology, results in an abolished effect of NaBut on TFPI expression. Studies are in progress to evaluate the effect of inactive AKT/downregulated AKT levels on the apoptotic activity of the cells after treatment with NaBut.
Conclusions: We conclude that TFPI participates in mediating the NaBut induced apoptosis in HEK293 cells since knockdown of TFPI impairs the increased apoptosis caused by NaBut treatment. Due to the activation of AKT and mTOR we hypothesize that the PI3K pathway is involved in this process. These results confirm previous findings that TFPI has anti-apoptotic properties in transformed cells and may partly explain the anti-cancer effect of NaBut.

PA 4.14-5

Factor VII antigen levels are differentially associated to etiological subtypes of ischemic stroke

Stanne TM, Hanson JB, Olsson S, Höglund J, Jood K, Blomstrand C and Jern C

Institute of Neuroscience and Physiology, Gothenburg, Sweden

Background: Factor VII (FVII) plays a key role in the coagulation cascade and has thus been implicated in thrombotic diseases. Several polymorphisms in the FVII gene, *F7*, as well as environmental factors have been associated with plasma FVII antigen (FVIIag) levels. While higher levels of FVII have been reported in patients with cardiovascular disease, the relationship between FVII and ischemic stroke (IS) remains unclear. IS is a heterogeneous disorder comprised of four main etiologic-subtypes: large-vessel disease (LVD), small-vessel disease (SVD), cardioembolic (CE) stroke and cryptogenic stroke. The mechanism of disease and the frequency of established risk factors differ between subtype, eg atrial fibrillation (AF) is much more prevalent in CE stroke compared to the other subtypes. Analysis with respect to subtype is therefore of importance. No studies have yet looked at FVII plasma levels in relation to IS etiologic subtypes.
Aims: (i) To investigate SNPs in *F7* in relation to IS and the etiological subtypes; (ii) To determine whether AF affects FVIIag levels; (iii) To investigate whether elevated plasma levels of FVIIag are associated with an increased risk of IS, and more specifically whether there are subtype-specific differences in FVIIag.
Methods: Two SNPs were analyzed in the Sahlgrenska Academy Study on Ischemic Stroke (SAHLSIS), which comprises 844 patients with IS and 668 controls. Stroke subtypes were defined according to the TOAST criteria. Blood samples were collected from the first 600 patients in the acute phase and 3 months after index stroke, as well as the first 600 controls. These were used for subsequent FVIIag ELISA analysis.
Results: (i) The SNP rs510317 was associated to elevated FVIIag levels, while rs6046 was associated to lowered FVIIag levels. No SNP was associated with overall IS after correcting for traditional risk factors. rs510317 was independently associated to the subtype LVD (OR 1.53, 95% CI 1.02–2.30; $P = 0.04$), however this did not withstand correction for multipe testing. (ii) Stroke patients with AF had significantly lower FVIIag levels compared to those without AF, both when comparing patients with and without warfarin. (iii) Elevated FVIIag levels were independently associated with IS at both time-points. Significant differences in FVIIag levels were observed between subtypes. LVD and SVD were associated with increased FVIIag after adjusting for traditional risk factors. CE stroke was associated with decreased FVIIag levels. This was not only attributed to the high proportion of patients on anticoagulant therapy in this group, but also due to the fact that patients with AF have lower levels of FVII.
Conclusion: (i) No association between the two SNPs in *F7* and overall IS or the etiologic subtypes were detected after correction for traditional risk factors and multiple testing. (ii) AF was determined to be an important and not fully recognized confounding variable in analyses of FVIIag. (iii) FVIIag is independently associated to overall IS and significant differences exist in FVIIag levels between etiological subtypes. These findings highlight the importance of using etiological sub-classification of IS in future prospective and case-control studies on FVII.

PA 4.14-6

Endogenous tissue factor pathway inhibitor and tissue factor expression in rabbit bleeding and clotting models

Almholt K, Lauritzen B and Johansen PB

Novo Nordisk A/S, Maaloev, Denmark

Background: Patients with haemophilia rely on prophylactic or on-demand replacement therapy that involves frequent intravenous injections of Factor VIII or Factor IX. Tissue factor pathway inhibitor (TFPI) is an endogenous inhibitor of coagulation initiation. TFPI is present in several forms; the majority is associated with the endothelium and a minor fraction is present in plasma and in platelets. Compounds that neutralise the function of TFPI present a novel strategy for future haemophilia therapy. The monoclonal antibody mAb 2021 that inhibits human TFPI is currently in clinical development with the aim of providing a subcutaneously administered prophylaxis option for patients with haemophilia.
Aims: We wanted to characterize experimental bleeding and clotting models with respect to endogenous expression of TFPI and tissue factor (TF).
Methods: We used immunohistochemistry to study the expression patterns of TFPI and TF in select rabbit tissues including the cuticle, ear,

and facial vein, which are sites commonly investigated in experimental bleeding and clotting models.
Results: TFPI was prominently present in the microvasculature of the cuticle and ear tissue, but only to a lesser extent in the endothelium of large vessels such as the facial vein. TF on the other hand was prominently expressed in the adventitia of medium-sized and large vessels, but not associated with the capillary network. The relative expression level of TFPI and TF thus varied greatly with TFPI dominating in the microvasculature and TF dominating in large vessels. In the rabbit cuticle, which contains a fine network of capillaries, the balance was shifted towards TFPI expression. In the facial vein, the balance was shifted towards TF expression, and there was an intermediate situation in the ear tissue.
Conclusions: The expression patterns of TFPI and TF show clear and consistent differences between the tissues that are studied in common experimental bleeding and clotting models. While these inherent differences may have implications for the interpretation of experimental results, the prominent expression of TFPI in the cuticle and ear suggest that these tissues provide relevant bleeding models, in which to study the effect of novel TFPI-neutralizing compounds.

PA4.15 – Factor XIII

PA 4.15-1
Factor XIII deficiency in elective hip or knee surgery

Von Depka Prondzinski M[1], Imke J[2], Böker M[3], Detering C[1] and Siebert C[3]
[1]*Werlhof-Institut;* [2]*Medizinische Hochschule Hannover;* [3]*Diakonie-Krankenhaus Annastift, Hannover, Germany*

Background: Factor XIII (FXIII) plays an essential role in fibrin stabilization and crosslinking of antifibrinolytic proteins to the fibrin clot. It is also known that FXIII has an impact on wound healing. Congenital FXIII deficiency is rare, whereas acquired FXIII deficiency is more common.
Aim: Evaluation of FXIII as useful predictor of total blood loss and in consequence of possible bleeding complications in surgery. Here, we report FXIII levels over time before and after elective hip and knee surgery correlated with blood loss.
Method: In this prospective study on 109 patients (m = 52/f = 57; mean age: 63.5 ± 10.9 years) 64 hip (58.7%) and 45 knee surgeries (41.3%) were performed. Blood samples were collected pre- and post-op 4–8 h and on Day 1, 2, 3, 4, 6 to analyse FXIII activity and antigen, VWF ristocetin cofactor activity and antigen among other coagulation parameters. Furthermore, volume of blood loss was assessed intra- and postoperatively. The analyses of data were done using descriptive statistics.
Result: A continuous decrease of FXIII activity was detected in the whole group from pre- (109.9 ± 21.9%) to D4 post-op (74.8 ± 18.3%; nadir) and in both subgroups depending on type of surgery. From D5 post-op, the FXIII-level increased in the total and all subgroups. Furthermore, highly significant differences of FXIII activity were found between patients with high amounts of blood loss in contrast to small blood loss (82.5 vs. 67.8%; $P < 0.000$). There was a significant correlation between intra-op and total blood loss, but not between post-op and total blood loss. This correlation was even more significant by cumulating the intra-op and D1-blood loss. Main blood loss occurred post-op (665 ± 621 mL in contrast to intra-op 458 ± 252). FXIII immediately post-op correlated with intra-op blood loss ($P < 0.01$) and total blood loss ($P < 0.05$). Furthermore no correlation was found between FXIII activity and VWF ristocetin cofactor and antigen.
Conclusion: FXIII activity strongly correlates with intra-op as well as post-op blood loss with a nadir on day 4 post-op. FXIII immediately post-op is an predictor of total blood loss and in consequence of possible bleeding complications. Avoiding prolonged hospital stay due to large blood loss might be of economic importance, e.g. costs of FXIII concentrate vs. prolonged hospitalization.

Effects of free factor XIII activation peptide on factor XIII function and fibrin formation and structure

Schroeder V[1], Duval C[2], Brown R[2], Handrkova H[1], Ariëns R[2] and Kohler HP[1]
[1]*University of Bern, Bern, Switzerland;* [2]*University of Leeds, Leeds, UK*

Background: We have previously shown that the activation peptide of coagulation factor XIII (AP-FXIII) is released into plasma upon activation by thrombin and can be detected in plasma samples from patients with an acute thrombotic event.
Aim: The aim of this study was to investigate whether free AP-FXIII may affect FXIII function, fibrin clot formation and structure, and thrombin function in terms of a negative feedback regulation.
Methods: FXIII function was assessed with the FXIII biotin incorporation assay. A turbidimetric clot formation assay was used to study fibrin clot formation in plasma. Clot formation and viscoelastic properties of the clot were also analysed by rotation thrombelastometry (ROTEM) performed in plasma and whole blood. The structure of plasma clots was investigated by permeation analysis and scanning electron microscopy (SEM). Thrombin activity was determined using chromogenic substrates. All experiments were performed in the presence of different concentrations of AP-FXIII or a scrambled peptide of the same amino acid composition but in random order as a negative control.
Results: AP-FXIII reduced FXIII-dependent biotin incorporation by up to 50% in a dose-dependent manner. When FXIII was pre-activated, AP-FXIII had no effect suggesting that AP-FXIII interferes with FXIII activation but not its transglutaminase reaction. In the turbidimetric clotting assay, kinetics of fibrin clot formation were not altered but maximum absorbance was reduced by up to 46% by increasing AP-FXIII concentrations. Maximum clot firmness measured by ROTEM was reduced by up to 30%. Plasma clots made in the presence of AP-FXIII showed significantly reduced permeability with a 40% reduction in pore size. SEM data, however, showed no significant effect of AP-FXIII on plasma clot structure. Thrombin activity towards chromogenic substrates were not altered by AP-FXIII. The scrambled peptide had no effects in any of the experiments.
Conclusions: We have found first evidence that AP-FXIII inhibits FXIII activation and has an effect on plasma clot structure. We propose that AP-FXIII might act as a negative feedback regulator of FXIII activation, and might interact with fibrin fibres during polymerisation and/or crosslinking. Further studies are needed to elucidate the underlying mechanisms and potential relevance of our findings.

PA 4.15-3
Factor XIII and corneal wound healing

Muszbek L[1], Muszbek L[1], Orosz Z[1], Bárdos H[1], Facskó A[2], Shemirani AH[1], Vereb G[1], Ádány R[1] and András B[1]
[1]*University of Debrecen, Medical and Health Science Center, Debrecen;* [2]*University of Szeged, Szeged, Hungary*

Background: In addition to its role in hemostasis, coagulation factor XIII (FXIII) is involved in wound healing and also exerts several other cellular functions. Beside plasma, the dimer of its potentially active A subunit (FXIII-A) is also present in various cells, like platelets, monocytes/macrophages, osteoblasts and chondrocytes. We have previously reported that FXIII is present in normal tears at very low concentration (Orosz et al. J Immunol Methods 2010;353:87–92), but following corneal surgery, particularly following corneal transplantation, its concentration increases up-to 25–40-fold (Orosz et al. Clin Chim Acta 2011;412:271–6). Based on these results we presumed that FXIII plays a role in the wound healing of corneal tissue.
Aims: The aim of the study was to provide more direct proofs on the involvement of FXIII in corneal wound healing and to explore if the cellular form of FXIII (cFXIII) is expressed in cells of human cornea.

Methods: Scratch wound healing experiments were performed on virus transformed human corneal epithelial cell (HCET) culture in the presence and absence of recombinant human FXIII-A_2 (rFXIII). Wound closure was monitored by video-microscopy and the area uncovered by cells was recorded at various times. The effect of rFXIII on cell proliferation and migration was investigated by EZ4U and xCELLigence RTCA DP Instrument using CIM-Plate 16, respectively. Thrombospondin-1 (TSP-1) content of the cells and media was determined by ELISA technique and Western blotting. Frozen sections of normal human corneas obtained from enucleated bulbus with posterior segment tumor were immunostained for cFXIII, for transgultaminase (TG) 1 and 2. Detection of cFXIII was combined with labeling for CD11b, CD34, CD45, CD68 and CD163 in double immunofluorescent staining. Corneas were analyzed for FXIII-A by Western blotting and FXIII-A mRNA by RT-PCR technique. The study was approved by the Regional Medical Ethics Committee.
Results: Addition of rFXIII to HCET cell culture, even at low concentration, significantly accelerated the healing of scratch wound. The improved scratch wound healing was due to increased proliferation of the cells rather than to an effect on their migration. Treatment of HCET cells with rFXIII resulted in the down-regulation of TSP-1 expression.
A significant part of keratocytes showed intensive staining for cFXIII, but not for TG-1 or TG-2. Neither epithelial nor endothelial cells were labeled by anti-FXIII antibody. FXIII-A positive cells were unevenly distributed in the corneal stroma, abundant in the subepithelial tertile and sparse in the subendothelial tertile. FXIII-A+ cells showed co-staining for CD34, however, a significant number of CD34+ cells were negative for cFXIII. The presence of cFXIII in the cornea was also confirmed by Western blotting. RT-PCR experiments indicated that stromal keratocytes are capable of synthesizing cFXIII.
Conclusions: FXIII promotes the healing of scratch wound in HCET cell culture. cFXIII is abundant in subepithelial keratocytes. It is suggested that in the case of corneal injury cFXIII released from subepithelial keratocytes, plus FXIII present in tears, play a role in the repair of corneal injury. Keratocyte FXIII might also be involved in the structural organization of corneal stroma.

PA 4.15-4

Pre-clinical safety and prolonged pharmacokinetic/pharmacodynamic (PK/PD) properties of a recombinant fusion protein linking activated coagulation factor VII with albumin (rVIIa-FP)

Zollner S, Schuermann D, Kaspereit F, Krege W, Weimer T, Müller-Cohrs J, Pragst I, Dickneite G and Schulte S
CSL Behring GmbH, Marburg, Germany

Background: Recombinant factor VIIa (rFVIIa) is approved to control bleeding in haemophilia patients who developed inhibitory antibodies to replacement therapy. rFVIIa is rapidly eliminated with a terminal half-life of approximately 2.5 h in humans. This short half life of rFVIIa necessitates frequent injections and considerably limits prophylactic use. A recombinant fusion protein linking activated factor VII with albumin (rVIIa-FP) was therefore developed to extend the half life of rFVIIa.
Aim: The present studies were conducted to support the clinical efficacy and tolerability evaluation of rVIIa-FP by gathering knowledge about its pharmacodynamic activity based on procoagulant effects in a preclinical venous stasis model and by assessing PK and safety aspects in animals.
Methods: During a GLP-compliant toxicity program in several animal species, the anaphylactic or allergic, immunogenic and prothrombotic potential of rVIIa-FP, its impact on safety pharmacology variables and systemic toxicity parameters as well as the local tolerability were assessed applying single or repeated dosing regimens. The PK profiles of both rVIIa-FP and NovoSeven®, a licensed rFVIIa, were recorded measuring selective FVIIa activity after a single treatment of cynomolgus monkeys at clinically relevant dose levels of 2700 and 270 μg/kg, respectively. When investigating PD responses and duration thereof, rVIIa-FP and NovoSeven® were administered intravenously to normal rabbits before induction of venous stasis followed by assessment of clot formation and systemic haemostasis parameters. In parallel, FVIIa activity was recorded in plasma samples.
Results: Overall, the safety program showed that administration of rVIIa-FP was well tolerated with no findings indicative of adverse systemic toxicity, anaphylactic or allergic reactions and without any safety pharmacology or local intolerability concerns. Intriguingly, in both animal species tested, the systemic bioavailability, clearance and in addition the terminal half-life ($t_{1/2\beta}$) of rVIIa-FP were significantly better in comparison to NovoSeven®. When recording FVIIa activity in plasma samples derived from monkeys, the 11-fold higher area under the curve (AUC) was accompanied by a fourfold longer $t_{1/2\beta}$, while *in vivo* recovery (IVR) of rVIIa-FP exceeded that of NovoSeven® by 70%. In rabbits, the 20-fold higher AUC was associated with a 5-fold extension in $t_{1/2\beta}$ and a fourfold increase in IVR when measuring selective plasmatic FVIIa activity. In this animal model, the procoagulant effect of rVIIa-FP was not different from NovoSeven® after treatment under acute conditions. However, at advanced time-points the prolonged systemic availability of rVIIa-FP translated into prolonged haemostatic activity.
Summary/Conclusion: Consequently, these animal studies confirmed that the recombinant albumin fusion technology was successfully applied to human recombinant FVIIa for improvement of pharmacokinetic parameters. The non-clinical pharmacology and safety program proved prolonged activity and a favourable tolerability profile of rVIIa-FP. The presented investigations did not reveal any safety concerns and support the evidence necessary for further clinical development in humans (PROLONG-7FP).

PA 4.15-5

Molecular interaction of factor XIII subunits

Katona E, Pénzes K, Csapó A, Kun M, Csapó J, Bagoly Z, Fazakas F and Muszbek L
University of Debrecen, Medical and Health Science Center, Debrecen, Hungary

Background: Plasma factor XIII (FXIII) consists of two catalytic A subunits (FXIII-A) produced by cells of bone marrow origin and two protective/inhibitory B subunits (FXIII-B) synthesized by hepatocytes. FXIII-B, a mosaic protein, consisting of 10 sushi domains, circulates in excess; approximately 50% of it is free in the plasma. The formation of FXIII-A_2B_2 complex takes place in the plasma. The exact binding constant between the two subunits is not known and the structures involved in the association of the two types of subunits are not well characterized. FXIII is also present in body fluids, cerebrospinal fluid, tears, bronchoalveolar lining fluid, although in much less concentration than in the plasma. However, in these body fluids the majority FXIII-A exists as free, non-complexed dimer.
Aims: To investigate the binding kinetics of the two subunits and to locate the binding site of FXIII-A on the B subunit. Using the Kd established for the association to calculate the ratios of free to total FXIII-A_2 in different body fluids and compare them with experimentally determined values.
Methods: Binding constant was measured by surface plasmon resonance and also by an ELISA type assay. Using this Kd and the total FXIII subunit concentrations in the body fluids the theoretical ratio of free to complexed FXIII-A_2 was calculated. The actual concentrations of free FXIII-A_2 was determined by ELISA technique after the complete removal of free FXIII-B and FXIII-A_2B_2 complex by immunoabsorption. To locate the epitopes responsible for the association of the two subunits a monoclonal anti-FXIII-B antibody preventing complex formation between the two types of subunits was produced. Epitope mapping was carried out by tryptic digestion of FXIII-B bound to our surface linked antibody. The tryptic fragments that remained associ-

ated with the antibody were identified by MALDI TOF analysis. Recombinant isolated sushi domains 1–2 of FXIII-B were produced in insect cells.
Results: The Kd was found to be in the range of 2.93–5.43 $\times$ 10^{-10} by both methods. Using this Kd it was calculated that approximately 1% of plasma FXIII-A_2 should be in free form. This value was experimentally confirmed using FXIII-B depleted plasma. In body fluids with much lower FXIII subunit concentrations, like cerebrospinal fluid or tears, a much higher percentage (80–90%) of FXIII-A_2 existed in free form. The calculated and measured values agreed in these cases, too. The antibody that prevented complex formation reacted with isolated sushi domains 1–2 produced in insect cells. The sequence of the tryptic fragments that remained associated with the antibody corresponded to the overlapping sequences between amino acids I90-K103 in the second sushi domain.
Conclusion: The two FXIII subunits are tightly associated, but depending on the concentration of the subunits certain amount of free FXIII-A_2 is also present in body fluids. The small percentage of free FXIII-A_2 in the plasma might contribute to the so-called innate plasma transglutaminase activity. Our results together with those of Suori et al. (Biochemistry 2005;47:8656–64) suggest that the N-terminal part of FXIII-B (sushi domains 1–2) are involved in the formation of FXIII-A_2B_2 complex.

PA 4.15-6
Common FXIII polymorphisms associate with abdominal aortic aneurysms and with overall survival rate

Macrae FL, Lee Evans H, Sohrabi S, Johnson A, Scott DJA and Ariëns R
The University of Leeds, Leeds, UK

Background: An abdominal aortic aneurysm (AAA) involves the dilatation of the abdominal aorta and if left untreated leads to high mortality due to rupture. Deposition of an intraluminal thrombus increases the rate of AAA expansion. It is thought blood coagulation FXIII may play a role in AAA due to its part in thrombus formation. Three common FXIII polymorphisms have been identified; FXIII-A Val34Leu, FXIII-B His95Arg and FXIII-B Splice Variant (intron K nt29576C-G). FXIII-A Val34Leu is a polymorphism that is known to affect FXIII activation rate and fibrin structure. FXIII-B His95Arg is a polymorphism associated with a moderately increased risk for venous thrombosis, and with increased dissociation of the FXIII subunits in plasma. The FXIII-B Splice variant leads to a novel splice acceptor site and a protein 15 amino acids longer at the C-terminus. The roles of these FXIII polymorphisms in AAA are currently unknown.
Aims: Our aims were to analyse FXIII-A Val34Leu, FXIII-B His95Arg and FXIII-B Splice Variant in patients with AAA compared with control subjects and assess the effect of on AAA survival.
Methods: DNA was extracted from 529 AAA patients and 469 controls. All subjects were enrolled as part of the Leeds Aneurysm Development Study (LEADS). All patients were Caucasian, aged $\geq$ 55 years and had an AAA $\geq$ 3 cm. These were compared to age and sex matched controls (also all Caucasian) who had an aortic diameter $\leq$ 2.9 cm. Samples were analysed by real-time PCR for the FXII-B His95Arg, FXIII-A Val34Leu and FXIII-B Splice Variant polymorphisms. Genotype distributions were tested by Chi-squared and Student *t* test, survival was analysed by Kaplan-Meier.
Results: Our data showed that FXIII-B Arg95 was more prevalent in AAA patients than controls. This difference was significant with 24% (n = 130) of the AAA patients possessing $\geq$ 1 Arg allele compared with 16.2% (n = 76) of the controls possessing $\geq$ 1 Arg allele (P = 0.001). There was no difference regarding FXIII-A Val34Leu or FXIII-B Splice Variant genotype distribution between AAA patients and controls (P = 0.666 and P = 0.733 respectively). Mean crude survival for AAA patients with > 1 Leu allele was 6.230 (CI 5.78–6.68) compared to 6.85 years (CI 6.48–7.22) for Val/Val, (P = 0.064). Although there was an increase in overall mortality for AAA, it was not significant. There was no significant difference in mean crude survival for FXIII-B His95Arg or FXIII-B Splice Variant polymorphisms.
Summary: This data suggests that (i) FXIII-B His95Arg may increase risk of rupture, complications or repair in AAA, (ii) FXIII-A Val34-Leu and FXIII-B Splice Variant polymorphisms alone are not a risk factor for AAA and (iii) FXIII-A Val34Leu influences overall mortality in this group of patients.

Conventional or age-adjusted D-dimer cut-off values to exclude venous thromboembolism in older patients: a systematic review and meta-analysis

Schouten HJ[1], Geersing GJ[1], Koek HL[1], Zuithoff NPA[1], Janssen KJM[2], Douma RA[3], Van Delden JM[1], Moons KGM[1] and Reitsma JB[1]
[1]University Medical Center Utrecht, Utrecht; [2]Mapi Consultancy, Houten; [3]Academic Medical Centre, Amsterdam, The Netherlands

Background: Since D-dimer levels increase with age, the proportion of false-positive D-dimer tests for detecting venous thromboembolism using conventional cut-off values (500 μg/L) increases in the elderly, and the specificity decreases. Age-adjusted D-dimer cut-off values (age*10 μg/L in patients aged > 50 years) have therefore been introduced.
Aims: To review the diagnostic accuracy of D-dimer testing in elderly patients suspected of venous thromboembolism, using conventional or age-adjusted D-dimer cut-off values.
Methods: MEDLINE and Embase databases were searched for studies, published before June 21, 2012, and authors of primary studies were contacted. We selected all studies that enrolled older patients suspected of venous thromboembolism in whom D-dimer testing -using both conventional and age-adjusted cut-off values- and reference testing were performed. The quality of the studies was appraised using the QUADAS-2 tool. 2 $\times$ 2 tables were reconstructed and stratified by age-category and applied D-dimer cut-off value.
Results: Thirteen cohorts including 4875 patients aged over 60 years and a non-high clinical probability, were included in the meta-analysis. The specificity of the conventional cut-off value decreased with increasing age, from 39.6% (95% confidence interval 33.6–46.5%), to 24.7% (19.7–30.5%) and 14.7% (11.2–19.2%) in patients aged 61–70, 71–80 and > 80 years respectively. Age-adjusted cut-off values revealed higher specificities over all age categories: 49.9% (42.8–58.9%), 44.4% (37.6–51.5%) and 35.8% (29.4–42.9%) respectively. Sensitivities of the age-adjusted cut-off remained above 97% in all age categories.
Conclusions: The application of age-adjusted cut-off values nearly doubles the specificity without modifying the sensitivity, thereby largely improving the clinical utility of D-dimer testing in the elderly.

PA 4.16-2
Arterial disease in patients with symptomatic venous thromboembolism. Findings from the RIETE registry

Monreal M[1], Madridano O[2], Lorenzo A[3], Del Toro J[4], Martín M[2], Gómez-Cerezo J[2], Prandoni P[5], Bura-Riviere A[6] and Rota L[7]
[1]Hospital Universitari Germans Trias i Pujol, Badalona; [2]Hospital Infanta Sofía; [3]Hospital Universitario La Paz; [4]Hospital Gregorio Marañón, Madrid, Spain; [5]Universita de Padova, Padova, Italy; [6]Hôpital de Rangueil, Toulouse, France; [7]Instituto Clinico Humanitas IRCCS, Milan, Italy

Background: The relationship between venous thromboembolism (VTE) and atherosclerosis has not been consistently explored.

Aims and Methods: We used the RIETE Registry data to compare the rate of arterial events and VTE recurrences during the first 3 months of therapy, and to identify risk factors for both events.
Results: As of October 2012, 17,485 consecutive patients in RIETE had information on risk factors for atherosclerosis and subsequent arterial events. Of these, 8272 initially presented with deep vein thrombosis (DVT) and 9213 with pulmonary embolism (PE). In patients presenting with DVT, the number of patients dying of arterial events (ischemic stroke 11, lower limb ischemia 4, myocardial infarction 3, mesenteric ischemia 3) exceeded the number of those dying of recurrent PE ($N = 11$). In patients initially presenting with PE, the rate of fatal arterial events after the second week of therapy (myocardial infarction 7, ischemic stroke 3, other 2) exceeded the rate of fatal recurrent PE ($N = 7$). On multivariate analysis, prior arterial disease (odds ratio [OR]: 1.4; 95% CI: 1.03–1.8), diabetes (OR: 1.4; 95% CI: 1.01–1.8), statin therapy (OR: 1.4; 95% CI: 1.07–1.8) and smoking habit (OR: 1.4; 95% CI: 1.1–1.9) independently predicted the risk for recurrent VTE, while unprovoked VTE (OR:0.6; 95% CI:0.4–0.96) and cancer (OR: 2.5; 95% CI: 1.6–3.9) independently predicted the risk for subsequent arterial events.
Conclusions: In patients with acute VTE the mortality due to subsequent arterial events may be worse than that due to VTE recurrences. Some risk factors for these complications have been identified.

PA 4.16-3
Incidence of superficial vein thrombosis: a community-based study

Buchmuller-Cordier A[1], Frappe P[2], Bertoletti L[1], Presles E[1], Couzan S[3], Preynat PH[3], Tardy B[1] and Decousus H[1]
[1]CHU Saint-Etienne; [2]University of Saint Etienne; [3]Cabinet de Médecine Vasculaire, Saint Etienne, France

Background: Superficial vein thrombosis (SVT) is perceived as a common and not entirely benign disease, managed by both general practitioners and vascular physicians.[1] Deep vein thrombosis (DVT) affects approximately 6–12 persons per 10,000 per year and Pulmonary embolism (PE) 3–6 per 10,000 per year, yet the incidence of SVT is still unknown.
Aims: To assess, in an unselected population and a well-defined geographic area, the annual incidence of symptomatic SVT of the lower limbs associated or not with concomitant symptomatic DVT and/or symptomatic PE.
Methods: A cross-sectional study was conducted for 1 year, involving the entire 265,686 residents of the urban area of Saint-Etienne, France, aged 18 years or older.
For each clinical suspicion of SVT, a standardized questionnaire was completed by the general practitioner and/or the vascular physician. Compression ultrasonography was systematically performed by the vascular physician in order to confirm SVT and to check for the existence of concomitant DVT. Each clinical suspicion of concomitant PE had to be confirmed by spiral computed tomography or high probability ventilation/perfusion lung scan. Based on these data, outcomes were validated by an independent adjudication committee. This protocol was approved by the ethical committee of the University Hospital of Saint-Etienne. All patients were informed of the study, however, no written consent was required.
All vascular physicians of the predefined area participated in this study. All general practitioners of this area were informed of the study and asked to refer any patient with clinically suspected SVT to a vascular physician in order to perform compression ultrasonography, as recommended in the latest ACCP guidelines.
Annual incidence rates (per ten thousand) were calculated as the number of cases of SVT occurring during the study period divided by the population of the predefined area aged 18 years or more. Ninety-five percent Confidence Intervals (CI) were also calculated. The frequencies of concomitant DVT and/or PE and their 95% CI were estimated.
Results: Between November 14, 2011 and November 13, 2012, a total of 175 patients had confirmed SVT. The incidence rate of symptomatic confirmed SVT was 6.6 per 10,000 per year (PY) (95% confidence interval [CI]: 5.6–7.6). Among them, 43 (24.6%; 95% CI: 18.4–31.6) were associated with concomitant DVT (of which 21 were proximal), and 8 (4.6%; 95% CI: 2.0–8.8) were associated with concomitant PE, all confirmed by spiral computed tomography.
Conclusion: Incidence of SVT is sizeable. It appears to be between the incidence of DVT and that of PE.

Exploring decisions to withhold diagnostic investigations in Dutch nursing home patients with a clinical suspicion of venous thromboembolism: a mixed method study

Schouten HJ, Koek HL, Kruisman-Ebbers M, Geersing GJ, Oudega R, Kars MC, Moons KGM and Van Delden JM
University Medical Center Utrecht, Utrecht, The Netherlands

Background: Imaging investigations can contribute to improved outcomes in patients with suspected venous thromboembolism by increasing the probability of the appropriate diagnosis and subsequent guidance of appropriate treatment-decisions. However, attendance of a hospital and undergoing diagnostic investigations can be burdensome for frail older patients. Therefore, many physicians would prefer to confirm or refute diagnoses without referring their frail older patients for additional diagnostic investigations.
Aims: To explore decisions to withhold additional diagnostic investigations in nursing home patients with a clinical suspicion of venous thromboembolism.
Methods: A mixed-method study was performed. The frequency of decisions to forgo diagnostic investigations was established with a cross-sectional observational study in nursing homes in the Netherlands on diagnostic strategies for elderly patients with a suspicion of venous thromboembolism. Patient characteristics, bleeding-complications and mortality were related to the decision to withhold investigations. For a better understanding of the physicians' decisions, 21 individual face-to-face in-depth interviews with elderly care physicians were performed and analysed by two researchers using the grounded theory approach.
Results: Referal for additional diagnostic investigations was forgone in 104/268 (38.8%) patients with an indication for diagnostic work-up. 'Blind' anticoagulant treatment was initiated in 79 (76.0%) of these patients. Patients in whom investigations were withheld were older and mortality and major-bleedings occurred more often within 3 months, compared to the referred patients (respectively 83.8 vs. 80.9 years; 34.0% vs. 18.2% and 6.7% vs. 1.2%). In their decisions to forgo diagnostic investigations, elderly care physicians estimated the proportionality of investigations: Considering the impact of the potential disease given the patients' burden and prognosis of chronic diseases, physicians estimated the benefits of the diagnostic investigation for the patient. This was balanced against the considered burden and risks of the diagnostic investigation and whether performing investigations agreed with established management goals in advance care planning. As a result of their decisions to forgo diagnostic investigations ('non-diagnosis decisions'), physicians were left with diagnostic uncertainty which they managed by acceptation of the possible consequences of the potential disease.
Conclusions: Referral for additional diagnostic investigations is commonly withheld in Dutch nursing home patients with a clinical suspicion of venous thromboembolism. Patients in whom investigations were withheld had higher mortality- and bleeding rates than referred patients. Physicians mainly based their decisions on their judgment concerning the proportionality of the investigation. Given the worse

outcomes of the non-referred patients and complexity of the decisions, more attention for decisions concerning withholding diagnostic investigations in older patients with suspected venous thromboembolism is needed.

PA 4.16-5

Prevalence of pulmonary embolism in patients with syncope

Barbar S, Filippi L, Di Pasquale I, Noventa F, Bilora F, Pesavento R and Prandoni P

Second Chair of Internal Medicine; University of Padua, Padua, Italy

Background: The clinical features of pulmonary embolism (PE) are extremely variable. While fainting or syncope has been reported to occur in up to 25% of patients with PE, the prevalence of PE among patients with syncope is unknown.
Aims: The primary study outcome was to assess the prevalence of PE in a large series of consecutive patients presenting with the first episode of syncope.
Methods: All patients with the first episode of transient and short-lasting loss of consciousness, consecutively referred to our Department in a 20-month period, had a diagnostic workup for the assessment of the most common causes of syncope, and were evaluated for the presence of PE with the use of an internationally accepted algorithm including a pre-test clinical probability (PTP according to the method of Wells et al.) and a high-sensitivity quantitative D-dimer assay. If the PTP was low and D-dimer was negative, PE was excluded. All other patients underwent confirmatory diagnostic tests (either computerized tomography or ventilation/perfusion lung scanning). A written informed consent was obtained from all patients. The study was approved by the local ethics committee.
Results: Among 201 eligible patients, 177 met the inclusion criteria. The mean age was 75 ± 14 years: 78 (44.1%) were males. In 100 (56.5%) no clear explanation for the loss of consciousness could be identified. One hundred and five patients (52.2%) had low PTP and negative D-dimer. Among the remaining 72 patients with high PTP and/or positiveD-dimer, PE was detected in 23. They all belonged to the group of 100 (23.0%) patients presenting with apparently unexplained syncope. Hence, the prevalence of PE in our series of unselected patients with syncope was 13.0% (95% CI, 8.0–17.9). This proportion became 23.0% (95% CI, 15.2–32.5) when confined to patients with unexplained syncope, and increased up to 31.9% (95% CI, 21.4–44.0) in patients with high PTP and/or positive D-dimer. All patients with PE-related syncope received conventional anticoagulation and had a favourable outcome.
Conclusions: Pulmonary embolism can account for up to 18% of all patients presenting with the first episode of syncope, up to 33% of those with unexplained syncope, and up to 44% of patients with high PTP and/or positive D-dimer. Accordingly, the occurrence of this life-threatening complication should be promptly investigated in all patients with syncope, especially in those with an apparently unexplained episode.

PA 4.16-6

Performance of five clinical decision scores to rule out pulmonary embolism in primary care: a validation study

Hendriksen J, Geersing GJ, Oudega R, Hoes AW, Moons KGM and AMUSE Study Group

University Medical Center Utrecht, Utrecht, The Netherlands

Background: Multiple clinical decision rules (CDRs) have been developed to help physicians to rule-out pulmonary embolism (PE) in a hospital based setting. These CDRs are used (combined with D-dimer testing) to identify low-risk patients where PE can be safely excluded without referral for spiral CT scanning. Such a rule-out approach seems ideal for primary care, where most suspected patients are first evaluated. Yet, validation studies of these CDRs are altogether lacking, for a primary care domain.
Aims: To assess the ability to safely rule-out PE using five available CDRs (i.e. original and simplified Wells, revised and simplified revised Geneva, and Charlotte Rule) in suspected patients in primary care.
Methods: We prospectively collected data in primary care, including all items needed to calculate the score of all five CDRs. Patients were eligible for inclusion if the participating general practitioners (GPs, $n = 300$) had a suspicion of acute PE. A qualitative D-dimer test (Clearview Simplify) was performed by the GPs. All patients were subsequently referred to secondary care. Confirmation of the final diagnosis was based on a composite reference standard, including spiral CT scanning and 3 months of follow-up in primary care. Sensitivity and specificity, efficiency (defined as proportion of patients at low risk) and safety (proportion of patients with PE in this low risk category) of all CDRs (combined with a negative D-dimer) were calculated. A clinical calibration plot of each CDR (i.e. a graph in which the score of the CDR is plotted against the observed outcome of PE) was created.
Results: We included 598 patients with suspected PE in primary care (mean age 48 years, 71% females). PE prevalence was 12%. Sensitivity of the CDRs without D-dimer testing was low (range 52–88%), except for the Charlotte Rule (93%). In combination with a D-dimer test, sensitivity increased: range 88–96%. The efficiency of all rules combined with negative D-dimer testing was good and comparable (range 44–48%), except for the Charlotte Rule (low efficiency; 17%). Both the Wells and the Charlotte rule had an acceptable low failure rate (range 1.2–1.5%) whereas the Geneva rules had higher failure rates (range 2.7–3.1%). Visual inspection of the calibration plots showed good calibration (i.e. the higher the score, the higher the probability of indeed having PE) for the two Wells scores, whereas this was not the case for the Geneva rules.
Summary/Conclusions: PE can be safely excluded in primary care, notably using the original and simplified Wells CDR combined with qualitative D-dimer testing. Using these rules leads to an efficiency of around 40% and an acceptable low failure rate of below 2% in primary care. Hence, using such a rule-out approach, PE can be excluded in primary care in about four in every 10 suspected patients.

Increased levels of nucleosome in human plasma in septic patients with DIC

Kawasugi K, Yamamoto T, Oka Y, Shirasaki R, Akiyama N and Shirafuji N

Teikyo University School of Medicine, Tokyo, Japan

Sepsis-related DIC is a life-threatening condition that is characterized by a whole-body inflammatory state (called a systemic inflammatory response syndrome, SIRS). Histones are essential for packing DNA into the cell nucleus and also play role in regulating gene expression but our study (last ISTH) have shown histones released into blood stream at the onset of sepsis-related DIC. However, western blot analysis is necessary for the detection of blood histone, and a result is not easily given. On the other hand, the nucleosome including histone is easily measurable by ELISA. Therefore, we measured the nucleosome in the sepsis-related DIC patient ($n = 15$) by ELISA (Cell Death Detection ELISA). Also, we investigated the nucleosome in the plasma from septic patients without DIC ($n = 5$). At the same time, extracellular histones in the plasma were examined by western blot analysis for histone H3 (H3).
The thrombin antithrombin complexes (TAT) levels were higher in septic patients with DIC as reported by others. We detected high levels

of nucleosome in the plasma of all septic patients with DIC by EISA. Also we recognized high levels of extracellular hisotones (H3) in the plasma of all septic patients with DIC by western blotting. However, in five septic patients without DIC, blood nucleosome became positive in two cases weakly, but was negative in three cases. Furthermore, in a sepsis-related DIC patient, blood nucleosome became negative when DIC was improved. Moreover, high-mobility group box 1 (HMGB1) concentrations in the human plasma were determined using ELISA kit (Shino-Test, Japan). Plasma levels of HMBG1 were negative for two cases in 10 septic patients with DIC. Also, Plasma levels of HMBG1 were negative in septic patients without DIC.
It was suggested that nucleosome in the plasma increased in the septic patients with DIC. Also these results suggest that assess of nucleosome in the plasma may be helpful in the making the diagnosis in septic patients with DIC.

PA 4.17-2

Dysregulation of inflammatory and hemostatic markers in sepsis associated disseminated intravascular coagulation

Fareed J[1], Tsuruta K[2], Hoppensteadt D[1], Mosier M[1], Osawa Y[2] and Kaul I[2]

[1]Loyola University Medical Center, Maywood, IL; [2]Asahi Kasei Pharma America Corporation, Waltham, MA, USA

Background: Disseminated intravascular coagulation (DIC) represents a complex pathophysiologic syndrome where marked alterations in the hemostatic system are manifested. As a result several inflammatory mediators are up regulated through multiple mechanisms.
Aims: The up regulation of inflammatory mediators such as anaphylatoxin C5a (C5a), procalcitonin (PCT), interleukin 6 (IL-6), interleukin 10 (IL-10), myeloperoxidase (MPO), C reactive protein (CRP), and circulating levels of hemostatic markers including protein C inhibitor (PCI), plasminogen activator inhibitor 1 (PAI-1), and protein C (Pr C) were evaluated in 741 subjects enrolled in a randomized, double-blind, placebo-controlled, Phase-2B study evaluating the safety and efficacy of recombinant thrombomodulin (ART-123) in subjects with sepsis and suspected DIC.
Methods: Thirty healthy male and female volunteers served as the control group. Commercially available ELISA methods PAI-1, AT and PrC (Diagnostica Stago, Parsippany, NJ), MPO (Assay Design, Ann Arbor, MI), IL-6 and IL-10 (R&D Systems (Minneapolis, MN), C5A (BD Biosceince, Franklin Lakes, NJ), CRP (Hyphen-Biomed, France), PCT (Brahms, Germany) and PCI (Technoclone, Austria) were used to measure the various mediators. Marked deviations in the circulating levels of these markers, as compared to controls, were observed.
Results: Subjects with sepsis associated DIC showed an increase in the circulating levels of most inflammatory markers. The percentage change from the normal controls of PCT (↑14.515%), IL-6 (↑6584%), CRP (↑1737%), IL-10 (↑836%), MPO (↑575%) and C5a (↑85%) where considerably higher in the DIC subjects whereas PCI (↓39%), Pr C (↓45%) and AT (↓42%) exhibited slight decreases. Wide individual variations were present. The PAI-1 (↑ 297%) levels were also increased in the DIC subjects.
Conclusion: These results clearly indicate that inflammation and impairment of fibrinolysis play a key role in the pathogenesis of sepsis associated DIC.

PA 4.17-3

Thrombin generation mediators and markers in sepsis associated coagulopathy and their modulation by recombinant thrombomodulin

Hoppensteadt D[1], Tsuruta K[2], Cunanan J[1], Hirman J[2], Kaul I[1], Osawa Y[2] and Fareed J[1]

[1]Loyola University Medical Center, Maywood, IL; [2]Asahi Kasei Pharma America, Waltham, MA, USA

Background: Severe sepsis remains the most common cause of death in critically ill patients and thrombin plays a crucial role in the pathogenesis of sepsis associated disseminated intravascular coagulation (DIC).
Aims: The purpose of this study was to profile prothrombin fragment (F1.2), thrombin antithrombin complex (TAT) and D-dimer (DD) throughout the course of hospital stay in subjects identified with sepsis.
Methods: Patients were randomized to receive either thrombomodulin (ART-123) 0.06 mg/kg/day intravenously ($n = 371$) or placebo ($n = 370$), in addition to standard of care for 6 days. Blood samples were drawn for the biomarkers at baseline (day 0), 24 h after the first dosage (day 1), day 3 immediately before the next dosage (day 3 pre) and 24 h after the second dosage (day 3 post) and on days 7 and 14. Plasma samples were analyzed using the commercially available ELISA kits for prothrombin F1.2 complex and thrombin antithrombin complex (Dade Behring Siemens Miami, FL) and Asserachrome D-dimer (Stago, Parsippany, NJ).
Results: Administration of ART-123 resulted in a decrease in F1.2, DD and TAT levels. This decrease in F1.2 and DD was significantly different ($P < 0.001$) between treatment groups for days 1, 3 and 7. The TAT levels were significantly different from the placebo group on days 1 and 3 ($P < 0.05$) and on day 7 ($P < 0.001$)
Conclusion: While the data was widely scattered, these results show that DIC represents a hypercoagulable state along with other hemostatic abnormalities and the activation of the inflammatory process. Modulation of these activation processes through such targets as DD, F1.2 and TAT may play an important regulatory role in the pathogenesis of sepsis associated coagulopathy. Moreover, this study validates the hypothesis that thrombomodulin down regulates the thrombin generation mediators/markers in sepsis associated DIC.

PA 4.17-4

DIC and DIC in septic shock: myth or reality? (Why clinical trials failed to improve survival.)

Delabranche X[1], Berger A[1], Lerolle N[2], Macchi L[2], Schenck-Dhif M[1], Grunebaum L[1], Mootien Y[3], Kouatchet A[2], Lavigne T[1] and Meziani F[1]

[1]Les Hôpitaux Universitaires de Strasbourg, Strasbourg Cedex; [2]CHU d'Angers, Angers; [3]CH de Mulhouse, Mulhouse, France

Background: For many years, in critically ill patients, DIC acronym has both significations: disseminated intravascular coagulopathy and death is coming. Many experimental studies point out the pivotal role of deregulated thrombin generation in the development of multiple organ failure and death.
Aims: To evaluate DIC scoring systems and clinician ability to diagnose DIC.
Methods: Two hundred and sixty-five patients with septic shock admitted in three French intensive care units were prospectively included in this observational study. DIC was diagnosed using ISTH 2001 'overt' and 'non overt' scores and JAAM 2006 score (reference score as specifically developed in critically ill patients). 'Non overt' score included antithrombin. Twelve clinicians unrelated to this study were asked for DIC diagnosis in 45 patients. After a 3-mounths period they were informed about DIC scores and asked a second time for the same patients. Statistical analysis uses k score to evaluate coherence between DIC scores and between clinicians and JAAM.

Results: DIC was present in 102 (38.5%), 92 (34.7%) and 91 (34.3%) patients according to JAAM, ISTH 'overt' and 'non overt' scores respectively. Nevertheless, k were 0.78 (JAAM/'overt'), 0.70 (JAAM/'non overt') and 0.69 ('overt'/'non overt') and only 50 patients were classified in DIC group by the three scores.
Clinicians poorly diagnosed DIC (k = 0.504 ± 0.115 [range: 0.305–0.728]) and only one used ISTH 'overt' score. In the second evaluation test, *k* was not significantly different despite scores supply. Clinicians did not calculate scores, or calculate 2 or 3 scores and were not able to make a choice. JAAM and 'non overt' were more frequently used by clinicians.
Mortality was not different regarding DIC diagnosis ($P = 0.053$, hazard ratio for no DIC 0.65 [0.43–1.01]). Then, we separate the 265 patients in three groups according to JAAM score and related haemostasis activation/deregulation: 1–2 (minimal, $n = 128$), 3–4 (intermediate, $n = 54$) and 5–8 (patent, $n = 83$). Patients in the third groups were more severely ill (SAPS2 and SOFA), had higher incidence of acute renal failure and renal replacement therapy requirement ($P < 0.05$) and 28-days mortality ($P = 0.006$, hazard ratio for no DIC 0.53 [0.30–0.75]). Prothrombin fragments 1 + 2 were increased regardless group confirming high thrombin generation in all septic patients, but fibrin monomers were higher and protein C lower in patients with higher JAAM scores (5–8). In multiple logistic regression models, only platelets count and D-dimers were associated with DIC diagnosis.
Summary/Conclusions: DIC remains difficult to diagnose without a rigorous scoring system and clinicians failed to recognise these patients. Moreover, mortality was not correlated with DIC but with JAAM score ≥ 5. A lower value was not associated with organ failure or mortality and targeted antithrombotic treatment would probably be inefficient if not deleterious as reported in large-scale randomised clinical trials with anticoagulants (TFPI, antithrombin and activated protein C) and one could suggest that only patients above this cut-off would be improved by specific therapies.

PA 4.17-5
New diagnostic strategy of sepsis induced disseminated intravascular coagulation (DIC)

Kawano Y, Ishikura H, Nishida T, Mizunuma M, Yuge R, Ichiki R, Hoshino K and Murai A
Fukuoka University, Fukuoka City, Japan

Background: Inflammation and coagulation are interrelated pathophysiologic processes that considerably affect each other. And various biomarkers such as proinflammatory cytokines, chemokines, adhesion molecules, tissue factor expression, platelet and endothelial activation are closely concerned with the complex interactions between inflammatory response and coagulopathy. However, there are different diagnostic criteria in sepsis and disseminated intravascular coagulation (DIC).
Aims: This study were to establish the diagnostic criteria of sepsis induced DIC.
Methods: A single center, prospective, observational study was carried out. Patients who had one or more systemic inflammatory response syndrome (SIRS) criteria were included in this study. The blood samples for measuring the markers were collected at the time of admission. Eighty two patients were enrolled for this prospective study from June 2010 to June 2011.
Results: Forty two patients (51.2%;42/82) were sepsis, severe sepsis or septic shock at the time of registration. In the receiver operating characteristics (ROC) analysis, the area under the curve (AUC) to distinguish sepsis was the highest for Procalcitonin (PCT) (0.91) followed by Presepsin (0.89), IL-6 (0.89), and CRP (0.84) as inflammatory biomarkers ($P < 0.0001$). Additionally, the AUC to distinguish sepsis was the highest for Protein C (PC) (0.83) followed by Thrombomodulin (TM) (0.81), Antithrombin (AT) (0.81) as coagulation biomarkers ($P < 0.0001$).
Logistic regression analysis that included PCT, Presepsin, IL-6, and CRP as inflammatory biomarkers identified only Presepsinlevel as independent predictor of the Japanese Association for Acute Medicine (JAAM) DIC and the optimal cut-off value was 899 pg/mL, and that included PC, TM, and AT as coagulation biomarkers that PC was only a predictor of JAAM DIC and the optimal cut-off value was 55%. On the other hand, the optimal cut-off value of sepsis in Presepsin and PC were 647 pg/mL and 47% respectively.
In the ROC analysis using both of Presepsin and PC, the AUC to distinguish sepsis and JAAM DIC were 0.911 and 0.913 respectively.
Summary/Conclusion: From these results, we defined the new diagnostic criteria of septic DIC which named sepsis induced DIC (SEDIC) as follow; Presepsin level > 900 pg/mL and PC < 45%. We strongly believe that this diagnostic criteria is very simply and useful.

PA 4.17-6
Heparin inhibits extracellular histones-induced HUVEC apoptosis

Mo X[1], Wang F[2] and Cao Q[2]
[1]The Institute of Pediatric Translational Medicine; [2]Shanghai Children's Medical Center, Shan, Shanghai, China

Background: Sepsis is a potentially deadly medical condition characterized by a whole-body inflammatory state caused by severe infection, and its progression to disseminated intravascular coagulation (DIC) or multiple organ dysfunction syndrome (MODS) is a major cause of death in PICU. It has recently been shown that extracellular histones are major mediators of death in sepsis.
Aims: We aim in this study to explore whether extracellular histone level could serve as diagnosis indicator for sepsis severity and what can be used as potential treatment is not known.
Methods: We first determined the histone concentration in patients' plasma, and then investigated *in vitro* the impact of extracellular histones on HUVEC, the underlying mechanism and potential treatment.
Results: In the present study, we have found that plasma histone level in sepsis patients ($n = 33$) is much higher than control samples ($n = 30$), and the concentration is correlated with sepsis severity (i.e., patients with MODS have much higher plasma histone level than those without MODS), suggesting that extracellular histone level may be an indicator of sepsis progression. Consistently, treatment of HUVEC with histones in PBS or serum-free media dose-dependently induces HUVEC apoptosis, which starts as early as 15 min after treatment. Further studies have demonstrated that histone-induced HUVEC apoptosis depends on Toll-like receptors 2 and 4. Addition of fetal bovine serum (FBS) or human plasma to HUVEC significantly alleviated HUVEC apoptosis, suggesting that certain component(s) in serum could protect HUVEC from apoptosis against extracellular histones, consistent with the phenomenon that normal people could tolerate low dose extracellular histones in plasma without developing any syndrome like sepsis. More importantly, treatment of HUVEC with heparin, which is allowed to be used as clinical treatment in China, completely inhibits histones-induced apoptosis, strongly suggesting that heparin could be used as potential treatment in sepsis patients.
Summary/Conclusion: In summary, our studies clearly suggest that extracellular histone level could serve as an indicator of sepsis severity, and heparin may be routinely used in sepsis treatment.

Venous thromboembolism risk assessment with a multilocus genetic risk score

Soria JM[1], Vila J[2], Morange PE[3], Souto JC[4], Salas E[5], Tregouet DA[6], Mateo J[4], Pich S[5], Elosua R[2] and Soria JM[4]
[1]Institut d'Investigació Biomèdica Sant Pau; [2]IMIM, Barcelona, Spain; [3]Inserm, UMR1062, Aix-Marseille University, Marseille, France; [4]Hospital de la Santa Creu i Sant Pau; [5]Gendiag.Exe, Barcelona, Spain; [6]UMR_S 937, Paris, France

Background: In the development of venous thromboembolism (VTE) genetics contribute in a relevant manner. In clinical routine the presence of two mutations Factor V Leiden (FVL) and G20210A Prothrombin (PT) are analysed to evaluate this genetic contribution. However, new and relevant genetic variants have been associated with VTE. Though these genetic variants have not been properly validated neither translated to clinical practise.
Aim: To evaluate whether the use of Genetic Risk Scores (GRS) with these new variants provides a better assessment of the VTE risk than a model based only on FVL-PT.
Methods: Three panels of genetic variants were compared: FVL + PT; TIC panel (FVL, PT, ABO group A1 carriers, FV Cambridge, FV Hong Kong, rs2232698 SerpinA10 gene, rs121909548 SerpinC1 gene, 46C>T F12, and rs5985 F13 gene); and TIC panel plus F11 (TIC panel, rs2289252 and rs2036914 in F11 gene). All these variants influence the coagulation pathway.
For each panel a multi-locus GRS was computed for each individual as the sum of the number of risk alleles, after weighting them by its effect size published in the literature. The GRS was validated in two case-control studies. MARTHA: 1150 cases (347 males, 803 females; 38.0 ± 13.9 years old), 801 controls (383 males, 418 females; 47.4 ± 14.0 years old) designated to assess the association of FVL and PT with other risk factors; and Sant Pau (SP): a study with Spanish population with 249 cases (111 males, 138 females; 47.1 ± 14.0 years old), 248 controls (109 males, 139 females; 49.0 ± 14.9 years old).
All models were adjusted by age and sex. The predictive capacity was assessed by the discrimination of the different GRS calculating the c-statistic (AUC-ROC); and by the reclassification when using the new GRSs compared with FVL + PT calculating the NRI (net reclassification improvement) and IDI (integrated discrimination improvement). Informed consent was obtained and the studies were approved by recognised ethics committees.
Results: When compared to FVL + PT, the use of TIC or TIC + F11 panels significantly improved the capacity to discriminate VTE in both populations (AUC-ROC: 0.57 vs. 0.68 and 0.67 respectively, in SP and 0.56 vs. 0.57 and 0.58 respectively, in MARTHA population,). When compared to the risk stratification by FVL+PT, only the use of TIC panel improved the capacity to reclassify both cases and controls in both populations (NRI, 19.2, $P < 0.005$ and 4.9, P-value > 0.05, IDI 5.5, $P < 0.001$ and 3,2, P-value < 0.01 for TIC panel vs. FVL+PT in SP and MARTHA populations, respectively). Moreover, clinical sensitivity (number of cases where a genetic thrombophilia was demonstrated) increases very significantly in relation to FVL + PT (19.7% and 50.4% of the cases for FVL + PT, 87.3% and 95.1% for TIC in SP and MARTHA populations, respectively). TIC + F11 did not further improve the reclassification.
Conclusions: TIC panel significantly improves the predictive capacity of VTE risk, by improving discrimination and reclassification when compared to FVL + PT. Thus, our study suggests that the use of algorithms with a set of confirmed susceptibility loci (TIC) improves disease risk assessment and could be also an aid in the prevention, diagnosis and treatment of VTE disease.

PA 4.18-2

Incidence and risk factors for venous thromboembolism (VTE) amongst adults with sickle cell disease

Wun T, Brunson A, Lei A and White R
UC Davis School of Medicine, Sacramento, CA, USA

Background: Sickle cell disease (SCD) is caused by mutations in the ß-globin gene. Morbidity is due to vascular occlusion and hemolytic anemia. Recent studies suggest increased risk of VTE in SCD patients.
Aim: To examine the association between SCD and VTE.
Methods: Using the California Patient Discharge Dataset and Emergency Department Utilization database, we found adult (18–65 years) cases with SCD in the years 1990–2010. Using unique record linkage numbers, these cases could be followed longitudinally over serial admissions. We then determined incident VTE. To determine the odds ratio (OR) for VTE associated with SCD, each SCD case was matched with five non-SCD controls for race/ethnicity, sex, age (± 2), and year of index admission (± 2). Conditional logistic regression was then performed. To determine risk factors predictive for VTE within the SCD cohort, OR were determined for sex, disease severity, age (5 year increments), race, and co-morbidities. The effect of VTE on death in SCD patients was determined using matched (1:4) Kaplan-Meier (K-M) survival curves, stratified by disease severity (≥ 3 admissions or ED visits/yr or < 3 visits/year), and analyzed by log-rank.
Results: There were 4280 unique adult cases with SCD; mean age 28 years (± 10.5), 91% were African American, and 56% female. Forty-two percent had severe disease. Overall there were 361 incident VTE (185 PE; 172 DVT; four both) for a cumulative incidence of 8.4%. Forty-six percent of these events occurred within 30 days of an antecedent hospitalization or ED visit. Compared to non-SCD controls, SCD patients had an overall OR of 5.9 (5.1–7.0) for VTE; the OR was 3.8 (3.0–4.8) for less severe and 9.5 (7.5–12.1) for severe disease patients. Co-morbidity also increased the odds of VTE: OR 1.8 (1.5–2.5) for 1–2 co-morbidities vs. none; 3.0 (2.2–4.1) for ≥ 3 conditions. Amongst SCD patients, female sex (OR 1.4; 1.1–1.8) and severe disease (OR 1.9; 1.5–2.5) were associated with increased risk of VTE, adjusted for age, race, and co-morbidities. The median K-M survival for SCD patients that developed VTE was 149 months and had not been reached for SCD without VTE ($P < 0.0001$, log-rank). For severe SCD patients with VTE the median survival was 105 months and had not been reached for non-VTE matched patients ($P < 0.0001$). Less severe patients had not reached median survival, but the mean survivals (± SE) were 118 months (± 5.9) and 195 months (± 2.7) for VTE and non-VTE, respectively ($P < 0.0001$)
Conclusions: SCD is associated with an increased risk of VTE compared to a matched population that also required hospitalization. Nearly half the incident VTE occurred within 30 days of a previous hospitalization or ED visit. This suggests painful episodes, which are inflammatory events and the most common reason SCD patients seek medical attention, as a provocation for VTE. Relative immobilization may also play a role, and argues for robust thromboprophylaxis in hospitalized SCD patients. In contrast to other populations, females had increased OR for VTE. As shown for other populations with chronic diseases, incident VTE in SCD patients was associated with decreased survival.

PA 4.18-3

Replication and meta-analysis of the association between F11 genetic variants and the risk of incident venous thrombosis by statin use

Harrington LB[1], Wiggins KL[1], Sitlani C[1], Blondon M[1], Van Hylckama Vlieg A[2], Rosendaal FR[2], Heckbert SR[1], Psaty B[1] and Smith NL[1]

[1]University of Washington, Seattle, WA, USA; [2]Leiden University Medical Center, Leiden, The Netherlands

Background: Two *F11* single nucleotide polymorphisms (SNPs), rs2289252 and rs2036914, are known to be associated with the risk of incident venous thrombosis (VT). Statin use may be associated with a decreased risk of VT and may modify the association of the *F11* SNPs with VT risk.

Aims: To better inform the possibility of a drug-gene interaction associated with the risk of VT by presenting new findings from the Seattle HVH data and meta-analyzing with MEGA findings. We hypothesized that statin use would diminish the VT risk associated with the SNP risk alleles.

Methods: In the HVH population-based study, we identified cases of incident VT occurring from 1995 to 2009 and their matched controls. Participants with cancer were excluded. Genotypes for rs2036914 were available for 747 cases and 1721 controls; genotypes for rs2289252 were available for 693 cases and 3112 controls. Current statin use was determined using prescription fills. Separate logistic regression models for the two SNPs estimated the risk of VT associated with carrying the risk allele, stratified by statin use, adjusted for matching variables: index year, age, hypertension, sex, and race. Results were meta-analyzed with MEGA study findings.

Results: HVH cases and controls had an average age of 63 and 66 years, respectively; 74% of cases and 95% of controls were women. Statins were used by 16% of cases and 20% of controls. For rs2036914, in HVH, statin users who carried 1 or 2 C alleles had an increased risk of VT compared with carriers of TT alleles (OR = 1.7, 95%CI: 1.0–2.8, and, OR = 2.2, 95%CI: 1.1–4.6, respectively). Among non-users of statins, ORs for carriers of 1 or 2 C alleles were 1.3 (95%CI: 1.0–1.7) and 1.3 (95%CI: 0.9–1.8), respectively. There was no evidence of interaction between the SNP and statin use. For rs2889252, in HVH, statin users who carried 1 or 2 T alleles had no evidence of an associated VT risk compared with carriers of CC alleles (OR = 1.1, 95%CI: 0.6–1.9, and, OR = 1.4, 95%CI: 0.6–2.9, respectively). Among non-users of statins, ORs for carriers of 1 or 2 T alleles were 1.2 (95%CI: 1.0–1.5) and 1.5 (95%CI: 1.1–1.9), respectively. There was no evidence of interaction.

Meta-analyzed results for rs2036914 suggested no difference in risk between statin users (OR = 1.6, 95%CI: 1.1–2.3 for 1 C allele, and, OR = 1.5; 95%CI: 0.9–2.4 for 2 C alleles) and non-users (OR = 1.3, 95%CI: 1.2–1.5 for 1 C allele, and OR = 1.7, 95%CI: 1.5–1.9 for 2 C alleles). For rs2889252, meta-analytic results suggested modest differences in risk between statin users (OR = 1.1, 95%CI: 0.8–1.5 for 1 T allele, and, OR = 1.2, 95%CI: 0.7–2.0 for 2 T alleles) and non-users (OR = 1.3, 95%CI: 1.2–1.5 for 1 T allele, and, OR = 1.8, 95%CI: 1.6–2.0 for 2 T alleles).

Summary/Conclusion: Replication results were less pronounced than discovery results. In meta-analyzed results, risk of VT by rs2036914 genotype did not appear to differ by statin use. Risk of VT associated with rs2889252 appeared to be modestly blunted among statin users, compared to among non-users, for those carrying the risk allele.

PA 4.18-4

Height and risk of venous thromboembolism: a mendelian randomization study

Smith EN[1], Braekkan SK[2], Carson AR[1], Jepsen K[1], Matsui H[1], Wilsgaard T[3], Harismendy O[1], Frazer K[1] and Hansen JB[2]

[1]University of California, San Diego, La Jolla, CA, USA; [2]University Hospital of North Norway; [3]University of Tromsø, Tromsø, Norway

Background: Height has been identified as a risk factor for venous thromboembolism (VTE), but it is unclear whether the relationship is causal or explained by confounding factors. Mendelian randomization studies can be used to investigate causal relationships underlying observed associations between exposure (height) and outcome (VTE) in epidemiological studies. Because genetic risk influences height, but is unaffected by environmental confounders, a significant association would provide evidence that height is causally related to VTE, whereas a lack of association indicates that the relationship is due to unrecognized confounding factors.

Aims: We wanted to investigate the association between a genetic score for height and risk of VTE.

Methods: We utilized genetic sequence data generated through exome sequencing. Cases who had a first VTE (n = 407) and age- and sex-matched controls (n = 406) were identified from a population-based, nested, case-cohort study (the Tromsø study) comprising 78% (n = 27,158) of the adult residents of Tromsø in Norway. Exome sequencing was performed to an average depth of approximately 100× in exome regions and approximately 0.5× in non-targeted regions. Utilizing on and off-target reads, genome-wide SNP genotypes were inferred by imputation using Beagle. We calculated a weighted height genetic score using independent markers previously identified in a large GWAS study, taking into account the original effect estimate and the imputation quality. The genetic score was tested for association with VTE case status. In addition, a previously published case-control study of VTE (N = 2596) was used to replicate these findings. The study was approved by the regional committee for research ethics, and all participants gave their informed written consent to participate.

Results: Imputation of the exome data using the 1000 Genome Project European haplotypes resulted in effective estimation of genotypes for 120 of the 180 SNPs recently identified as associated with height. We recapitulated the association between height and VTE (OR = 1.31 for a 10 cm difference, P = 0.008) after adjustment for age and sex. We also showed that the established height genetic score was associated with height (R^2 = 0.04, 2.6 cm difference between upper and lower halves, $P = 4 \times 10^{-13}$). However, we did not observe a significant association between the height genetic score and risk of VTE. Thus, the height genetic score did not explain the relationship between height and VTE. Similar analyses using the GENEVA VTE study showed consistent results.

Conclusions: These results do not provide support that the association between height and risk of VTE is causal, but suggest that the effect could be mediated by other confounding factors. Due to the small amount of variation that the genetic score explains, our finding may be limited by power and would benefit from confirmation in a larger study.

PA 4.18-5

Not all factor V Leiden or prothrombin G20210A mutations are equal: results from a retrospective cohort family study

Bucciarelli P[1], De Stefano V[2], Passamonti SM[1], Ciminello A[2], Legnani C[3], Tormene D[4], Castaman G[5] and Martinelli I[1]

[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan; [2]Institute of Hematology, Catholic University, Rome; [3]University Hospital S. Orsola-Malpighi, Bologna; [4]University Hospital of Padua, Padua; [5]San Bortolo Hospital, Vicenza, Italy

Background: Factor V Leiden (FVL) and G20210A prothrombin gene mutation (PT20210) are risk factors for venous thromboembolism (VTE). In family studies the risk of VTE in relatives heterozygous or homozygous for FVL or PT20210 might be influenced by either the genotype or the clinical presentation of the proband. This risk might be higher in relatives selected from kindreds with heterozygous symptomatic probands than in those belonging to kindreds with homozygous asymptomatic probands, because in the former case the proband is symptomatic despite a lower risk of thrombosis is expected with heterozygous than homozygous mutation.

Aims: To assess whether or not the selection of kindreds according to genotype and clinical presentation of the proband influences the risk of VTE in relatives.

Methods: A retrospective cohort family study of 192 kindreds with at least one member with homozygous FVL or PT20210 were collected in five Italian centers, for a total of 886 relatives [380 males, 506 females; median age 39 years (IQR: 25–54 years); 129 heterozygous PT20210, 378 heterozygous FVL, 36 homozygous PT20210, 101 homozygous FVL, 38 combined heterozygous, 204 wild-type]. The proband of the family was heterozygous for FVL or PT20210 in 69 kindreds and homozygous or combined heterozygous in 123. Twenty-three probands were asymptomatic, 11 had had arterial thrombosis, seven obstetrical complications, and 151 venous thrombosis (29 superficial and 122 VTE). According to the genotype and clinical presentation of the proband, the study population was divided into four groups: relatives belonging to kindreds with (i) homozygous proband without VTE (reference), (ii) homozygous proband with VTE, (iii) heterozygous proband without VTE, and (iv) heterozygous proband with VTE. For each group, the annual incidence of VTE (and its 95% CI) was calculated. The follow-up started at the date of birth and ended at the date of either the first VTE or the first visit to the centers. The hazard ratio (and 95% CI) for VTE in each group compared to the reference was estimated by using a multivariable Cox's proportional hazard model, with adjustment for a possible confounding effect of age, sex, type of genetic defect and genotype of the relatives.

Results: A total of 27 objectively-documented episodes of VTE during 34,966 patient-years of follow-up were recorded, for an overall incidence rate of 0.77 × 1000 patient-years (95%CI:0.48–1.06). Twelve episodes of VTE were unprovoked (44%) and 15 (56%) secondary to transient risk factors. Excluding probands, the incidence of VTE (×1000 patient-years) in relatives was higher when the proband had heterozygous than homozygous mutation [1.22 (95%CI:0.71–1.86) vs. 0.45 (0.20–0.79)], and when the proband had had VTE instead of other clinical presentations [0.95 (0.57–1.42) vs. 0.50 (0.19–0.96)]. Compared to the reference group, the adjusted hazard ratio of VTE for relatives from kindreds with heterozygous proband with VTE was 3.97 (95% CI:1.12–14.09).

Conclusion: Both the genotype and the clinical presentation of probands influence the VTE risk in relatives with FVL or PT20210. This index event bias can in part explain the different risk of VTE in family members with the same genetic defect.

PA 4.18-6

Association of ABO blood type with cognitive decline: the REasons for Geographic and Racial Differences in Stroke Study

Alexander K[1], McClure L[2], Wadley V[2], Unverzagt F[3], Zakai N[1], Gillett S[1], Callas P[1] and Cushman M[1]

[1]University of Vermont, Colchester, VT; [2]University of Alabama at Birmingham, Birmingham, AL; [3]Indiana University, Bloomington, IN, USA

Background: ABO blood group is associated with many forms of cardiovascular disease, including stroke, coronary heart disease and venous thromboembolism. This is likely due, in part, to the link between non-O blood groups and higher levels of the procoagulant proteins von Willebrand factor and factor VIII (FVIII). Many cardiovascular disease risk factors have been identified as also contributing to cognitive decline, but there are currently no published data on the relationship between ABO group and cognitive decline.

Aims: To study the association of blood types A, B, AB, and O with cognitive decline in the REasons for Geographic and Racial Differences in Stroke (REGARDS) study.

Methods: The REGARDS cohort consists of 30,239 black and white US individuals ≥ 45 years old, enrolled between 2003 and 2007, with 4.5 years follow up for cognitive function. Incident cases of cognitive decline were defined based on longitudinal scoring using three cognitive domain tests: list learning, list recall, and verbal fluency. ABO blood group was measured by SNP genotyping in a case-control sample of 495 cognitive decline cases and 587 controls. The odds ratios for cognitive decline by ABO status were calculated using logistic regression models, with blood group O as the reference group. All models were adjusted for age, sex, and race. FVIII was then added to this model as a continuous variable to examine its contribution to any observed associations. Because blacks have a higher stroke risk and differing blood group frequencies than whites, an interaction term between race and blood group was tested, with an interaction $P < 0.10$ considered statistically significant.

Results: All non-O blood groups showed significantly higher levels of FVIII compared with the O group (mean 104; 95% CI 100–107), with the highest level seen in type AB (mean 142; 95% CI 126–202). Blood group AB was associated with incident cognitive decline in a model that included age, race, and sex (OR 1.78; 95% CI 1.13–2.81), while blood groups A and B showed no association. When FVIII was added to the model, every 40 IU/dL higher FVIII was associated with cognitive decline (OR 1.22; 95% CI 1.08–1.37) and the odds ratio for group AB was reduced to 1.67 (95% CI 0.99–2.83). There was no significant difference in AB blood group association by race (P interaction = 0.95).

Summary: Blood group AB was associated with incidence of cognitive decline in this prospective study. This relationship was only partially mediated by FVIII. These data support the hypothesis that while blood group may impact cognitive function through its effects on FVIII levels, differences in the ABO glycosyltransferase that determines ABO blood group are likely to affect the glycosylation of other proteins, which may alter cognitive decline risk.

PA4.19 – TTP/Thrombotic Microangiopathies – II

PA 4.19-1

International registry for patients with hereditary thrombotic thrombocytopenic purpura (TTP) – upshaw-Schulman syndrome

Mansouri Taleghani M[1], Fujimura Y[2], George JN[3], Hrachovinova I[4], Lämmle B[1], Knoebl P[5], Quist-Paulsen P[6], Schneppenheim R[7] and Kremer Hovinga JA[1]

[1]Bern University Hospital and University of Bern, Bern, Switzerland; [2]Nara Medical University, Kashihara, Japan; [3]University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA; [4]Institute of Hematology & Blood Transfusion, Prague, Czech Republic; [5]Medical University of Vienna, Vienna, Austria; [6]St Olavs Hospital Trondheim University Hospital, Trondheim, Norway; [7]University Medical Center Eppendorf, Hamburg, Germany

Background: Hereditary TTP, or Upshaw-Schulman syndrome (USS), is a rare, and recessively inherited disorder, due to homozygous or compound heterozygous mutations in the ADAMTS13 gene located on chromosome 9q34. TTP has a wide variation in clinical presentation from only mild thrombocytopenia to severe recurrent TTP episodes leading to end organ damage or even death. The first occurrence of USS is variable with onset in the neonatal period up to older age. Due to the rareness of hereditary TTP evidence based guidelines on prophylaxis with different ADAMTS13 sources such as fresh frozen plasma and knowledge of long-term outcome are lacking, which emphasizes the need of a multicenter cooperation.

Aims and Method: An electronic database system for USS patients and their interested family members (www.ttpregistry.net, ClinicalTrials.gov NCT01257269) has been established to gather baseline information and in patients long-term follow-up data. They contain the clinical courses, therapeutic as well as prophylactic treatment regimens and performed laboratory investigations in order to identify yet unknown triggers of TTP episodes and factors influencing the clinical course. Eventually this leads to improved treatment and better understanding of this potentially fatal disease.

Eligibility criteria are:

1 ADAMTS13 activity $\leq$ 10% on two separate occasions at least 1 month apart and
2 Absence of a functional ADAMTS13 inhibitor and
3 $\geq$ 2 ADAMTS13 gene mutations and/or a positive infusion trial (full recovery and plasma half life of 2–3 days of infused plasma) or
4 Being a family members of a confirmed patient.

Information is collected retrospectively up to enrollment as well as prospectively every 12 months and when acute TTP episodes occur. Analysis of ADAMTS13 related parameters including molecular analysis of the ADAMTS13 gene are free of charge to patients and their family members.

Results: Today, 30 participants from eight different countries (CH, CRO, CZ, NOR, PL, ESP, TU, USA) have been entered into the database and another eight countries (AUT, CAN, D, DAN, FIN, IND, IL, JP) have confirmed their participation with 1 to over 40 patients per study site. The data acquisition is in progress. A first point of interest is the investigation of episodes of thrombocytopenia during infections or pregnancies in a number of obligatory or confirmed heterozygotes, so far generally reported as being asymptomatic.

Conclusion: The international network and knowledge platform established to exchange information and experience on USS will help to improve diagnosis, treatment and prevention of acute episodes in affected patients. All Physicians are invited to contact us for diagnostics and enrollment of their patients with USS.

PA 4.19-2

Measurement and prevalence of circulating ADAMTS13-specific immune complexes in autoimmune thrombotic thrombocytopenic purpura

Lotta LA[1], Valsecchi C[2], Pontiggia S[2], Mancini I[2], Artoni A[2], Mikovic D[3], Trisolini S[4] and Peyvandi F[2]

[1]Angelo Bianchi Bonomi Hemophilia and Thrombosis Center; [2]Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico, Milan, Italy; [3]Blood Transfusion Institute of Serbia, Belgrade, Serbia; [4]Università "La Sapienza", Rome, Italy

Background: Autoimmune thrombotic thrombocytopenic purpura (TTP) is a thrombotic microangiopathy characterized by the presence of autoantibodies against the von Willebrand factor cleaving-protease, ADAMTS13. The formation of non-covalent antigen-autoantibody associations in the bloodstream (i.e. circulating immune complexes, CIC) occurs and is a pathophysiologic mechanism in several autoimmune disorders. CIC have a wide range of properties, including complement-system and leukocyte activation, which may promote inflammation and cellular damage in autoimmune conditions. Although autoimmune TTP is an autoantibody-mediated disease, the role of ADAMTS13-specific CIC in TTP has not been studied.

Aims: The goals of our study were (i) to develop a method to assess the presence of and quantify ADAMTS13-specific CIC in patients with autoimmune TTP and (ii) to evaluate the prevalence and the association of CIC with ADAMTS13- and anti-ADAMTS13-related measurements in patients with autoimmune TTP.

Methods: We developed an ELISA method for the detection of ADAMTS13-specific CIC. The linearity and specificity of the assay were validated by experiments including immunoprecipitation of CIC from normal and TTP plasma. Intra- and inter-assay coefficients of variation were calculated to assess the precision of the method. We measured ADAMTS13-specific CIC by ELISA in 36 patients with autoimmune TTP from the Milan TTP Registry (URL:http://www.ttpdatabase.org/) who had anti-ADAMTS13 autoantibodies at the time of measurement (acute disease for 15 and remission for 21 patients). Measurements were carried out in duplicate and results were expressed in optical density units (OD) standardized for a positive control. The cutoff for the presence of anti-ADAMTS13 CIC was defined as the 99th percentile of the distribution of normalized OD in 22 control subjects. The associations between ADAMTS13-specific CIC levels and ADAMTS13 activity, ADAMTS13 antigen and anti-ADAMTS13 IgG levels were assessed by linear regression.

Results: The anti-ADAMTS13 CIC ELISA test had intra- and inter-assay coefficients of variation of 5.3 and 9.6. The 36 patients with TTP included in the study had a median age at study measurement of 41 years (interquartile range [IQR]: 34–52 years) and were predominantly of female sex (n = 30, 83%). All 36 patients had severely deficient ADAMTS13 activity (< 10% of normal), a median value of ADAMTS13 antigen of 24% (IQR: 13–45%) and a median level of anti-ADAMTS13 IgG of 20% (IQR: 6–48%). The median normalized OD of ADAMTS13-specific CIC measurement was 0.37 (IQR: 0.28–0.45). The prevalence of CIC in TTP patients was 47% (n = 17; 95% confidence intervals [CI]: 32–63%). The normalized OD value was not associated with ADAMTS13 activity, ADAMTS13 antigen or with anti-ADAMTS13 IgG levels. In patients with acute TTP at measurement, increasing levels of ADAMTS13-specific CIC were associated with higher number of plasma exchange procedures required to attain remission (per 0.1 increase in normalized OD values, beta: 2.9; 95% CI: −0.7 to 6.5).

Summary/Conclusions: Approximately one half of patients with autoimmune TTP display ADAMTS13-specific CIC. Levels of ADAMTS13-specific CIC measured by this ELISA method are not associated with ADAMTS13 or anti-ADAMTS13 IgG levels. A thorough investigation of the prognostic relevance of ADAMTS13-specific CIC levels in patients with autoimmune TTP is warranted.

PA 4.19-3

Sequelae of chronic relapsing idiopathic thrombotic thrombocytopenic purpura

Falter T, Alber K and Scharrer I

Universitätsmedizin Mainz, Mainz, Germany

Background: ADAMTS13 (a disintegrin and metalloproteinase with TSP-1-like domains) cleaves high molecular and prothrombotic von Willebrand factor (VWF) multimers into smaller molecules. Severely decreased levels of ADAMTS13 are in most cases caused by autoantibodies but also in rare cases by mutations leading to thrombotic thrombocytopenic purpura (TTP). Different trigger factors contribute to the clinical manifestation of TTP. These life-threatening acute episodes alternate with relatively symptom-free phases of remission. Acute episodes are characterized by consumptive thrombocytopenia, hemolytic anemia and spontaneous VWF-platelet aggregation leading to microvascular thrombus formation in arterioles and capillaries of different organs. The brain is frequently affected inducing different neurological abnormalities of varying severity. Further typical symptoms are bleedings, gastro-intestinal complaints, fever and hematuria, chest pain and weakness. Without treatment, TTP may result in many cases in deterioration and death. Presently, plasma exchange is still the mainstay therapy, often combined with immunosuppressive drugs. Aim of therapy is to achieve a persistent remission with complete recovery characterized by normal physical condition and regular laboratory data for platelets, hemoglobin and lactate dehydrogenase.
Aims: Aim of the study was to investigate risks of persisting neurocognitive impairments as well as anxiety and depression in consequence of relapsing idiopathic TTP.
Methods: Sequelae of 20 idiopathic TTP patients were analyzed by means of different questionnaires, medical records and reports.
The medical records/reports come either from a psychiatrist or from the TTP-treating hematologists and have been collected from first manifestation until now.
Three different standardized questionnaires were used. The questionnaire IRES (developed by Gerdes and Jäckel) was used as an indicator for rehabilitation; HADS/D evaluates anxiety and depression; mental performance was examined by the questionnaire for complaints of cognitive disturbances (FLei).
Results: Ten of 20 patients have been treated due to depression, and many of them need psychological help. One patient has been under inpatient psychiatric treatment. Furthermore, many patients complain of anxiety disorders. As a result of depression and anxiety disorders, these patients suffer from general fatigue, exhaustion, lag of drive, adjustment disorders, social anxiety disorder and chronic insomnia.
Neurocognitive impairments including brain-fag syndrome, lack of concentration, amnesic aphasia and dysphasia, disturbance of long-term and short-term memory occur frequently, as well.
Two patients are afflicted with epilepsy, a sequelae of stroke. Four patients developed renal insufficiency. Many of the patients suffer from side effects of cortisone and further immunosuppressive drugs, especially from Cushing's syndrome, cortisone acne, overweight, osteopenia and alopecia.
Most of the patients stated to be living seclusively and to possess only a reduced quality of life. They emphasized problems in their daily life, social communication and relationships. Their professional life is impaired to the point of a temporary or permanent disability.
Summary: Altogether TTP-patients recover well from their acute phase with regard to physical examination results and laboratory data, despite low ADAMTS13 activity and high inhibitor titer.
However, many of them suffer from neurocognitive impairments, anxiety disorders and depressions. As a result, they have to cope with a permanent restriction of their daily routine in private as well as in professional life.

PA 4.19-4

Characterization of hereditary thrombotic thrombocytopenic purpura (TTP) from one of blood centers in China

Bai X, Su J, Cao L, Yu Z, Wang Z and Ruan C

Jiangsu Institute of Hematology First Affiliated Hospital of Soochow University, Suzhou, China

Background: Hereditary thrombotic thrombocytopenic purpura (TTP) is characterized by abnormally disseminated thrombus due to the mutations of ADAMTS13, which can cleave its substrate von Willebrand factor (VWF) in normal conditions.
Aims: To characterize the clinical and genetic molecular features of ten patients with congenital TTP.
Methods: ADAMTS13 activities were analyzed by residual collagen binding assay (R-CBA) plus FRET-VWF substrate. And the inhibitors of ADAMTS13 were analyzed by 9:1 mixture of patient and pooled normal plasma followed by R-CBA. The intracellular location and secretion of recombinant ADAMTS13 mutants were studied.
Results: Ten patiens, among whom, eight patients with pregnancy aged between 25 and 31 years old and one girl aged 16 years old plus one male aged 39, were diagnosed with congenital TTP because their ADAMTS13 activities were < 5% (both R-CBA and FRET-VWF substrate) and absence of ADAMTS13 inhibitors. The following mutations were found in these patients, which included: R193W, R1095W, R349C, R498C, R692C, Y177C, E1005V, C265Y, M1260-S1264, Nt:1335G(Del), Nt:3677C(Del), Nt: 1435 + 2insG. In addition to the previously reported mutation of R498C, all the novel missense mutations (including C265Y, E1005V, Y177C) had the impaired secretion and retained in the HEK293 cells.
Conclusion: Among ten patients registered in our institution, eight patients were pregnant women, which implies that it may be necessary to screen ADAMTS13 activity in pre-pregnancy checkup for TTP prophylaxis.

PA 4.19-5

Safety and efficacy of cryosupernatant as a replacement fluid for plasmapheresis in thrombotic thrombocytopenic purpura: a single center restrospective evaluation

Stefanello B, De Paula EV, Orsi FA, Marques-Junior JFC, Roveri EG, Colella MP, Ozelo MC, Annichino-Bizzacchi JM and Addas-Carvalho M

INCT do Sangue Hemocentro Unicamp (University of Campinas), Campinas, SP, Brazil

Background: Thrombotic thrombocytopenic purpura (TTP) is a severe systemic disease caused by decreased activity of ADAMTS13, resulting in reduced clearance of ultra-large VWF multimers and thrombotic microangiopathy. Treatment of TTP is based on daily plasmapheresis (Px) with replacement with fresh frozen plasma (FFP), aiming to reestablish normal ADAMTS13 activity and VWF multimer distribution. Cryosupernatant (CSP), the remaining of a FFP unit after the removal of cryoprecipitate, is a plasma product with lower concentrations of large VWF multimers and similar amounts of ADAMTS13. It has been hypothesized that CSP might be preferable replacement fluid for Px in TTP patients. CSP is at least as efficacious as FFP in the treatment of TTP, but evidence of additional benefits has not been demonstrated, as showed in a meta-analysis of three randomized clinical trials comparing FFP with CSP. Besides, none of these studies reported on the frequency of adverse events of using CSP.
Aims: To evaluate the efficacy of Px in patients with TTP treated with CSP or FFP and the safety of either option.
Methods: In our center, both CSP and FFP are available as replacement fluid for Px, being the choice between these two options

performed before the 1st session at the assistant physicians'discretion. Once initiated, only one type of replacement fluid was used until the 1st remission. We retrospectively evaluate the efficacy of Px with either product based on the number of sessions, volume of plasma product exposure and frequency of acute exacerbations and relapses. In addition, we evaluated the safety of either option by reporting the frequency and nature of adverse events.

Results: From June 2007 to October 2012, 14 patients with newly diagnosed TTP were treated at our center. The proportion of CSP:FFP use was 5:9. There were no significant differences in age, ethnic background, initial platelet count, hemoglobin levels, LDH, or etiology of TTP (idiopathic × secondary) between groups. Regarding efficacy, we observed a trend towards a higher median number of Px sessions (15 vs. 7) and higher plasma exposure in CSP, compared to FFP-treated patients. Although the number of relapses was not significantly different between groups, acute exacerbations were more frequent among patients treated with CSP than FFP. Regarding safety, the frequency of adverse reactions was not different between CSP or FFP-treated patients. Mild allergic reactions were the most common treatment-related adverse event in both groups.

Summary: Our results confirm the lack of benefit of using CSP as a replacement fluid in TTP compared to FFP. In addition, our data raises the possibility that in newly diagnosed TTP, CSP use might be associated with worse outcomes, as evidence by a higher frequency of acute exacerbations during the 1st 30 days, and a trend towards a higher number of Px sessions and higher exposure to plasma products. Considering that obtaining large volumes of CSP to treat TTP requires special logistic actions and increases treatment costs, our data corroborate the concept that CSP should not be used as 1st line treatment of TTP.

PA 4.19-6

In vitro characterisation of two ADAMTS13 mutants (I143T, Y570C) identified in two patients with congenital thrombotic thrombocytopenic purpura (TTP)

Underwood M[1], Garagiola I[2], Mackie IJ[1], Machin SJ[1], Metin A[3], Gurgey A[4] and Peyvandi F[5]

[1]University College London, London, UK; [2]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [3]Ankara Children's Hematology Oncology Training and Research Hospital; [4]Hacettepe University, Ankara, Turkey; [5]Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, University of Milan, Milan, Italy

Background: Congenital TTP is a heterogeneous condition with respect to age of disease onset and need for plasma exchange/infusion. ADAMTS13 genetic defects have been identified in congenital TTP patients. Although over 100 mutations have been identified, only about 30% have been expressed *in vitro* and of these, the majority (84%), lead to reduced (< 50%) secretion of mutant recombinant ADAMTS13.

Aims: Two mutations present in different congenital TTP patients were studied *in vitro* for their effects on the secretion and sub-cellular location of ADAMTS13, in order to investigate the contribution of ADAMTS13 genotype to disease phenotype.

Methods: Two ADAMTS13 missense mutations (I143T, Y570C) were introduced into wild type (WT) ADAMTS13-cDNA separately by site directed mutagenesis and used for subsequent transient transfection of HEK 293T cells. The presence of WT or mutant ADAMTS13 within cell supernatant and lysates was investigated using western blotting. The quantity of protein in cell supernatant was measured using an antigen ELISA assay and the activity measured by FRET assay (detection limit 2.5%). Expression of the mutant proteins was compared to that of WT (assigned a value of 100%). Localisation of the WT and mutant proteins was investigated in the endoplasmic reticulum (ER) and Golgi by confocal microscopy.

Results: Both patients presented with acute TTP during adolescence having undetectable ADAMTS13 activity and antigen in plasma and receive regular prophylactic plasma exchange. Patient 1 was homozygous for the mutation I143T (metalloprotease domain) and patient 2 for the mutation Y570C (spacer domain). *In vitro* both mutants were detected within cell lysates, at a slightly greater quantity than WT. However in the supernatant the quantity of each mutant secreted was either undetectable ($n = 3$) or very low (2% of WT, $n = 1$). In both cases no ADAMTS13 activity could be detected. Confocal microscopy showed that both mutants localised within the ER ($n = 3$) and the Golgi ($n = 6$).

Conclusion: In conclusion *in vitro* expression of the I143T and Y570C ADAMTS13 mutants demonstrated a severe secretion defect. This correlates with the undetectable ADAMTS13 activity and antigen present in the patient's plasma. Within the cell both mutants localised within the ER and Golgi suggesting a potential defect in the transport from the Golgi to the extracellular environment. Further investigation is underway in order to determine if these mutants are degraded within the cell by the cell proteasome or lysosomes before they can be secreted.

Platelet adhesion to collagen under flow conditions is increased in essential thrombocythemia patients

Vignoli A[1], Van der Meijden PEJ[2], Giaccherini C[1], Swieringa F[2], Marchetti M[1], Ten Cate H[2], Heemskerk JWM[2] and Falanga A[1]

[1]Hospital Papa Giovanni XXIII, Bergamo, Italy; [2]Cardiovascular Research Institute Maastricht, Maastricht University, Maastricht, The Netherlands

Background: Essential thrombocythemia (ET) is a myeloproliferative neoplasm characterized by high incidence of both arterial and venous thromboembolic events. The acquired activation of vascular cells, particularly leukocytes and platelets, has been previously demonstrated in ET patients and suggested to promote the development of thrombosis.

Aim: This proof-of-principle study aimed to assess whether the increased activation of platelets from ET patients may lead to an increase in their thrombus formation potential *in vitro* under flow conditions.

Methods: Nine ET patients (mean platelet count 755×10^9/L, range 240–1409) and nine healthy control subjects (mean platelet count 244×10^9/L, range 216–323) were enrolled into the study after informed consent. Peripheral venous whole blood samples, withdrawn in sodium citrate, were recalcified and anticoagulated with heparin and perfused over a collagen coated surface at a shear rate of 1000/s. Platelet adhesion and thrombus formation was evaluated after 4 min with the EVOS fluorescence microscope system. In particular, platelets were stained with an anti-CD2P (P-selectin)-FITC antibody as an index of platelet activation, and annexinA5-Alexa Fluor 647 that provides a measure of platelets exposing a procoagulant surface (namely phosphatidylserine). After staining, images of adherent platelets in random fields were taken using phase contrast and fluorescence imaging. Results are expressed as mean ± SD of the percentage of area covered by all or fluorescently-labeled platelets.

Results: After 4 min of blood perfusion, the area covered by adherent platelets was found significantly greater in ET patients compared to healthy controls (38.7 ± 5.1 vs. 20.4 ± 3.1% coverage, $P < 0.05$). No statistically significant correlation between platelet count and percentage of coverage was found. However, in the four ET patients with a platelet count > 700×10^9platelet/L, the% coverage was significantly higher compared to the five ET patients with a platelet count < 700×10^9platelet/L (i.e. 54.9 ± 17.5 vs. 25.8 ± 11.3% coverage, respectively, $P < 0.05$). Similarly to what observed with the overall adherent platelets, the area covered by P-selectin positive platelets was significantly ($P < 0.05$) higher in ET patients vs. controls. On the

contrary, the coverage by annexinA5-positive adherent platelets was not statistically significantly different between ET patients and controls.

Conclusions: These preliminary results show that, compared to healthy subjects, blood from ET patients has an increased tendency of shear-dependent platelet adhesion at a collagen surface, indicative of a greater thrombus formation capacity, without increase in platelet-dependent coagulation. These results support an active role of platelet adhesiveness in the prothrombotic state of patients with ET. A possible influence of the patients' characteristics and treatment type is also under evaluation.

PA 4.20-2

The shear rate dependence of nitric oxide inhibition of platelet aggregation

Sylman JL[1], Lantvit SM[2], Reynolds M[2] and Neeves KB[1]

[1]Colorado School of Mines, Golden, CO; [2]Colorado State University, Fort Collins, CO, USA

Background: The concentration of nitric oxide (NO) at an injury site and how it affects platelet function under flow is poorly defined. For example, reports of the NO concentrations necessary to inhibit platelet aggregation vary widely in the literature (5 nM–4 μM) (Marcondes et al., *PNAS*, 103, 2006). The signaling pathway of NO inhibition is also a source of debate. It is generally accepted that NO inhibition occurs primarily through soluble guanylyl cyclase (sGC)/cyclic guanosine monophosphate (cGMP)-dependent pathways (Dangel et al., *JTH*, 8, 2010). But, recent studies suggest that cGMP-independent mechanisms may also mediate inhibition at millimolar NO concentrations (Zhang et al., *Blood*, 118, 2011).

Aims: The first aim was to identify the shear rate dependent regulation of platelet aggregation by NO at a controlled NO wall flux. The second aim is to determine the relative role of sGC dependent and independent pathways.

Methods: A NO-releasing polymer containing an NO donor, dialkyldiamine-based diazeniumdiolated, was used to control the wall flux of NO into a whole blood flow assay. The NO flux from the polymer was determined by chemiluminescence. Whole blood collected by venipuncture into FPR-chloromethylketone (PPACK), was treated or not treated with the sGC inhibitor 1H-[1,2,4]oxadiazolo[4,3-a]quinoxalin-1-one (ODQ) and perfused at 200, 500, and 1000/s over type I fibrillar collagen adsorbed to the NO-releasing polymer. The accumulation of fluorescently labeled platelets and volume of the resultant platelet aggregates was recorded by confocal microscopy. A computational model was developed to estimate the near wall NO concentration as a function of NO flux and shear rate.

Results: The NO-releasing polymer films produced fluxes ranging from 0.07×10^{-10} to 12×10^{-10} mol/cm^2/min, above and below reported fluxes from cultured endothelial cells (Vaughn & Kuo, *AJP*, 274,1998). A NO flux of 2.5×10^{-10} mol/cm^2/min was found to abrogate platelet aggregation, but not initial adhesion, on collagen at 200 and 500/s as effectively as the $\alpha_{2b}\beta_3$ antagonist abciximab. The dynamic range of NO fluxes found to induce measurable inhibition of platelet aggregation spanned from 0.33×10^{-10} to 2.5×10^{-10} mol/cm^2/min at 200 and 500/s. These fluxes correspond to near-wall NO concentrations of 230–2200 nM based on a computational model of NO transport. Preliminary studies show that a sGC independent mechanism may be shear rate dependent.

Conclusions: A NO-emitting material was built into a flow assay for quantitatively measuring platelet function as a function of NO flux and shear rate. NO begins to attenuate the height of the thrombus at approximately 230 nM, which interestingly corresponds to the equilibrium dissociation constant of sGC (Stone et al., *Biochemistry*, 35, 1996). At 1.5 μM NO, platelet aggregation was completely inhibited. Even at the highest NO concentration, platelet were able to adhere to collagen, suggesting that NO does not affect GP1b-VWF and GPVI-collagen interactions. We are in the midst of measuring the relative importance of sGC dependent and independent pathways under flow.

Angiogenesis and permissiveness to invasion in the human endometrium: role of anticoagulant heparan sulfate distribution during the cycle and in tumorigenesis

De Agostini AI[1], Bouchet N[2], Filipe A[2] and Tille J-C[1]

[1]Geneva University Hospital; [2]Geneva University, Geneva, Switzerland

Background: Anticoagulant heparan sulfate (aHS) is present in blood vessel walls where its anti-protease activity is thought to limit tissue remodeling and confer stability to the vessels. Preliminary evidence in rodent ovary suggests that aHS are downregulated during angiogenesis. In human uterus, the endometrium undergoes constant remodeling under hormonal control during the estrous cycle, with elongation of blood vessels. Angiogenic factors, like VEGF induce vascular permeability and fibrin deposition in vessel walls serving as provisional pro-angiogenic matrix. Downregulation of endothelial aHS could facilitate fibrin formation. Endometrial carcinoma is a frequent cancer with variable clinical outcome for which currently available markers have limited predictive value of tumor aggressivity. aHS could serve as marker of tissue stability and the abundant aHS present in follicular fluid could modulate tissue invasion in the endometrium.

Aim: Study aHS distribution in normal endometrium and in endometrioïd cancer to reveal if modulations of aHS expression occur during the cycle and in cancer.

Methods: We study normal human endometrium during the estrous cycle and endometrioïd carcinoma grade G1, with approval of the local ethics committee.

Endometrium sections are stained with Alexa^{488}-coupled probes, Anti-thrombin for detection of aHS and endothelial markers CD-31 and D2-40 for blood and lymphatic vessels.

Results: During the menstrual cycle, aHS is present in blood and lymphatic vessels and in basement membranes of surface and glandular epithelium. Vascular aHS is present and does not vary during the cycle and the vessel numbers remain stable in the endometrium. In contrast, epithelial aHS is downregulated in superficial layers of the endometrium during the secretory phase.

In endometrioïd carcinoma, aHS is suppressed to undetectable levels, in the endometrial epithelium but also in the vasculature, as well as in tumoral tissue.

Conclusion: During endometrial regeneration in the proliferative phase, angiogenesis occurs by elongation of existing vessels involving minimal changes in the vessel walls and no alteration of aHS. In the secretory phase, aHS disappearance from the endometrial epithelium corresponds to the implantation window, during which the embryo invades the maternal endometrium. In endometrioïd cancer, the complete absence of aHS indicates active tissue plasticity. These data support our hypothesis that aHS is expressed in stable vascular and epithelial walls and is downregulated during tissue remodelling, angiogenesis and tumor invasion. Further experiments are underways to correlate the mechanisms of implantation and cancer invasion with the disappearance of aHS.

Deep vein thrombus formation induced by flow reduction in mice is determined by venous side branches

Brandt M[1], Schönfelder T[1], Schwenk M[2], Becker C[2], Jäckel S[1], Walter U[1], Massberg S[3], Münzel T[4], Von Brühl M-L[5] and Wenzel P[1]

[1]Center for Thrombosis and Hemostasis, University Medical Center Mainz; [2]Department of Dermatology, CTH, University Medical Center Mainz, Mainz; [3]German Heart Center, Munich; [4]2. Medical Clinic, University Medical Center Mainz, Mainz; [5]German Heart Center and Medical Clinic, Technical University Munich, Munich, Germany

Background: Interaction between vascular wall abnormalities, inflammatory leukocytes, platelets, coagulation factors and hemorheology in the pathogenesis of deep vein thrombosis (DVT) is incompletely understood, pointing to the need to develop well defined animal models of human disease.

Methods and Results: We subjected male C57BL/6 mice to ligation of the inferior vena cava (IVC) as a flow reduction model to induce DVT. Thrombus size and weight were analyzed macroscopically and sonographically by B-mode, pulse wave (pw) Doppler and power Doppler imaging (PDI) using high frequency ultrasound (HFUS). Thrombus size varied substantially between individual procedures and mice, irrespective of the flow reduction achieved by the ligature. Interestingly, PDI accurately predicted thrombus size in a very robust fashion ($r^2 = 0.9734$, $P < 0.0001$). Distance of the insertion of side branches from the ligation suture significantly determines thrombus weight ($r^2 = 0.5597$, $P < 0.0001$) and length ($r^2 = 0.5441$, $P < 0.0001$) in the IVC with distances < 1.5 mm drastically impairing thrombus formation, regardless of the flow measured by pw-Doppler. Occlusion of side branches prior to ligation of IVC did not increase thrombus size, probably due to patent side branches inaccessible to surgery.

Conclusion: Venous side branches influence thrombus size in experimental DVT and might therefore prevent thrombus formation. This renders vessel anatomy and hemorheology important determinants in mouse models of DVT, which should be controlled for.

PA 4.20-5

Human platelet activation/secretion and a membrane-associated urokinase-like activity induce the activation of the latent form of platelet transforming growth factor-β1 (TGF-β1)

Panes O, Gutierrez J, Iruretagoyena M, Brandan E and Mezzano D

Pontificia Universidad Catolica de Chile, Santiago, Chile

Background: TGF-β1, a multifunctional cytokine, plays key roles in many physiological and pathological processes, i.e, cell proliferation and differentiation, immune response and tissue matrix deposition. Platelets store and transport most of the TGF-β1 in the circulation, released it when activated by various agonists. Nearly all platelet TGF-β1 is in its latent, inactive form and requires to be activated for biologic effect. Shear force in the circulation activates platelet TGF-β1; in tissues, proteolytic cleavage appears as a prominent activation mechanism. Plasmin, derived from urokinase activation of plasminogen, is the best known protease with TGF-β1-activating capacity.

Aims: To test if shear-independent platelet activation results in expression of active TGF-β1 and to explore possible mechanisms involved in this process.

Methods and Results: Human, leukocyte-free platelets express TGF-β1 mRNA (RT-PCR) and synthesize the protein (metabolic radiolabeling). A 12 kDa protein, presumably active form, was revealed in platelet membrane fractions of non-stimulated, TRAP and VWF/Ristocetin-stimulated platelets, but not in platelet releasates (Western blotting). Barely visible bands of the 12 kDA protein were observed in cytosolic fractions obtained after centrifuging the membranes. Activated platelets co-incubated (30 min) with human or mice fibroblast cell lines revealed rapid translocations of Smad-2 into fibroblast nuclei (IF of pSmad-2). After 2 h incubation fibroblast CTGF mRNA expression, a pro-fibrotic molecule downstream of TGF-β1, was observed in TRAP > VWF-Ristocetin > Non-activated platelets. Relative CTGF-mRNA expression in VWF-Ristocetin stimulated platelets was equivalent to that of fibroblasts stimulated with 5 ng/mL TGF-β1 and 3-fold higher in TRAP stimulated platelets. This TGF-β1 mediated effect required fibroblast-platelet contact, and was not observed when fibroblasts were cultured only with platelet releasates or in the presence of SB 525324 (specific inhibitor of TGF-β1 receptor kinase activity). Aspirin abolished the effect of TRAP, but not that of VWF-Ristocetin. Induction of CTGF-mRNA expression, independent of the agonist used, was abolished by pre-incubation of platelets with amiloride (urokinase inhibitor), though not by aprotinin (plasmin inhibitor). Synthesis of type I collagen and fibronectin observed in co-cultures (48 h) of human platelets with human or mice fibroblast cell lines was inhibited by SB 525324.

Conclusions: (i) Human platelets activate fibroblast signaling mediated by TGF-β1 present in platelet membrane requiring platelet-fibroblast contact. This activity increases substantially after PAR-1 (TRAP) or GPIbα (VWF-Ristocetin) platelet activation. (ii) Inhibition of platelet thromboxane A_2 synthesis abolishes the potentiating effect of TRAP. (iii) Fibroblast activation can be triggered by a short time (30 min or less) contact with platelets. (iv) An inhibitor of urokinase abolishes the TGF-β1 activity of platelets, suggesting a role for urokinase or plasmin on TGF-β1 activation. However, plasmin inhibition by aprotinin has no effect on TGF-β1 activity. This contrasts with the known activating effect of plasmin on TGF-β1 and needs further elucidation. (v) Our observations support the notion that platelet adhesion and activation by subendothelium components rapidly trigger the cascade of events ending in wound healing. So, platelets would fastly deposit their cargo at the correct site and at the right time.

Plasma levels of intercellular cell adhesion molecule-1 (sicam-1) in elderly with and without Alzheimer disease

Faria MC, Gonçalves GS, Silveira JN and Carvalho MG

Federal University of Minas Gerais, Belo Horizonte, Brazil

Introduction: Alzheimer's disease (AD) is a multifactorial disease and the diagnosis is purely clinical. Discovery of a specific, sensitive and reliable biomarker may be crucial for early diagnosis. Microvascular alterations in the brain have been associated with AD and may precede neurodegeneration. In particular, plasma levels of biomarkers of microvascular lesions such as vascular cell adhesion molecule-1 (sVCAM-1) and intercellular adhesion molecule-1 (sICAM-1) are reported to be increased in AD (Breteler, 2000; Ewers et al. 2009).

Purpose: To evaluate plasma levels of intercellular adhesion molecule-1 (ICAM-1) in elderly patients with Mild Cognitive Impairment (MCI) or with AD, and in elderly individuals without cognitive impairment (controls).

Methods: Participants were selected from University Hospital at the Federal University of Minas Gerais, Brazil, after informed consent by themselves or relatives. Blood samples from a total of 159 individuals, including those with AD ($n = 48$), MCI ($n = 53$) and aged individuals without cognitive impairment ($n = 58$) and then plasma levels of sICAM-1 were measured using an enzyme-linked immunosorbent assay (ELISA – R & D Systems, Minneapolis, MN, USA). The results are shown as medians and interquartile intervals (II = Q3–Q1) and groups were compared using ANOVA and Kruskal Wallis test.

Results: The median value of sICAM-1 found in the control group was 272.95 (II = 102.69) ng/mL; for patients with MCI was 303.24

(II = 146.49) ng/mL and for patients with AD was 356.8 (II = 174.23 ng/mL. Patients in the AD group had values above those ones considered normal for healthy adult individuals (115–306 ng/mL). In the current study, plasma levels of sICAM-1 was shown to gradually increase in the three groups as follows: control, MCI and DA groups ($P < 0.0001$; DA × Control).

Conclusion: The comparison among the three groups showed that the elevated plasma levels of sICAM-1 in DA patients, a biomarker of microvascular injury, seem to be associated with the development of AD, which reinforces the idea that microvascular injury may precede neurodegeneration.

PB1.21 – Antiplatelet Agents: ADP Receptors – II

PB 1.21-1

Evolving pattern of platelet P2Y12 inhibition during maintenance therapy in acute coronary syndrome patients

Joshi R, Hossain R, Morton AC, Ecob R, Judge H, Wales C, Karunakaran A and Storey RF

University of Sheffield, Sheffield, UK

Background: Dual antiplatelet therapy with aspirin and clopidogrel has previously been the standard of care for patients with acute coronary syndromes (ACS) but international guidelines have been evolving over the last 5 years with the introduction of prasugrel and ticagrelor. Prasugrel was approved in October 2009 by NICE in the UK for use in patients with ST-elevation myocardial infarction (STEMI) undergoing primary PCI, diabetics with non-ST-elevation (NSTE) ACS undergoing PCI and patients with stent thrombosis and other ACS patients were to continue receiving clopidogrel. Ticagrelor was approved in October 2011 by NICE for use in patients with moderate-to-high risk NSTE ACS or STEMI undergoing primary PCI and was recommended in preference to clopidogrel in ESC guidelines. These recommendations were adopted in our region, constituting a population of 1.8 million, following each NICE approval.

Aims: To study the effect of changing patterns of $P2Y_{12}$ inhibitor usage on levels of platelet inhibition during maintenance therapy.

Methods: Patients admitted to Northern General Hospital, Sheffield, with NSTE ACS or STEMI managed with primary PCI were enrolled in this study over two periods of time: May 2010–November 2011 (T1); and October 2012–January 2013 (T2). Venous blood samples were obtained at 1 month after the onset of ACS when patients were established on maintenance dual-antiplatelet therapy. Platelet-rich plasma derived from citrate-anticoagulated blood was used for light transmittance aggregometry (LTA) with ADP 20 mM as the agonist and final aggregation response was determined. VASP phosphorylation assay, Multiplate ADP test and VerifyNow P2Y12 assay were also performed. Results were determined as mean ± SD and compared by unpaired t test.

Results: One hundred and sixteen patients were enrolled in T1 of whom 82 were receiving clopidogrel and 34 were receiving prasugrel. Twenty patients were enrolled in T2, all of whom were receiving ticagrelor. All except one patient in the clopidogrel group was receiving low-dose aspirin. Demographic characteristics of the ticagrelor and clopidogrel patients were similar whereas the prasugrel-treated patients had a lower mean age, more often were smokers at ACS presentation and had a greater proportion of STEMI reflecting the recommendations for prasugrel. Mean LTA results according to treatment with clopidogrel, prasugrel and ticagrelor were 50 ± 24%, 37 ± 23%, and 10 ± 8%, respectively. Prasugrel was associated with significantly lower platelet aggregation responses than clopidogrel ($P = 0.006$) and ticagrelor was associated with significantly lower platelet aggregation responses than both prasugrel and clopidogrel (both $P < 0.001$). The results of the other assays showed consistent patterns of $P2Y_{12}$ inhibition.

Conclusions: International guidelines and NICE approval have led to increasing levels of $P2Y_{12}$ inhibition in ACS patients in this UK centre between May 2010 and January 2013. Ticagrelor was associated with significantly greater $P2Y_{12}$ inhibition than both clopidogrel and prasugrel during maintenance therapy.

PB 1.21-2

Comparison of two platelet function analysers in patients having taken clopidogrel and awaiting cardiac surgery: single centre experience in 50 unselected patients

Davidson SJ

Royal Brompton Hospital, London, UK

Background: There is increased bleeding risk associated with continued clopidgrel treatment up to the point of cardiac surgery. Guidelines suggest patients who have been taking clopidogrel should stop for 5–7 days before cardiac surgery to limit the risk of bleeding complications. Approximately 30% of patients do not respond to clopidogrel treatment it is therefore reasonable to assume that these patients would benefit from earlier surgical intervention. There has been a rising demand for platelet function testing of patients that have taken clopidogrel to identify those patients at risk of perioperative bleeding and subsequent reoperation. There continues to be much debate regarding the use of platelet function analysis in patients on antiplatelet therapy and which assays are most appropriate.

Aims: We compared two platelet analysers Multiplate and VerifyNow that have been used in this field to determine results and respective cut-offs for patients going for cardiac surgery with an attempt to identify those with a minimal risk of bleeding due to their antiplatelet therapy and if the results between the two analysers were interchangeable.

Methods: The VerifyNow P2Y12 cartridge (ADP 20 μM) was used for clopidogrel analysis using a single Greiner citrate sample (0.109 M). A single Hirudin sample was taken for Mulitplate analysis using ADP reagent (6.4 μM). Cut-off values for surgery were defined as < 20% inhibition with the P2Y12 VerifyNow assay (therapeutic range > 40%) and values > 45AUC (therapeutic range 0–45AUC) for the Multiplate. Fifty patients awaiting surgery were tested. Our current practice is to use the VerifyNow in this setting. As no extra blood samples were required than would be normally taken this was seen as a service evaluation of best clinical practice requiring no ethical approval. We used Spearman rank correlation to compare the two tests.

Results: The 50 patient samples tested only 47 were suitable for comparative analysis due to errors in three samples on the VerifyNow analyser resulting in no results. Of the 47 patients tested Multiplate results were median 35.5AUC range 2–90AUC, VerifyNow median 23.5% range 0–93%. Of those patients tested with the Multiplate analyser 12 patients would be classed as fit for surgery and using the VerifyNow device 23 patients would be accepted for surgery. There was agreement between the analysers in 22 patients and discordant results in 25 patients. Using the VerifyNow device we would have classified 25.5% of the patients as clopidogrel non-responders and 19% with the Multiplate. Spearman correlation −0.4714 ($P = 0.001$).

Conclusions: There was some disparity of results between the two analysers. Some of this discrepancy is likely due to differences in ADP concentrations used in the tests with 3× greater ADP concentration in the VerifyNow. This may explain why the VerifyNow device appeared to classify more quickly those patients stopping clopidogrel at 3–4 days as having platelet function acceptable for surgery than the Multiplate. This raises the question of which test is suitable in this scenario. This small patient sample highlights the need for further work to be conducted on the appropriate assays used when measuring the effect of antiplatelet drugs.

PB 1.21-3

Clopidogrel therapy has additional inhibitory actions on cyclo-oxygenase and thrombin receptor-mediated pathways in platelets

Ford I[1], Scott N[1], Herd V[1], Mitchell L[1], Williams D[2] and Brittenden J[1]

[1]University of Aberdeen, Aberdeen, UK; [2]Royal College of Surgeons in Ireland, Dublin, Ireland

Background: Clopidogrel in combination with low-dose aspirin is an effective therapy after acute coronary syndromes. The principal mode of action is by irreversible inhibition of the platelet P2Y12 receptor, thereby preventing platelet activation and aggregation by adenosine diphosphate (ADP). Previously published work has suggested that thienopyridines also affect other platelet pathways when tested *in vitro* or at higher than recommended doses.
Aims: To investigate the effects of clopidogrel on other platelet pathways including cyclo-oxygenase and thrombin receptor-mediated pathways during therapy with the recommended therapeutic dose.
Methods: We studied 159 patients with stable coronary artery or peripheral artery disease who were taking part in a randomised controlled trial to investigate clopidogrel rebound. Patients taking 75 mg daily aspirin and statin, were randomised to 75 mg clopidogrel or placebo for 28 days. After informed consent, blood samples were taken for aggregometry with arachidonic acid (AA) and ADP; Fibrinogen binding with ADP or Thrombin receptor activating peptide (TRAP); P-selectin expression with ADP; Verify Now Aspirin; Verify Now P2Y12; and VASP-P, at baseline (aspirin alone), after 28 days on treatment, and at 7, 14 and 28 days after stopping the study medication.
Results: In patients taking clopidogrel plus aspirin there were, predictably, statistically significant decreases on-treatment compared with baseline (aspirin alone), in ADP-induced aggregation, ADP-induced P-selectin, ADP-induced fibrinogen binding, Verify Now P2Y12, and VASP-P (all $P < 0.01$, paired t-test). There were no statistically significant changes in unstimulated platelet P-selectin, fibrinogen binding, or AA-induced aggregation. However, there were statistically significant decreases in Verify Now Aspirin [baseline 436 (407–477) ARU; on-treatment 396 (385–430); median(iqr)] and TRAP-induced fibrinogen binding [baseline 41.8 (38.8–62.1)%; on-treatment 10.6 (4.64–23.4)%]. No significant changes were found in the placebo plus aspirin group. At 7 days after stopping clopidogrel, all parameters had returned to baseline levels [Verify Now Aspirin 7d post 422 (408–467) ARU; TRAP-fibrinogen 7d post 37.4 (25.2–54.8)%]. Values for Verify Now Aspirin and AA-aggregation were consistent with adequate aspirin inhibition in all but two subjects, both of whom were in the placebo plus aspirin group.
Summary/Conclusions: This study shows additional inhibitory effects of clopidogrel therapy on the cyclo-oxygenase and thrombin receptor pathways which could contribute to the drug's antithrombotic actions or towards increased bleeding. Further investigation is required to determine if there is direct antagonism, or whether the observed effects are due to prevention of amplification of aggregation by endogenous ADP.
The study was funded by Heart Research UK, and Ethics approval obtained (NOSRES 08/S0801/087).

PB 1.21-4

The effect of CYP4F2 G1347A polymorphism and of clinical factors on platelet reactivity in patients, treated with dual antiplatelet therapy

Tatarunas V, Kupstyte N, Jankauskiene L, Skipskis V, Kozlovaite V and Lesauskaite V

Institute of Cardiology of Lithuanian University of Health Sciences, Kaunas, Lithuania

Background: Dual antiplatelet therapy by aspirin and clopidogrel is used to prevent recurrent ischaemic heart events after stent implantation, myocardial infarction or in patients with unstable heart disease. Indeed, some patients are 'resistant' to antiplatelet therapy. It has been proved that platelet hyperreactivity is associated with stimulation of platelet surface membrane receptors by epinephrine. Through activation of these (α2 adreno-) receptors, the dense granule secretion is higher and the aggregatory effect of other agonists (such as ADP, collagen, thrombin) can be amplified. There is also a synergistic effect between epinephrine and thromboxane A2, as with the downregulation of autocrine agents (thromboxane A2) the potentiating effect of catecholamines is inhibited. The binding of thromboxane A2 to its target-thromboxane/prostaglandin H2 (PGH2) receptor leads to platelet activation, otherwise, this receptor is inhibited by binding of 20-hydroxyeicosatetraenoic acid, which is produced from arachidonic acid by a member of hepatic P450 enzymes – CYP4F2 monooxygenase.
Aims: The aim of the study was to reveal whether clinical factors and *CYP4F2* G1347A (*rs2108622*) polymorphism had a significant effect on platelet reactivity in patients, treated with aspirin and clopidogrel due to acute coronary syndromes.
Methods: Totally 89 patients, who had been hospitalized due to acute coronary syndromes at the Department of Cardiology, of 2nd Hospital in Kaunas, Lithuania, from September of 2009 to January of 2010 and who continued clopidogrel and aspirin therapy for at least of 14 days, were included into the further study. A standard 75 mg/day clopidogrel and 100 mg/day aspirin doses were prescribed to all of the represented patients. Blood was taken for genetic test and for platelet aggregation. Tests for platelet aggregation and for genotyping were performed in the laboratory of Molecular Cardiology of the Institute of Cardiology of Lithuanian University of Health Sciences. The polymorphism *CYP4F2* G1347A (*rs2108622*) was assessed by using commercial Taqman probes (Applied Biosystems, UK) on ABI 7900HT Fast Real-Time PCR Thermocycler (USA).
This study was done according to the Declaration of Helsinki. Written informed consent was obtained from all patients included in the study. Permission for this study was obtained from Regional bioethics committee of Kaunas (Lithuania) in 2008.11.05. The permission number is BE-2-51.
Results: Platelet aggregation with epinephrine was higher in CYP4F2 GA genotype carriers (56.65 ± 24.46) as compared to GG (46.26 ± 21.53) ($P = 0.04$) or AA (34.42 ± 18.15) ($P = 0.01$) carriers. The frequency of GA, GG, and AA genotype carriers in studied population was 45.5%, 46.6% and 7.9%, respectively. The patients, who used angiotensin-converting enzyme inhibitors ($n = 5$), had lower platelet aggregation induced by epinephrine vs. non-users (28.80 ± 13.25 and 51.15 ± 23.50, $P < 0.03$, respectively).
Summary/Conclusions: CYP4F2 G1347A genotype has an impact on the hyperreactivity and 'resistance' to antiplatelet treatment. The antiplatelet effect of both clopidogrel and aspirin is augmented by concomitant use of angiotensin-converting enzyme inhibitors.

PB 1.21-6

Antiplatelet activity, P2Y1 and P2Y12 inhibition, and metabolism in plasma of diastereomers of the Ap4A analog diadenosine-5′,5‴-P1,P4-dithio-P2,P3-chloromethylenetetraphosphate

Frelinger AL III[1], Chang H[2], Dix EJ[3], Yanachkova M[3], Li Y[4], Barnard R[1], Wright E[3], Michelson AD[1] and Yanachkov IB[3]

[1]Boston Children's Hospital, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA, USA; [2]Chang Gung Memorial Hospital, Chang Gung University, Taipei, Taiwan; [3]GLSynthesis Inc.; [4]University of Massachusetts Medical School, Worcester, MA, USA

Background: Diadenosine 5′,5‴-P^1,P^4-dithio-P^2,P^3- chloromethylenetetraphosphate (Ap(S)pCHClpp(S)A), compound 5, an analog of the naturally occurring platelet dense granule constituent diadenosine

5′,5‴-P^1,P^4- tetraphosphate (Ap_4A), inhibits adenosine diphosphate (ADP)-induced platelet aggregation by inhibiting both platelet ADP receptors, $P2Y_1$ and $P2Y_{12}$. The modifications to Ap_4A in compound five result in chiral centers, giving rise to multiple diastereomers.

Aim: To determine whether the diastereomers of compound five differ in their inhibition of platelet aggregation, $P2Y_1$ and $P2Y_{12}$ function, and stability in plasma.

Methods: Four diastereomers of compound 5 (5.1, S_pS_p; 5.2, $S_pSR_p \equiv R_pSS_p$ or $S_pRR_p \equiv R_pRS_p$; 5.3, $S_pRR_p \equiv R_pRS_p$ or $S_pSR_p \equiv R_pSS_p$; 5.4, R_pR_p.) were separated by preparative RP-HPLC in a pH 7, 20 mM potassium phosphate/methanol buffer system. ADP 3 μM-induced platelet aggregation was evaluated by light transmission aggregation (LTA), $P2Y_{12}$ inhibition by the vasodilator-stimulated phosphoprotein (VASP) phosphorylation assay, and $P2Y_1$ inhibition by changes in cytosolic Ca^{2+} in FLUO-4 loaded platelets. Recovery of the diastereoisomers following 37 °C incubation in plasma was used to determine stability.

Results: The ability of the diastereomers to inhibit LTA and the platelet $P2Y_{12}$ receptor, and their stability in plasma strongly depended on the stereo configuration of the chiral P^1- and P^4-phosphorothioates, the S_pS_p diastereomer (5.1) being the most potent inhibitor and completely resistant to degradation in plasma, and the R_pR_p diastereomer (5.4) being least potent inhibitor and with lowest plasma stability. The inhibitory activity of S_PR_P diastereomers depended on the configuration of the chiral P^2,P^3- chloromethylene group, one of them being significantly more active than the other. Their plasma stability did not differ significantly, being intermediate to that of the 5.1 and the 5.4 diastereomers. The differences between the diastereomers in their inhibitory effect on platelet $P2Y_1$ receptors were less remarkable.

Conclusion: The S_pS_p diastereomer of diadenosine 5′,5‴-P^1,P^4-dithio-P^2,P^3- chloromethylenetetraphosphate (Ap(S)pCHClpp(S)A), compound 5.1, showed greater stability in plasma and greater inhibition of LTA and the platelet $P2Y_{12}$ receptor than other diastereomers of compound 5. These results will be useful for structural and mechanistic studies, development of novel antiplatelet agents that inhibit both $P2Y_1$ and $P2Y_{12}$ ADP receptors, and drugs for the therapeutically important fields of purinergic receptors and ecto-nucleotide pyrophosphatase/phosphodiesterase enzymes.

PB1.22 – Standardizing Platelet Function Tests

PB 1.22-1

A simplified approach to monitoring changes in VASP phosphorylation in platelets and other blood cells

Glenn JR, White AE, Dovlatova N, Heptinstall S and Fox SC
University of Nottingham, Nottingham, UK

Background: Measurement of the degree of phosphorylation of vasodilator-stimulated phosphoprotein (VASP) is used as a surrogate measure for platelet cAMP. Recently we developed a cytometric bead assay for the sensitive and reproducible measurement of VASP-phosphorylation in platelets. This procedure has now been simplified by the development of a one-step solution which lyses, captures and fluorescently labels phosphorylated VASP (VASP-P) in platelets and other blood cells.

Aims: To validate the assay and demonstrate its use as a simple means of detecting the effects of various G_s-coupled agonists on platelets in platelet-rich plasma (PRP) or blood, and of assessing inhibition of the platelet $P2Y_{12}$ receptor.

Methods: Anticoagulated blood or PRP from healthy volunteers was incubated with the appropriate agents (e.g. PGE1, iloprost, ADP) for 5 min at room temperature (final volume 125 μL). An aliquot (5 μL) was removed and mixed with the one-step solution (25 μL). The sample was then incubated for 2 h in the dark at room temperature or frozen and stored at −20 °C for subsequent analysis. Samples were then analysed using a Becton Dickenson LSRII flow cytometer using FACSDiva acquisition software. The results are expressed as median fluorescence (mf).

Results: Values of VASP-P following platelet stimulation appeared to be lower in blood than PRP possibly because of dilution with VASP from other cells. Values were identical when expressed as percentage of maximal VASP-P. A strong linear relationship was obtained between the amount of VASP-P in the sample and the median fluorescence obtained ($R^2 = 0.99$). Intra-assay variation ranged from 1% to 6%, with a mean of 3%. Inter-assay variation ranged from 2% to 9%, with a mean of 6%. The flow cytometric analysis can be performed shortly after venepuncture or the samples stored for analysis at a later date. Once the one-step solution has been added to blood, samples may be stored until it is convenient to analyse them on the flow cytometer. Frozen samples remain stable for at least 2 months. Our approach to determining the effectiveness of P2Y12 antagonists as inhibitors of platelet function involves determining the increase in the level of VASP-P in platelets in blood by adding an agent such as iloprost and comparing this with the level attained with simultaneous addition of ADP. Effective inhibition by a P2Y12 antagonist results in persistence of VASP-P induced by iloprost even in the presence of ADP. Results demonstrate clear effects of the potent P2Y12 antagonist prasugrel or cangrelor with varying effects with clopidogrel depending on the donor used. The assay is not affected by aspirin.

Conclusions: A one-step method of measuring VASP-P in platelets has been identified and validated as described above. This novel assay provides a simple, sensitive, reproducible and flexible method for determination of VASP phosphorylation in platelets.

PB 1.22-2

Simultaneously measuring adenosine triphosphate (ATP) release and light transmission aggregation does not potentiate platelet aggregation in participants with clinically diagnosed bleeding disorders

Lordkipanidze M[1], Lowe GC[2] and Watson SP[2]
[1]University of Birmingham; [2]Birmingham Platelet Group, Birmingham, UK

Background: Current guidelines recommend the use of lumi-aggregometry to simultaneously assess dense granule secretion with platelet aggregation when investigating platelet disorders, as there is evidence that dense granule secretion defects can be misdiagnosed if relying solely on platelet aggregometry. However, a recent publication has suggested that the addition of the commercial reagent Chronolume® to measure ATP release potentiates platelet aggregation responses and may mask a platelet defect in some patients, especially in response to epinephrine (adrenaline) (Thromb Haemost 2012;107:726–34).

Aims: We sought to investigate whether potentiation of platelet responses to epinephrine occurred in a cohort of patients with clinically diagnosed bleeding disorders.

Methods: Participants with clinically diagnosed excessive bleeding and healthy volunteers were recruited to the Genotyping and Phenotyping of Platelets study (GAPP, ISRCTN 77951167) from April 2012 to January 2013 from UK Comprehensive Care Haemophilia Centres. The study aimed to determine the prevalence of platelet function defects in this patient group. Platelet function testing was carried out by light transmission aggregometry alongside measurement of ATP secretion using a dual-channel Chronolog lumi-aggregometer (Model 460 VS). Platelet aggregation measurement with and without Chronolume® was carried out simultaneously. This study was approved by the National Research Ethics Service Committee and all participants gave written informed consent.

Results: One hundred participants were included ($n = 73$ with suspected platelet function defects and $n = 27$ healthy volunteers). A platelet defect was found on platelet function testing in 40% of participants with bleeding symptoms (60% had no demonstrable platelet defect, 18% had a Gi-type defect, 11% had a dense granule secretion defect, 7% had a defect in the thromboxane pathway and 4% had a

complex phenotype). Addition of Chronolume® did not result in a significant increase in maximal platelet aggregation in response to epinephrine 10 μM in healthy volunteers (Δ = 0.7, 95%CI −7.5 to 9.0, $P = 0.74$), or in participants with bleeding symptoms ($n = 57$, 78%) who had a sustained and biphasic response to epinephrine 10 μM (Δ = −1.0, 95% CI −4.0 to 1.9, $P = 0.48$). In 16 (22%) participants with bleeding symptoms, there was no secondary wave in response to epinephrine 10 μM. Addition of Chronolume® in this group resulted in a non-statistically significant increase in maximal platelet aggregation in response to epinephrine 10 μM (Δ = 10.6, 95%CI −1.8 to 23.1, $P = 0.09$). In four out of 16 participants who had no secondary wave in response to epinephrine, addition of Chronolume® induced a secondary wave of aggregation. However, out of 57 participants with biphasic aggregation, addition of Chronolume® resulted in abrogation of a secondary wave in three participants. Overall, the McNemar test showed no impact of adding Chronolume® on induction of a secondary wave in response to epinephrine 10 μM ($P = 1.0$).

Summary/Conclusions: Our data support the use of Chronolume® to simultaneously assess dense granule secretion with platelet aggregation when investigating patients with excessive bleeding, and suggest that this practice does not mask platelet defects including those that reduce platelet aggregation response to epinephrine.

PB 1.22-3

Label-free detection of platelet adhesion to collagenous substrates

Farndale RW[1], Swieringa F[2], Tsim M[1], Howes JM[1], Jung SM[1], Bihan D[1] and Hamaia SW[1]

[1]University of Cambridge, Cambridge, UK; [2]University of Maastricht, Maastricht, The Netherlands

Background: Platelets use vessel wall collagens as both an anchorage and a stimulus during thrombus deposition on the damaged vessel wall. Discriminating the adhesive and activatory roles of collagens is not simple, since the native collagens combine both functions. Both collagens I and III are present in the vessel wall.

Aims: To develop a rapid, real-time means of identifying adhesive and activatory collagen motifs using the collagen Toolkits in conjunction with the Acea xCELLigence® impedance-based adhesion platform. Toolkits are libraries of triple-helical peptides used to map the sites where interacting proteins bind collagen, ideal for the homotrimeric collagen III, but less than optimal for heterotrimeric collagen I.

Methods: Washed platelets were dispensed into ePlates, 96-well plates containing micro-electrode arrays, onto which collagenous peptides were coated, providing real-time readout (called Cell Index) of thrombus accretion on the base of the well. Cell adhesion occurs over 5–60 min as platelets contact the surface, attach and spread. We optimised platelet numbers for this study. Sites were mapped onto Toolkit III, and compared with known sites for platelet receptor binding. We used the homotrimeric Toolkit II as a surrogate for collagen I, since the alpha1 chains are most highly conserved amongst the collagens. Wells were coated using 10 μg/mL of each peptide.

Results: We identified peptides specific for GpVI and for integrin α2β1, and could discriminate between activatory and adhesive peptides by including antagonists of αIIbβ3 in the suspending medium, which abolished fibrinogen-mediated accumulation of platelets on the growing platelet mass. Key α2β1-specific peptides could be identified by integrin blockade, and since they contained GxOGER or related recognition motifs. Sites for GpVI tended to be GPO-rich, as peptide III-30, and were blocked using anti-GpVI antibodies.

Summary/Conclusion: New platelet-reactive collagen peptides were identified rapidly and in real time. The method is suitable for multiwell aggregometry, provided that adhesive substrates (relevant proteins such as collagen, fibronectin or fibrinogen) are used. Data indicate a much closer apposition (faster kinetics and higher Cell Index) mediated by α2β1 than by GpVI.

PB 1.22-4

Effect of platelet count on platelet aggregation measured by impedance aggregometry (Multiplate – analyzer) and by light transmission aggregometry

Scavone M[1], Femia EA[1], Lecchi A[2] and Cattaneo M[1]

[1]Università degli Studi di Milano; [2]Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico, Milano, Italy

Background: The *in vitro* evaluation of platelet aggregation is useful to characterize patients with defects of primary hemostasis. In some laboratories, it is also used to monitor antiplatelet treatment. Traditionally, platelet aggregation is measured by light transmission aggregometry (LTA), which measures the transmission of light through a sample of platelet-rich plasma (PRP) or platelet suspensions in buffer, which increases when platelets aggregate. Impedance aggregometry (IA), which measures the increase in electrical resistance between two electrodes brought about by platelet adhesion and aggregation, allows to measure platelet aggregation also in whole blood. We previously demonstrated that a platelet count within the range of 150–600 × 10^9/L does not affect the results of platelet aggregation measured by LTA. However, considering that the extent of platelet aggregation measured by IA is a function of the volume of platelet mass accumulating on the electrodes, it is likely that platelet count affects its results. As a matter of fact, a positive correlation between platelet count and the extent of platelet aggregation measured by IA (Multiplate™ analyzer) has been found in a study of patients on treatment with aspirin. No studies have so far measured the changes in the extent of platelet aggregation measured by IA under conditions in which platelet count is the only variable.

Aim: This study was to evaluate the effects of varying the platelet count in platelet suspensions on the extent of platelet aggregation, measured by IA (both in the presence and absence of red blood cells [RBC]).

Methods: Platelets from blood anticoagulated with acid-citrate-dextrose of 15 healthy subjects were washed and resuspended in Tyrode buffer containing apyrase. The platelet count was adjusted to 75, 150, 250, 500 and 750 × 10^9/L with Tyrode buffer. Platelet aggregation induced by collagen (3.2 μg/mL), thrombin receptor activating peptide-6 (TRAP, 32 μM) or ADP (20 μM) was measured by Multiplate™ (in absence and presence of 40% washed autologous RBC) and, for comparison, also by LTA.

Results: Platelet aggregation increased linearly as a function of the platelet count, when measured by Multiplate™ both in presence and absence of RBC. In the presence of RBC, the extent of platelet aggregation ranged between 576 (75 × 10^9/L) and 1737 (750 × 10^9/L) AU*min (TRAP), 359–1391 (collagen) and 119–434 (ADP). For every 50 × 10^9/L increase in platelet count, we observed an increase of 111.8 AU*min (TRAP), 80.1 (collagen), 27.3 (ADP). In contrast, collagen- and TRAP-induced platelet aggregation measured by LTA was similar at platelet counts ranging between 150 and 750 × 10^9/L, but was significantly reduced at a platelet count of 75 × 10^9/L. ADP-induced platelet aggregation measured by LTA was similar at platelet counts ranging between 150 and 500 × 10^9/L, confirming previous results, but was reduced at platelet counts of 75 and 750 × 10^9/L.

Conclusions: Slight variations in the platelet count within the normal range cause remarkable variations in the results of platelet aggregation, as measured by IA (Multiplate™). This effect should be taken in due consideration when platelet function of patients with bleeding disorders or on treatment with antiplatelet agents is measured by this technique.

PB 1.22-5

Thrombin generation and microparticalassociated procoagulant activity as new assays to characterize the hemostatic profile of platelet concentrates

Russo L[1], Marchetti M[1], Tartari CJ[1], Vignoli A[1], Diani E[1], Giaccherini C[1], Verzeroli C[1], Gargantini C[1], Woodhams B[2] and Falanga A[1]

[1]Hospital Papa Giovanni XXIII, Bergamo, Italy; [2]HaemaCon Ltd, Bromley, UK

Introduction: The hemostatic quality of platelet concentrates (PC) is affected by preparation methods and storage conditions. Different *in vitro* techniques can be used to analyze PC quality, including platelet adhesion and aggregation assays. However, these tests are not able to characterize the procoagulant capacity of platelets. Thrombin generation (TG) and microparticle-associated procoagulant activity (MP-PCA) are two emerging assays to characterize the hemostatic profile of plasma samples.

Aims: In this study we evaluated the suitability of MP-PCA and TG assays to assess the procoagulant properties of PC prepared for transfusion use and the sensitivity of these assays to the different PC preparation methods.

Methods: Eighteen PC were obtained from pooled buffy coats of overnight stored whole blood. Of them, 10 were prepared by separation with the Fenwal System (FS) and eight by separation with the Terumo TACSI System (TTS). PC were sampled the day of preparation (D0) and after 3 days of storage (D3) at 22 °C. Supernatants of PC (S-PC), obtained by centrifugation, were tested for TG potential (CAT assay; Stago) and MP-PCA (PPPL kit, Stago).

Results: At D0, both TG and MP-PCA of S-PC displayed values similar to that measured in normal pool plasma (NPP). The analysis according to the method of PC preparation, showed TG values significantly ($P < 0.05$) higher in S-PC prepared by TTS compared to FS (ETP: 1400 ± 95 vs. 1134 ± 65 nM*min), while no differences were found in the MP-PCA levels. At D3, in S-PC prepared by TTS a statistically significant reduction in TG (ETP: 900 ± 180 vs. 1304 ± 191 nM*min; $P < 0.05$) occurred in parallel to a significant ($P < 0.05$) increase in MP-PCA. Differently, no significant modifications were detected in S-PC prepared by FS. Of interest, the lowest TG and the highest MP-PCA values were found in S-PC from B blood phenotype.

Summary/Conclusions: Our data support the validity of these assays in the assessment of procoagulant activity of PC. The increased MP-PCA observed in samples collected after 3 days of storage reveals the occurrence of platelet activation/apoptosis, particularly in S-PC prepared by TTS. These results provide background for the utility of these new tests to assess the quality of PC, in terms of capacity to contribute to restore a normal hemostasis in patients with severe bleeding complications.

PB 1.22-6

Subdivision according to size is necessary for correct interpretation of data regarding platelet expression of active GPIIb/IIIa and phosphatidylserine

Sodergren AL, Ollinger K and Ramstrom S

Linkoping University, Linkoping, Sweden

Background: Platelets analyzed by flow cytometry are often identified based on size and gated as a single population to investigate expression of activation markers. Platelets may also be divided into platelets and microparticles. In addition we have observed that activated platelets may form a third population of intermediate size.

Aims: To investigate how platelet size is affected by activation and how the expression patterns of active GPIIb/IIIa (α2bß3) and phosphatidylserine (PS) differ between different platelet subpopulations.

Methods: Platelets in heparinized whole blood were activated with PAR1-activating peptide (AP), PAR4-AP or collagen-related peptide (CRP) as single or combined agonists at high (30, 150 μM and 0.93 μg/mL) or low concentrations (2.5, 5 μM and 0.01 μg/mL). Flow cytometry was performed to detect platelets (GPIIb-RPE positive events) and their expression of the active conformation of GPIIb/IIIa (binding PAC-1-FITC) and PS (binding annexin V-APC).

GPIIb-RPE positive events were divided into different populations/gates based on size (forward scatter properties): 'normal-sized platelets' (approximately > 0.7 μm, lower limit excluding 1–2% of resting platelets), 'smaller platelets' (0.5 < ~0.7 μm), and 'platelet fragments' (< 0.5 μm) and was compared to a gate including all platelets. Expression of active GPIIb/IIIa and PS was then compared between these populations.

Results: Changes in platelet size depend both on the agonist used and the level of activation. With low as well as high concentrations of PAR1-AP together with PAR4-AP, approximately 90% of the platelets were located in the 'normal-sized platelets' gate. In contrast, when high concentrations of CRP in combination with PAR1-AP and/or PAR4-AP were present, the fraction of platelets located in the 'normal-sized platelets' gate decreased to 40–60%.

As an example, upon activation with high concentrations of PAR1-AP, PAR4-AP and CRP, 41.3 ± 13.8% of the platelets were located in the 'normal-sized platelets' gate, 37.3 ± 10.4% in the 'smaller platelets' gate and 13.4 ± 4.8% in the 'platelet fragments' gate ($n = 4$). With this stimulation the expression of active GPIIb/IIIa and PS in the 'all platelets' gate (36.9 ± 15.3% and 46.6 ± 16.8%, respectively) was distinctly different from that seen when the population was divided into 'normal-sized platelets' (77.0 ± 9.8% and 7.2 ± 6.3%), 'smaller platelets' (2.9 ± 1.7% and 77.1 ± 10.8%) and 'platelet fragments' (0.3 ± 0.1% and 86.3 ± 5.9%).

Summary/Conclusions: Upon activation with low concentrations of agonists, the use of a single platelet gate including normal-sized platelets or all platelets will give quite an accurate estimation of the expression pattern of the entire population. However, upon activation with high concentrations of CRP together with PAR1-AP and/or PAR4-AP a large fraction of platelets will turn into smaller platelets and platelet fragments. The different sized platelet populations show distinctly different expression patterns regarding active GPIIb/IIIa and PS, where normal-sized platelets primarily express an active GPIIb/IIIa and smaller platelets and platelet fragments primarily express PS.

Thus, the use of a single gate for all platelets will give an overall estimation of the platelet population but will not detect the characteristic expression patterns related to platelet size, which may make a correct interpretation of data more difficult. We therefore recommend that platelets are subdivided according to size before interpreting results investigating down-regulation of active GPIIb/IIIa and expression of PS.

PB1.23 – Platelet Integrins – I

PB 1.23-1

The role of the fibrinogen NGR motif in mediating platelet adhesion and activation

Cox D, Moriarty R, Tilley T, Lambert M and Kerrigan S

Royal College of Surgeons in Ireland, Dublin, Ireland

Introduction: The integrin $\alpha_{IIb}\beta_3$ on resting platelets can bind to immobilized fibrinogen resulting in platelet spreading and activation but requires activation to bind to soluble fibrinogen. $\alpha_{IIb}\beta_3$ is known to interact with the general integrin-recognition motif RGD (arginine-glycine-aspartate) as well as the fibrinogen-specific γ-chain dodecapeptide; however it is not known how fibrinogen binding triggers platelet activation. The amino acid sequence NGR (asparagine-glycine-arginine) has been identified as an integrin-recognition motif and is present on both the β and γ chains of fibrinogen.

Aims: To determine if the NGR-sequence in fibrinogen can mediate an interaction with $\alpha_{IIb}\beta_3$.
Methods: Recombinant fibrinogens lacking either the β-chain (Fgβ$^-$) or γ-chain (Fgγ$^-$) NGR sequences were prepared by substitution with AAA. Platelet adhesion to recombinant fibrinogens was quantified by measuring acid phosphatase activity. Platelet spreading was characterized by confocal microscopy. Platelet adhesion was also quantified after blood was sheared over immobilized recombinant fibrinogen in a parallel plate flow chamber.
Results: Static, resting platelet adhesion to the mutant fibrinogens was reduced compared to plasma fibrinogen (pFg) (Fgβ$^-$: 38.7 ± 11.9% $P < 0.01$, $n = 14$ and Fgγ$^-$: 44.3 ± 16.4% $P < 0.05$, $n = 14$ reduction compared to pFg) and the percentage of spread platelets was also reduced (Fgβ$^-$: 16.1 ± 7.4%, Fgγ$^-$: 27.6 ± 11.4%,pFg: 55.1 ± 9.5% of total platelets spread, One way ANOVA, $P = 0.005$, $n = 8$) while the time to spreading was increased for Fgβ$^-$ (pFg 15.7 ± 1.3 min, Fgβ$^-$: 20 ± 2.5 min, $n = 3$, $P = 0.013$). When platelets were pre-activated with TRAP there were no longer any differences in the adhesion to recombinant fibrinogens and plasma fibrinogen. Under shear conditions (200/s) platelet adhesion was abolished ($P < 0.0001$, $n = 3$).
Conclusions: The NGR motif in fibrinogen specifically binds to resting $\alpha_{IIb}\beta_3$ and is responsible for triggering platelet spreading. It also plays a significant role in the adhesion of resting platelets to immobilized fibrinogen under shear conditions.

PB 1.23-2
Regulation of platelets collagen receptor a2β1 integrin and the possibility of intermediate affinity

Hamaia SW, Bihan DG and Farndale RW
University of Cambridge, Cambridge, UK

Background: Collagen-binding integrins (a1b1, a2b1, a10b1 and a11b1) form a class of I domain-containing integrin. They differ structurally from leucocyte integrins ($\alpha_M\beta_2$, $\alpha_L\beta_2$, $\alpha_X\beta_2$, and $\alpha_D\beta_2$) by the presence of a small helix of about five amino acids named the c-helix. Integrin a2b1 is a surface-expressed heterodimer, important in adhesion of platelets to damaged blood vessel wall, in the normal function of endothelium, and in the migration and development of vascular smooth muscle cells. Much progress has been made in unraveling the complexity of conformational states in integrins. At least three different activation states, represented by different quaternary conformations have been described: (i) a closed conformation (resting state), unable to bind its ligand; (ii) an extended conformation with closed headpiece (low affinity state); and (iii) an extended conformation with open head-piece (high affinity state). The two extended, active conformations are favored by outside-in and inside-out signaling and can bind their natural ligand. Molecular dynamic simulations showed that both aL and aM I domains can adopt three conformations where the b6-a7 loop moves successively between three ratchet positions, from closed to intermediate, and then to open. The same study suggested that collagen-binding integrins cannot adopt the intermediate conformation due to F-to-E substitution of the second ratchet residue at the top of helix 7. In a different study, two functional active conformations of a2b1 were identified on the platelet surface using a conformation-sensitive antibody.
Aim: To explore the collagen binding activity of the human and rat collagen-binding integrins, to investigate possible intermediate affinity states.
Methods: We designed a series of single and double amino acid substitutions in helix 7 and the c-helix. Site-directed mutagenesis was carried out in the I domain expressing vectors. Collagen II and III triple-helical Toolkit peptides of differing affinity for the integrins were used as adhesive substrates in solid-phase binding assays. Conventional ELISA-like methodology was used.
Results: The I domains display characteristic binding distribution across the Toolkit peptides, patterns of binding that reflect the affinity state of the I-domain
The data showed that a2 I domain is the only collagen binding I domain that can adopt an intermediate affinity.
Conclusions: The structure of a mutant that adopts intermediate affinity is equivalent to a closed conformation, as found in the crystal structure of the wild-type I domain, but with some differences around the MIDAS that must be responsible for its enhanced binding activity.

PB 1.23-3
Mass spectrometry of platelet lipid raft fractions reveals a substantial pool of active integrin aIIbβ3

Jones CI, Tucker KL, Barrett EN, Wen Y, Leake DS and Gibbins JM
University of Reading, Reading, UK

Background: Platelet membranes are divided into micro-domains in part by the formation of 'rafts' enriched with cholesterol and glycolipid, which can be isolated as detergent resistant fractions (DRFs). Most activatory signaling occurs in DRFs, yet integrin function is largely assumed to be outside the DRF, despite numerous reports that a small proportion of integrin αIIbβ3 can be detected in lipid rafts by western blotting. This led us to explore the possibility that this assumption is incorrect.
Aim: We hypothesised that integrin αIIbβ3 could be an important but overlooked component of DRFs.
Method: Resting or collagen receptor (GPVI) stimulated platelets from three healthy subjects were lysed with equivalent volume of ice cold 0.05% Triton X-100 buffer containing protease inhibitors. DRFs were isolated by mixing lysed samples with Optiprep (Sigma, UK) to a final concentration of 25% w/v iodixanol on top of which was layered a density gradient of 20%, 15% 10%, 5% w/v iodixanol, containing 0.025% Triton X-100, and centrifuged at 52,000 ***g*** for 90 min at 4 °C. Sequential 1 mL samples were collected from the bottom of each tube and DRFs were identified by the distribution of cholesterol, LAT and PAG-1. DRFs were analysed by MS/MS performed using HCT ion-trap (ESI) and peptides were analyzed by SwissProt_57.15.fasta.
Results: Using mass spectrometry to assess the relative abundance of proteins within DRFs we identified 149 proteins, dominated by GTPases, cytoskeletal and secretory proteins. In line with previous reports using western blotting, only 10% of total platelet integrin β3 was found within the DRF, yet because of the abundance of integrin αIIbβ3 on the platelet surface this represents a large number of molecules (approximately 8000 per cell). Using mass spectrometry to simultaneously assess the relative abundance of proteins within DRFs, we determined that contrary to the current dogma integrin αIIbβ3 was one of the major components in DRFs. Integrin αIIbβ3 and associated proteins accounted for 21%, by exponentially modified protein abundance index (emPAI), of the proteins identified in DRFs. Furthermore, β3 integrin within DRFs bound filamin in resting and stimulated platelets, and in resting platelets was bound to talin, an association that was reduced upon stimulation. These results suggest that integrin αIIbβ3 is functionally active within the DRF.
Summary/Conclusions: Knowledge of cellular location helps place proteins in their functional context, allowing more appropriate interpretation of functional, biochemical and physiological studies. In light of the data presented here the role of DRF resident integrin αIIbβ3 in controlling platelet response during haemostasis and its regulation should be re-evaluated.

PB 1.23-4

The fibronectin binding partner Msb2 of *Candida albicans* impairs the platelet-mediated host attack

Stoldt VR, Scharf RE and Huynh KC

Department of Experimental and Clinical Hemostasis, Hemotherapy, and Transfusion Medi, Dusseldorf, Germany

Background: Platelets can bridge innate and adaptive immunity. To attack microorganisms, platelets store microbicidal and immune stimulatory proteins in their α-granules. *C. albicans* can bind fibronectin which has specific binding sites for platelet integrins (α5β1, αvβ3, and αIIbβ3). The ability of *C. albicans* to grow in hyphae is a relevant factor of virulence *in vivo*. The *C. albicans* surface integrity during filamentation is sensed by Msb2, a transmembrane protein. Recently, it has been shown that Msb2 can be shedded.

Aims: We examined whether or not shedded Msb2 binds to fibronectin, providing a putative mechanism by which *C. albicans* can escape from opsonisation by fibronectin and subsequent platelet attack.

Material and Methods: To induce germination, *C. albicans* exponentially growing in complete medium at 30 °C and starved for 1 h, was diluted in PBS containing 10% FCS and incubated at 37 °C. Msb2 heme agglutinin-tagged purified by affinity chromatography was kindly provided by J. Ernst (PLoS Patho. 2012;8:e1002501). Plates (24 wells) coated either with purified Msb2 (10 μg/mL) or unlabeled fibronectin (10 μg/mL) were incubated with various concentrations fibronectin-alexa fluor 488 for 60 or 120 min. This fluorescent fibronectin was also used to study binding to *C. albicans* or platelets. The readout was performed by flow cytometry, confocal laser scanning microscopy (LSM, Zeiss) and fluorometry (Thermo Scientific) to quantify fluorescent fibronectin.

Results: Binding of 5, 10, 50, and 100 μg/mL fibronectin to 10 μg/mL immobilized Msb2 revealed saturation at 10 μg/mL fibronectin. Immobilized Msb2 bound 2.6-fold more fluorescent fibronectin than BSA ($P = 0.016$). Immobilized fibronectin bound 30% more fluorescent fibronectin than Msb2 and significantly more than BSA ($P < 0.01$). *C. albicans* germination over time at 30, 60, and 120 min generated 5–10%, 40%, and 90% hyphae, as determined by microscopy and confirmed by flow cytometry. Induction of *C. albicans* hyphae enhanced binding of fibronectin (40 μg/mL) from 1.7% positive yeast cells (baseline) to 6% at 30 min, 11.7% at 60 min, and 12.6% at 120 min ($P < 0.05$). As shown by LSM, *C. albicans* germ tubes were a target for fluorescent fibronectin. Germination of *C. albicans* yeast increased binding of platelets up to 5-fold after 30 min and 20-fold after 60 min ($P < 0.05$). Moreover, pretreatment of *C. albicans* hyphae with fibronectin (40 μg/mL) enhanced binding of platelets mediated by interaction of αIIbβ3 with fibronectin. Abciximab (2 μg/mL), a specific αIIbβ3 antagonist, blocked binding of platelets to *C. albicans* opsonized by fibronectin. Binding of fluorescent fibronectin was not homogeneously distributed on the cell surface of *C. albicans*. Upon addition of soluble Msb2, binding of fluorescent fibronectin decreased.

Conclusion: *C. albicans* hyphae, a relevant virulence factor, are attacked by platelets. Fibronectin, a ligand of the platelet integrins, opsonizes the hyphae of *C. albicans* and enhances platelet binding to *C. albicans*. Hence, platelets and fibronectin, with its intrinsic binding sites to integrins (α5β1, αIIbβ3, αvβ3) can support the platelet-mediated host defense against *C. albicans*. Msb2 is a novel fibronectin binding protein. Binding of fibronectin to *C. albicans* is impaired in the presence of soluble Msb2. Hence, shedding of Msb2 *in vivo* can protect *C. albicans* against the platelet-mediated host attack.

PB 1.23-5

Involvement of protein disulfide isomerase (PDI) in beta3 integrin-mediated adhesion of nucleated cells to immobilized fibrinogen

Rosenberg N[1], Sheptovitsky V[2], Romanenco O[1] and Lahav J[2]

[1]*Sheba Medical Center, Ramat Gan;* [2]*Rabin Medical Center, Beilinson Hospital, Petah Tiqva, Israel*

Background: Extracellular protein disulfide isomerase (PDI) was previously shown to play a role in integrin-dependent platelet adhesion, aggregation and thrombus formation. PDI is secreted from platelets and endothelial cells, and its accumulation at the vascular injury site depends on the presence of β3 integrins. In addition to thiol isomerase and reductase activity, PDI has chaperone-like effect on tissue factor-dependent coagulation.

Aims: In this study we investigated the role of disulfide exchange-activity of PDI in β3 integrins-mediated adhesion of nucleated cells to immobilized fibrinogen.

Methods: We co-expressed in baby hamster kidney (BHK) cells αIIbβ3 and/or αvβ3 integrins together with WT-PDI or the inactive mutant in which the active-sites cysteines were replaced by alanine and serine respectively (ASAS-PDI) and tested the adhesion of these cells to immobilized fibrinogen. In addition, we examined the effect of exogenous PDI and of bacitracin, a membrane impermeable PDI inhibitor, on the adhesion.

Results: The presence of β3 integrins was necessary for BHK cell adhesion to fibrinogen, threefold increase was found in cells expressing integrin αIIbβ3 compare to αvβ3 alone. Bacitracin decreased the adhesion to 33% and to 54%, respectively. Over expression of WT-PDI enhanced the adhesion of BHK cells expressing αvβ3 to 322% while mutant ASAS-PDI enhanced the adhesion to 233%. In contrast, over expression of mutant ASAS-PDI had no effect on adhesion to fibrinogen of BHK cells expressing αIIbβ3and over expression of WT-PDI increased the adhesion only to 120% which was not statistically significant. Interestingly, simultaneously expressing of endogenous PDI and integrin αIIbβ3 resulted in 30%-50% decrease in integrin surface expression, suggesting that cell adhesion dependent on amount of both, PDI and integrin surface expressed. Bacitracin inhibited adhesion to fibrinogen of BHK cells expressing either WT-PDI or mutant ASAS-PDI together with both integrins αvβ3 and αIIbβ3. In the presence of exogenously added PDI, both cell types showed enhanced adhesion that was totally inhibited by bacitracin.

Conclusions: Adhesion of cells expressing integrin αIIbβ3 and/or αvβ3 to fibrinogen depends on surface-expressed cellular PDI. Over-expression of WT-PDI or increased concentration of exogenous WT-PDI increased adhesion, suggesting that surface-expressed PDI is a limiting factor in integrin-mediated adhesion. ASAS-PDI mutant (lacking oxidoreductase activity but retaining its activity as a chaperone), also increased adhesion mediated by αvβ3, suggesting that chaperone activity contributes to cell adhesion.

PB 1.23-6

Surface expressions of platelet glycoprotein Iba, GP?b/?a, and P-selectin are elevated in lung cancer patients

Dai K, Zhang J, Zhao L and Huang J

Jiangsu Institute of Hematology, Suzhou, China

Background: Thromboembolic events are common symptoms in patients with cancer, and the mechanisms are not totally understood. The platelet adhesion moleculars play important roles in the process of thrombus formation.

Aims: The aim of the current study is to investigate the surface expression of platelet glycoprotein (GP) Ibα, GPIIb/IIIa, and P-selectin in patients with lung cancer.

Method: Platelets were isolated from patients with lung cancer and normal volunteers, and then the surface expressions of platelet GP

Ibα, GPIIb/IIIa, and P-selectin were measured by Flow cytometry. The glycocalicin (GC) fragments in the peripheral blood of patients with lung cancer were tested by Western blot. The surface expressionof GP Ibα on normal volunteers' platelets incubated with the platelet-poor plasma (PPP) of patients with lung cancer was measured by Flow cytometry and Western blot.

Results: The surface expressions of platelet GP Ibα, GPIIb/IIIa, and P-selectin were obviously increased in patients with lung cancer compared with that of normal volunteers, and the GC fragments in PPP were also increased in patients with lung cancer. Incubation of control platelets with the PPP from cancer patients resulted in the elevationof the surface expression of GP Ibα in control platelets. Furthermore, the expressions of GP Ibα, GPIIb/IIIa, and P-selectin on platelets from patients with advanced stage of lung cancer (III–IV stage) were significantly higher than those with early stage (I-II stage) ($P < 0.05$). However, there were not significantly difference in the surface expressions of GP Ibα, GPIIb/IIIa, and P-selectin among the pathological types of lung cancer (squamous cellcarcinoma, adenocarcinoma, small cell lung carcinoma, large cell lung carcinoma) ($P > 0.05$).

Conclusion: The surface expressions of platelet GP Ibα, GPIIb/IIIa, and P-selectin were obviously elevated in patients with lung cancer, and the plasma from cancer patients is responsible for the elevations. These findings provide a new view to understand the pathogenic mechanisms of thromboembolic events in the patients with lungcancer.

PB1.24 – Platelet Apoptosis

PB 1.24-1

Arsenic trioxide induces platelet apoptosis

Dai K[1], Wu Y[1], Dai J[2], Zhang W[1], Yan R[1] and Ruan C[1]

[1]Jiangsu Institute of Hematology, Suzhou; [2]Peking University, Beijing, China

Background: Arsenic trioxide, a component of Traditional Chinese Medicine, is known as an effective anticancer druge specially in the treatment of acute promyelocytic leukaemia (APL). APL has emerged as the most curable subtype of acute myeloid leukaemia since the widely use of arsenic trioxide-based chemotherapy. However, recent researches show that thrombocytopenia occurred in 79% of the relapsed or refractory APL patients treated with arsenic trioxide, and part of the APL patients had to be stopped treatment because of catastrophic bleeding, such asintracranial and pulmonary haemorrhage. Thrombocytopenia also occurred in 43% of the myelodysplastic syndromepatients treated with arsenic trioxide. Recently, arsenic trioxide has been proved to have a pro-apoptotic effect on various kinds of nucleated tumour cells or non-tumour cells. The effect of arsenic trioxide on enucleated platelet, however, still remains unclear.

Aims: The aim of current study is to investigate whether arsenic trioxide induces platelet apoptosis.

Methods: Washed platelets (3×10^8/mL) were incubated with different concentrations of arsenic trioxide or vehicleat 37 °C for 4 h. Then, mitochondrial inner transmembrane potential ($\Delta\Psi m$) and phosphatidylserine (PS) exposure were tested by flow cytometry. In the mean time, the treated platelets were analyzed by western blot for the expression levels of pro-apoptotic protein (Bax), and anti-apoptotic proteins (Bcl-2 and Bcl-XL). Activation of caspase-3 was also examined by western blot using an anti-caspase-3 antibody.

Results: $\Delta\Psi$ depolarization and PS exposure were dose-dependently induced in platelets incubated with different concentrations (2, 4, 8, 16 μM) of arsenic trioxide as detected by flow cytometry, and the lowest concentration of arsenic trioxide incurring $\Delta\Psi m$ depolarization and PS exposure was 4 μM. Simultaneously, arsenic trioxide induced up-regulation of Bax and down-regulation of Bcl-2 and Bcl-XL in a dose-dependent manner. Furthermore, 17 kD cleaved caspase-3 fragments were dose-dependently induced in platelets treated with different concentrations of arsenic trioxide indicating that caspase-3 was activated by arsenic trioxide.

Conclusions: Taken together, the data indicate that arsenic trioxide induces platelet apoptosis *in vitro*, which might suggest a novel pathogenic mechanism of thrombocytopenia in the patients who treated with arsenic trioxide.

PB 1.24-2

Caspase-3 activation regulates platelet lifespan but it is not involved in microparticle (MP) formation and phosphatidylserine (PS) exposure

Kozuma Y[1], Kojima H[2], Tashiro Y[1] and Ninomiya H[1]

[1]University of Tsukuba, Tsukuba; [2]Ibaraki Prefectural Central Hospital and Cancer Center, Kasama, Japan

Background: Previous reports have indicated the possibility that activation of a key effector molecule of cellular apoptosis, caspase-3 (Casp-3), is involved in MP formation and PS exposure of platelets (Plts). Although this hypothesis is based on the morphological similarity observed during cellular apoptosis and Plt activation, much is not known whether Casp-3 activation is involved in MP formation and PS exposure. 2.

Aims: In the present study, by using *vav-bcl-2* transgenic (Tg) mice, whose Casp-3 is hardly activated by apoptotic stimulation, we investigated whether Casp-3 activation regulates Plt lifespan and is involved in MP formation and PS exposure. 3.

Methods: After stimulation of washed Plts prepared from WT, *vav-bcl-2* Tg mice, and healthy volunteers, MP formation and PS exposure were assayed by flow cytometry using annexin-conjugated FITC. Casp-3 activation in Plts was analyzed by western blotting using an anti-Casp-3 polyclonal antibody. Plt half-life was measured by tracing biotin-labeled Plts using flow cytometry after intravenous injection of sulfo-NHS-LC-Biotin into mice. 4.

Results: Pretreatment of healthy human Plts with a broad Casp inhibitor, z-VAD-fmk, affected neither MP formation nor PS exposure induced by A23187. Furthermore, there was no difference in MP formation and PS exposure between WT and Tg Plts stimulated with various concentrations of A23187. Combined with the finding that activation of Casp-3 was not detected in A23187-stimulated healthy Plts by western blotting, we concluded that Casp-3 activation is not involved in MP formation and PS exposure. In contrast, Plt half-life in vav-bcl-2 Tg mice was significantly longer than that in WT mice (68 vs. 56 h). In accordance with that, Casp-3 activation was detected by western blotting in healthy human platelets incubated at 37 °C for 1–3 days, and this activation was inhibited by adding z-VAD-fmk. 5.

Summary/Conclusion: These data collectively suggest that Casp-3 activation regulates Plt lifespan but it is not involved in MP formation and PS exposure.

PB 1.24-3

Inner mitochondrial membrane disruption is closely associated with both Bax/Bak and cyclophilin D-mediated platelet phosphatidylserine exposure

Choo H and Jobe S

Emory University and Children's Healthcare of Atlanta, Atlanta, GA, USA

Background: Two primary intracellular pathways regulate platelet phosphatidylserine (PS) exposure. In response to strong agonists, a sustained increase of cytoplasmic calcium levels initiates cyclophilin D (CypD)-regulated mitochondrial permeability transition pore formation and subsequent PS exposure. Treatment of platelets with Bcl-xL inhibitors initiates Bax/Bak dependent caspase activation and PS exposure. The role of mitochondrial events in regulating these platelet

pathways has primarily been investigated through evaluation of mitochondrial transmembrane potential (deltapsi(m)) using fluorescent lipophilic cationic dyes, such as TMRM or JC-1. A limitation of these studies is their inability to distinguish whether deltapsi(m) loss occurred due to disruption of the electrical gradient, such as occurs in response to protonophore treatment or respiratory chain inhibition, or through inner mitochondrial membrane (IMM) disruption, or pore formation.

Aims: Here we utilize novel assays to closely examine and compare the sequence of mitochondrial events regulating platelet PS exposure in response to physiologic agonists and the Bcl-inhibitor ABT-737.

Methods: To evaluate mitochondrial outer membrane permeabilization (MOMP), platelets were incubated with 0.01% digitonin for one minute for plasma membrane permeabilization. Cytochrome C retention was evaluated by cytochrome c immunofluorescence.

To directly assess IMM disruption, a calcein-cobalt fluorescence assay was utilized. Platelets were preincubatedwith calcein-AM and $CoCl_2$, and calcein fluorescence was assessed following agonist(s) stimulation. IMM disruption allows mitochondrial entry of cobalt, which quenches calcein fluorescence.

To evaluate mitochondrial calcium influx, or ROS generation, washed platelets were preincubatedwith 5 mM Rhod-2 or 5 mM H_2-DCFDA, respectively, and stimulated with 1 mM ABT-737.

Results: In both ABT-737 treated and physiologic agonist (thrombin and convulxin (T/C) stimulated platelets IMM disruption, not MOMP, was temporally associated with PS exposure. The sequence of events responsible for PS exposure was more closely examined in ABT-737-treated platelets. ABT-737 treatment caused rapid MOMP, occurring within 5 min. IMM disruption and PS exposure were closely associated and occurred approximately 30 min after ABT-737 treatment. In Bax/Bak double deficient platelets, mitochondrial inner and outer membrane disruption and high-level PS exposure were all markedly blunted. Caspase inhibition had no effect on MOMP, but both IMM disruption and PS exposure were markedly blunted. CypD's absence had minimal effects on ABT-737 initiated events. As in ABT-737-treated platelets, in T/C stimulated platelets IMM disruption, not MOMP, was closely correlated with PS exposure. Influx of mitochondrial calcium ($Ca^{2+}{}_{mit}$) and ROS, key regulators of mPTP formation, were examined in ABT-737-stimulated platelets. As in T/C-stimulated platelets $Ca^{2+}{}_{mit}$ increased significantly in ABT-737-stimulated platelets prior ro PS exposure. However, in contrast to T/C stimulated platelets, abrogation of $Ca^{2+}{}_{mit}$ entry neither decreased IMM disruption nor PS exposure.

Conclusions: Platelet PS exposure in response to both Bax/Bak and CypD-mediated PS exposure is temporally associated with IMM disruption. CypD and caspase-regulated events mediate IMM and PS exposure in response to T/C and ABT-737, respectively. Increased $Ca^{2+}{}_{mit}$ occurs in ABT-737 stimulated platelets, but is not required for PS exposure.

PB 1.24-4

Platelet apoptosis in uremic patients

Dai K, Li M, Ma T, Lu G, Deng K and Yan R

Jiangsu Institute of Hematology, Suzhou, China

Background: Apoptosis, which serves for the regulation of cell life span and is long attributed exclusively to nucleated cells, has been well-documented in anucleate platelets. Diverse cell-external chemical and physical stimuli have been reported to induce transformation of resting platelets to apoptotic state. Uremia, a clinical syndromeassociated with retention of various solutes that would normally be excreted by the kidneys, is frequentlyaccompanied by bleeding tendency, and the mechanism remains unclear.

Aims: The aim of the present study is to investigate whether platelet apoptosis occurs in uremia patients.

Methods: Venous blood was drawed from 13 patients with end stage renal disease (ESRD) who exhibited uremia syndrome and 13 health controls. Platelet-rich plasma (PRP) was prepared and then was detected for apoptotic events including depolarization of mitochondrial inner membrane potential ($\Delta\Psi$m), phosphatidylserine (PS) exposure, variations of apoptotic Bcl-2 family proteins, activation of caspases-3 by Flow cytometry or Western-blot. Furthermore, normal washed platelets were incubated with the poor- platelet plasma (PPP) from uremic patients, and then were detected for apoptotic events. The comparisons of the data were made using paired Student's t-test.

Results: Compared with controls, $\Delta\Psi$m significantly depolarizated in platelets from uremic patients ($P < 0.05$). Furthermore, Bax was up-regulated, Bcl-2 and Bcl-X_L were down-regulated, and caspase-3 was activated inplatelets from uremic patients. However, there was not significant difference in PS exposure and P-selectin expression between the platelets from uremic patients and health contols ($P > 0.05$). Next, PPP from uremic patients was incubated with normal platelets, and the platelets presented $\Delta\Psi$m depolarization, up-regulation of Bax, down-regulation of Bcl-2 and Bcl-X_L, and caspase-3 activation.

Conclusion: The data demonstrate that platelets are incurred apoptosis in uremia patients. The finding might suggest a novel pathogenic mechanism for bleeding tendency in uremic patients.

PB 1.24-5

The effects and mechanisms of cyanidin-3-glucoside on platelet apoptosis

Chen L[1], Tian J[2], Song F[2], Ren J[2], Deng X[2], Ling W[2] and Yang Y[2]

[1]Sun Yat-sen University; [2]Department of Nutrition, School of Public Health, Sun Yat-sen University, Guangzhou, China

Background: The platelet activation, aggregation and apoptosis are involved in the atherosclerotic development. It has been evidenced that the process of the platelet apoptosis is different from that of the activation and aggregation. Our previous studies have found that anthocyanins significantly inhibited platelet activation, adhesion and aggregation and induced platelet apoptosis both *in vitro* and *in vivo*. However, the effects and mechanisms of anthocyanins on platelet apoptosis were not fully understood.

Aims: In this study we aimed to explore the effects of anthocyanin cyanindin-3-glucoside (Cy-3-g) on platelet apoptosis and BCL-2/BCL-X_L mediated intrinsic mitochondrial apoptosis signaling pathway.

Methods: Cyanidin-3-glucoside (Cy-3-g), the predominantly bioactive compound of anthocyanin, was bought from Polyphenol AS Company inNorway. Purified gel-filtered platelets from healthy volunteers were incubated at 37 °C for 40 min with different concentrations (0.5, 5 and 50 mM) of Cy-3-g or PBS buffer as a control. The mitochondria membrane potential ($\Delta\psi$m) was detected with the dye JC-1, and the membrane phospholipid phosphatidylserine (PS) exposure was assessed with Annexin V-FITC by flow cytometry. The expression of anti-apoptotic protein BCL-2 and BCL-XL and pro-apoptotic proteins such as BAK, BID, BAX as well as gelsolin, caspase-3,8,9 were determined by Western Blotting.

Results: In purified gel-filtered platelets, Cy-3-g concentration-dependently stimulated dissipation of the mitochondrial membrane potential ($\Delta\psi$m), 50 μM Cy-3-g obviously stimulated dissipation of the mitochondrial membrane potential ($P < 0.005$). While 0.5 μM Cy-3-g and 5 μM Cy-3-g showed no significant differences. Five micromolar Cy-3-g significantly induced PS exposure ($P < 0.01$), 5 and 50 μM Cy-3-g significantly inhibited the expression of BCL-2 and BCL-X_L respectively ($P < 0.05$), while 5 μM Cy-3-g increased the expression of pro-apoptotic proteins such as BAX, BAK and BID ($P < 0.05$). The level of gelsolin was reduced by Cy-3-g in a dose dependent manner (0.5 μM vs. control, $P < 0.05$, 5, 50 μM vs. control, $P < 0.01$). The results showed that Cy-3-g markedly induced the caspase-3, 8, 9 activation in a dose dependent manner but this tendency need to be further confirmed.

Conclusions: Our primary data demonstrated for the first time that purified anthocyanin (Cy-3-g) induced platelet apoptosis through

BCL-2/BCL-XL mediated endogenous mitochondrial apoptosis signaling pathway.

PB1.25 – Platelet Disorders: Gain-of-Function

PB 1.25-1

Platelet apoptosis and agonist-mediated activation in myelodysplastic syndromes

Butta NV, Martín M, De Paz R, Fernández Bello I, García Arias Salgado E, Álvarez MT and Jiménez Yuste V
Hospital Universitario La Paz-IDIPaz, Madrid, Spain

Background: Myelodysplastic syndromes (MDS) patients have a defect in the differentiation of bone marrow multipotent progenitor cells. Even when thrombocytopaenia is frequently observed in MDS patients, some of them may present normal or high platelet count. Thrombocytopaenia in MDS patients may be due to premature megakaryocyte death, but platelet apoptotic mechanisms may also occur.
Aims: This study aimed to study function and apoptotic state of platelets from MDS patients with different platelet count in order to elucidate whether they reflect anomalies corresponding to a stem cell disorder.
Methods: We recruited 75 patients with MDS, divided into three groups according to IPSS score: 39 with low, 27 with intermediate-1 and 9 with high risk, composed of intermediate-2 plus high risk patients. Sixty-eight healthy controls were included in the study. Reticulated platelets, platelet activation (measured through PAC1 binding and P-selectin surface expression after PAR-1 receptor stimulation with thrombin receptor-activating peptide 6, TRAP), activated caspases and annexin-V binding were evaluated by flow cytometry. Pro-apoptotic Bax and Bak proteins were determined by western blots, and plasma thrombopoietin by ELISA.
Results: High plasma thrombopoietin levels and low immature circulating platelet count showed a pattern of hypoplastic thrombocytopaenia. Regardless of platelet count, platelets from MDS patients bound less PAC1 and expressed reduced levels of P-selectin in comparison to controls after stimulation with TRAP. A significant correlation was observed between activation markers expressed on the surface of circulating platelets after stimulation with TRAP and platelet count (Spearman test $r = 0.354$, $P < 0.05$ for PAC1 binding and $r = 0.446$, $P < 0.0001$ for P-selectin exposure).
Platelets from all MDS patients, even those with a normal platelet count, exposed more phosphatidylserine (PS) than controls. To determine if PS exposure was related to apoptosis, levels of activated caspases-3, 7, -8 and -9 were evaluated in a group of MDS patients with normal platelet count. A significantly higher proportion of platelets from MDS patients contained activated caspases -3, 7, -8 and -9. Moreover, platelets from MDS patients showed increased Bax and Bak levels; Bax with a strong positive correlation with the AnnexinV binding values (Spearman test $r = 0.740$, $P < 0.0005$). On the other hand, AnnexinV binding and Bax expression showed an inverse correlation with platelet count (Pearson test $r = -0.255$ $P < 0.05$ and Spearman test $r = -0.712$, $P < 0.005$, respectively). Impairment in platelet function significantly correlated with platelet surface exposure of PS (Spearman test $r = -0.558$. $P < 0.001$).
Conclusion: Our results showed that platelet function was undermined in patients with MDS and that this impairment seemed to be related to increased apoptosis. Moreover, platelet dysfunction and apoptosis is more pronounced in patients with thrombocytopaenia, appearing to reflect that MDS is a stem cell disorder, and so both, number and function of progeny cells are affected.

PB 1.25-2

H2 haplotype of ADP-P2Y12 receptor gene is associated with increased platelet response to ADP in Taiwanese population

Liu CZ, Chen YH and Lin JL
Tzu Chi University, Hualien, Taiwan

Background: In Caucasians, carriers of the P2Y12 receptor gene H2 haplotype exhibited increased platelet reactivity, higher risk of arteriothrombosis, and lesser clinical response to antithrombotic agents, suggesting that patients with the H2 haplotype need intensive antithrombotic remedies. This useful information remains lacking in Taiwan.
Aims: To establish genetic markers that are associated with increased platelet reactivity in Taiwanese population, we examined the variability of ADP-induced platelet aggregation among healthy subjects and its relation to the P2Y12 receptor gene polymorphism.
Methods: Citrated platelet-rich plasma (2×10^8/mL) was prepared and subjected to light transmittance aggregometry with various doses of ADP (2.5–30 μM). The H1 and H2 gene haplotypes of P2Y12 receptor were determined by DNA sequencing of the corresponding PCR products. Statistic analysis was performed with Two-tailed Mann–Whitney U test. This study was approved by the Ethical Committee of the Tzu Chi Buddhist General Hospital and all the healthy blood donors, including 47 females and 38 males, aged between 20 and 50 years old, gave their written informed consent.
Results: The response of platelets to ADP (5 μM) varied markedly among individuals ($n = 85$) and the variation was shown associated with the gene polymorphism of P2Y12 receptor, carriers with the P2Y12 gene H2/H2 haplotypes ($n = 19$) exhibited higher platelet aggregation response to ADP as compared with the H1/H1 haplotypes. The individual variability of ADP-induced platelet aggregation become insignificant as the platelets had been pretreated with aspirin, an irreversible cyclooxygenase inhibitor.
Conclusion: There is a marked difference in ADP-induced platelet aggregation among Taiwanese healthy subjects and this variation might be attributed to the distinct level of thromboxane A2 formation in platelets following ADP activation. The H2 haplotype of P2Y12 receptor gene associated with enhanced platelet reactivity might be a useful genetic marker in distinguishing between patients who need more intensive antithrombotic treatment in Taiwanese population.

PB 1.25-3

Purified dietary anthocyanin inhibited platelet secretion in hypercholesterolemia

Song F[1], Shi Z[2], Zhu Y[2], Tian J[2], Chen L[2], Ling W[2] and Yang Y[2]
[1]Sun Yat-sen University; [2]Department of Nutrition, School of Public Health, Sun Yat-sen University, GuangZhou, China

Background: Platelet secretion has been established to be a safe and effective target to prevent atherosclerosis and thrombosis formation. Hypercholesterolemia is one of the major risk factors for CVDs, in which platelet secretion is increased and enhance the formation of thrombosis and atherosclerotic lesions. Anthocyanins are major phytochemicals abundant in plant food and have been shown to play a protective role against CVDs. Our previous studies showed that anthocyanin could inhibit platelet activation and attenuate thrombosis formation, however, the effects of anthocyanin on platelet secretion in hypercholesterolemia are still unclear.
Aims: To explore the effects and mechanisms of anthocyanin on platelet secretion in hypercholesterolemia patients *in vivo* and *in vitro* respectively.
Methods: *In vivo* study, 150 subjects with hypercholesterolemia consumed purified anthocyanin mixture (320 mg/day) or a placebo twice a day for 24 weeks in a randomized, double-blind trial. To estimate the platelet secretion levels, plasma levels of platelet factor-4(PF4), soluble

platelet selectin (sP-selectin), soluble CD40 ligand (sCD40L), regulated upon activation normal T cell expressed and secreted (RANTEs), transforming growth factorβ1 (TGF-β1), β-thromboglobulin (β-TG) were detected by ELISA, all of which are mainly derived from platelet granules. To confirm the effects, platelets from both healthy volunteers and hypercholesterolemia patients were then separated and purified and then incubated with purified anthocyanin mixture as well as the main two compounds of the mixture cyaniding-3-glucosides (Cy-3g) and delphinidin-3-glucoside (Dp-3-g) respectively *in vitro*. Platelet P-selectin and CD63 secretion induced by thrombin were detected by flow cytomety and the ATP release were measured in platelet Lumi-aggregometer. RANTES and serotonin contents were evaluated by ELISA.

Results: After intervention with purified anthocyanin mixture for 24 weeks in hypercholesterolemia patients, we observed significant reduction in the plasma levels of sP-selectin, sCD40L, RANTEs and β-TG as compared with the control group. PF4 and TGF-β1 levels were also reduced obviously though they didn't reach statistical significance. *In vitro* study in healthy volunteers, we found that purified anthocyanin mixture, Dp-3-g and Cy-3-g significantly inhibited platelet P-selectin and RANTES secretion, both of which stands for the α-granule secretion. The dense granule secretion levels evaluated by CD63, serotonin and ATP were also significantly reduced by purified anthocyanin mixture, Dp-3-g and Cy-3-g. Study in platelets separated from hypercholesterolemia patients showed similar inhibitory effects of these three compunds on platelet granule secretion though the effects were slightly weaker than that in healthy volunteers' platelets. We further found that Cy-3-g attenuated thrombin-induced P38 MAPK and ERK1/2 phosphorylation in platelet in a dose dependent manner.

Conclusions: Our data clearly demonstrated for the first time that purified anthocyanin markedly inhibited platelet secretion in both hypercholesterolemia patients and healthy volunteers, the P38 MAPK and ERK1/2 signaling pathway were possibly one of the mechanisms of anthocyanin.

PB 1.25-4

Polymorphism of human platelets antigens in Tunisian patients with acute ischemic stroke

Houki R[1], Ben Said M[1], Sfar I[1], Dhaouadi T[1], Younes S[2], Bannour I[3], Boughamoura L[4], Guermazi S[1], Ben Abdallah T[1] and Gorgi Y[1]

[1]Charles Nicolle Hospital of Tunis, Tunis; [2]Tahar Sfar Hospital of Mahdia, Mahida; [3]Faculty of Medicine of Monastir; [4]Fattouma Bourguiba Hospital, Monastir, Tunisia

Background: The role of genetic risk factors in ischemic stroke is unclear. The polymorphism of human platelets antigens (HPA) has been implicated in the pathogenesis of arterial thrombotic diseases mainly the myocardial infarction.

In the context of the Identification of stroke susceptibility genes, we investigated the gene frequencies of five major human platelets antigens (HPA 1–5) in Tunisian population and to assess if polymorphism of HPA is associated with acute ischemic stroke (AIS) in Tunisian.

Patients and Methods: DNA was isolated from peripheral blood collected from 71 consecutive stroke patients and 100 healthy blood donors.

HPA 1–5 genotyping was performed by the polymerase chain reaction method using sequence-specific primers (PCR-SSP).

Gene frequency distribution was tested by Hardy-Weinberg equilibrium. Comparisons of HPA gene frequencies between the patient and control groups were made by chi-square test. Haplotype associations were tested by SNPStat software.

Results: The allelic frequencies of HPA-1, 2, 3, and 4 among patients and controls did not reveal significant differences. However, the HPA-5a allele was significantly more frequent in patients than in controls ($P < 0.002$).

The genotype distribution of HPA-4 polymorphism reveals that the HPA-4a4b genotype was more frequent in patients (67/71: 94.36%) than in controls ($P < 0.001$). The frequency of HPA-1b1b and HPA-3a3a were higher in control subjects than patients ($P = 0.009$ and $P = 0.01$ respectively).

The haplotype distribution of HPA-1, HPA-3 and HPA-4 (located on the same glycoprotein complex GPIIb/IIIa) showed that aab and abb haplotypes were statistically more frequent in patients than in controls ($P < 0.001$ and $P < 0.001$ respectively).

Conclusions: In the literature, the involvement of human platelets antigens in the occurrence of an ischemic stroke is conflicting.

In our population, a positive association between HPA-4a4b and stroke is found. The aab and abb haplotypes of HPA-1, HPA-3 and HPA-4 seem to be also implicated. HPA-1b1b and HPA-3a3a were identified as a protective genotype.

The value of HPA polymorphisms as useful markers for potential risk of ischemic stroke deserves to be confirmed on larger studies.

PB 1.25-5

Modeling and molecular dynamics simulations: structural comparison of the V33 variant of the integrin subunit β3 with its L33 (HPA-1a) and P33 (HPA-1b) forms

Jallu V[1], Poulain P[2], Fuchs PFJ[2], Kaplan C[1] and De Brevern AG[2]

[1]INTS; [2]Inserm U665 – INTS, Paris, France

The human platelet antigen (HPA)-1 system carried by the αIIbβ3 integrin is characterized by a leucine (allele 1a)-to-proline (allele 1b) substitution in position 33 of the mature β3 subunit. This alloantigenic system is the first cause of alloimmune thrombocytopenia in Caucasian populations and the allele HPA-1b may be a risk factor for thrombosis. The HPA-1 system presents a third variant defined by a valine in position 33, a variant not described as immunogenic (Santoso et al, Transfusion 46:790–799, 2006). Sera containing alloantibodies to the HPA-1a antigen react variably with the V33 form of β3. This suggests structural alterations of the V33 β3 although leucine and valine have similar physical and chemical properties; they differ only by the size of their side chain as valine lacks a -CH2- radical. In this work, we studied the structural modifications related to the L33V substitution, and compared the structures of the three β3 variants.

A 3D structural model of the V33 β3 extracellular domain was obtained by *in silico* mutagenesis of a L33 β3 model (Jallu, Poulain et al, PLoS One. 2012;7(11):e47304,). Molecular dynamics simulations showed that the high flexibility of the PSI, I-EGF-1, and I-EGF-2 domains is conserved. L33 and V33 β3 structural models share many characteristics although V33 β3 adopt specific features. We use a series of 16 small protein prototypes named Protein Blocks (PBs) to analyze precisely the local protein conformation (de Brevern et al, Proteins; 41:271–287, 2000). PBs analysis revealed in particular that the L33V substitution strongly displaces structural equilibriums toward a loop tightly maintained by hydrogen bonds for residues 27–31 of the PSI domain, and toward a β-turn with a start of a helical motif for residues 435–338 of the I-EGF-1 domain (more than 90% of occurrences in both cases). In L33 and P33 β3, these structures are in dynamical equilibriums with extended conformations (more than 40% of occurrences).

Despite common features between leucine and valine amino acids, our study showed that the L33V substitution effectively affects the dynamic equilibrium of the structural model of β3. Nonetheless, structural similarities between L33 and V33 β3 models underlie the variable reactivity of anti-HPA-1a alloantibodies with V33 β3. Unlike the L33P substitution, the L33V change is not expected to significantly affect the flexibility, if at all, of the PSI, I-EGF-1, and I-EGF-2 domains composing the β3 knee, suggesting that the functions of αIIbβ3 are not altered.

Characterization of HPA-1a epitopes is challenging, yet important regarding the high clinical impact of this platelet alloimmune system. Studies on HPA-1a epitopes are still needed to develop new techniques or applications and to understand underlying mechanisms.

PB 1.25-6

Diagnostic laboratory validation of platelet transmission electron microscopy

Chen D[1], Uhl CB[1], Barness R[1], Olson MC[1], Gossman S[1], Erdogan S[1], Gamb S[1], Charlesworth JE[1], Miller RS[1], Salisbury JL[1], Nichols L[1] and White JG[2]

[1]Mayo Clinic, Rochester, MN; [2]University of Minnesota School of Medicine, Minneapolis, MN, USA

Background: Among various hereditary qualitative platelet disorders, storage-pool deficiencies (SPD), such as dense granule (DG) deficiency (including Hermansky-Pudlak syndrome), are relatively common. Platelet whole mount (WM) and thin section (TS) transmission electron microscopic studies (TEM) are the gold standard Methods for diagnosing DG deficiency as well as other ultra-structural abnormalities. Nevertheless, platelet TEM tests are still largely research tools and have not been thoroughly validated and standardized as clinical tests according to current diagnostic laboratory quality standards and requirements. Furthermore, normal reference ranges of mean platelet DG counts/platelet (DGC) have not been adequately established.

Aim: Our goals were to validate platelet WM and TS TEM tests, and establish the normal reference ranges of platelet DGC.

Methods: Based on previously established methods (Blood, 33:598–606), whole blood samples collected in ACD-(A or B) tubes from healthy donors were employed for this study. We first optimized and standardized various pre-analytical, analytical and post-analytical procedures including sample matrix, sample stability, platelet-rich plasma (PRP) preparation, coated-grid options, platelet WM protocol, automated sample processing for TS, and lastly establishment of DG counting criteria. We started a large normal range (confident intervals, CI) study of the DGC, and have recruited 32 healthy donors to date. Statistical analyses by JMP 10 program were employed in this study.

Results: Of the two ACD tubes, ACD-B anticoagulated whole blood samples gave a more stable DGC and better TS ultra-structure quality than those of ACD-A samples. Both mean DGC and platelet ultra-structure were stable when ACD-B whole blood samples were stored at room temperature (RT) for up to 4 days. The optimal centrifugation setting for preparing PRP is 200 g for 20 min at RT. Interestingly, after centrifugation, platelets that were devoid of any DG were enriched in the upper 1/3 proportion of the PRP. The lower 2/3 proportion of PRP thus gave a more consistent DGC. Among various commercial grids, formvar-carbon coated 200 mesh grids (Electron Microscopy Science) gave the most reliable platelet adhesion and DGC. Platelet TS sample processing was automated by using an agar embedding procedure on a Leica processor. The DG counting criteria were developed based on previous publications and guidance from Dr. James G. White. Using the same WM TEM images and DG counting criteria, agreements among different technologists ($n = 5$) improved from 60% to 95%. Finally the on-going DGC normal range study (nine male and 23 female; age range 22–72 years; scoring 100–200 platelets from each donor) showed that the DGC distribution of each sample was positively skewed (skewness = 0.7–1.5) with on average 17% of platelets (95% CIs: 5–32) being empty. The mean DGC was 2.6 with 95% CIs at 1.6 and 4.0. Neither gender nor age was associated with the mean DGCs.

Conclusion: We investigated and validated platelet WM and TS TEM procedures. Our on-going normal range study of the DGC demonstrated a distinct distribution pattern. We also noticed that the DGC was procedure-dependent, further underscoring the importance of platelet TEM procedure standardization.

PB1.26 – Platelet Function in Disease

PB 1.26-1

Enhanced lipid peroxidation and platelet activation as potential contributors to increased cardiovascular risk in the low-HDL phenotype

Vazzana N[1], Ganci A[2], Cefalù AB[2], Lattanzio S[1], Noto D[2], Santoro N[1], Saggini R[3], Puccetti L[4], Averna M[2] and Davì G[1]

[1]Center of Excellence on Aging, "G. d'Annunzio" University of Chieti, Chieti; [2]Internal Medicine, University of Palermo, Palermo; [3]Department of Neuroscience and Imaging, "G. d'Annunzio" University of Chieti, Chieti; [4]Atherothrombosis Center, Division of Hematology, University of Siena, Siena, Italy

Background: Low HDL levels are major predictors of CV events, even in patients on statin treatment with LDL at target. In animal models HDLs protect LDL from oxidation and blunt platelet activation. Our study is aimed at examining whether HDL levels are related to *in vivo* oxidative stress and platelet activation, as determinants of atherothrombosis.

Methods and Results: Urinary 8-iso-$PGF_{2\alpha}$ and 11-dehydro-TXB_2, *in vivo* markers of oxidative stress and platelet activation, respectively, were measured in 65 CHD normocholesterolemic patients with HDL $\leq$ 35 mg/dL, and in 47 CHD patients with HDL > 35 mg/dL. The two eicosanoids were also measured before and after fenofibrate treatment in otherwise healthy subjects with low HDL ($n = 10$).

Patients with HDL $\leq$ 35 mg/dL showed significantly higher urinary 8-iso-$PGF_{2\alpha}$ [median (25th-75th percentile): 289 (189–380) vs. 216 (171–321) pg/mg creatinine, $P = 0.019$] and 11-dehydro-TXB_2 [563 (421–767) vs. 372 (249–465) pg/mg creatinine, $P = 0.0001$] than patients with higher HDL. A direct correlation was found between urinary 8-iso-$PGF_{2\alpha}$ and 11-dehydro-TXB_2 in the entire group of patients (Rho = 0.77, $P < 0.0001$). HDL levels were inversely related to both 8-iso-$PGF_{2\alpha}$ ($\rho = -0.32$, $P = 0.001$) and 11-dehydro-TXB_2 ($\rho = -0.52$, $P < 0.0001$). On multiple regression, only 8-iso-$PGF_{2\alpha}$ ($\beta = 0.68$, $P < 0.0001$) and HDL levels ($\beta = -0.29$, $P < 0.0001$) were associated to urinary 11-dehydro-TXB_2 excretion, independently of gender, age, smoking, hypertension, diabetes, previous myocardial infarction, total cholesterol, LDL, and triglycerides. Fenofibrate treatment significantly reduced the two eicosanoids in healthy subjects, in parallel with an HDL increase.

Conclusions: A low HDL phenotype, both in CHD patients and in healthy subjects, is associated with increased lipid peroxidation and platelet activation. These data provide novel insight into the mechanisms linking low HDL to increased CV risk.

PB 1.26-2

Platelet activation and thrombin-generation in paediatric patients with acute ITP, chronic ITP and chemotherapy-induced thrombocytopenia

Schmugge M, Winkler J, Kroiss S and Speer O

University Children's Hospital Zurich, Zürich, Switzerland

Background: Immune thrombocytopenic purpura (ITP) is a common hematologic disorder in children that can lead to severe bleeding symptoms in rare occasions. Yet no biological markers were identified to predict bleeding severity or the risk for life threatening bleeds. Platelet count helps to identify patients at risk, but does not help to predict severe bleeding events. Therefore we investigated platelet activation and thrombin generation in children with ITP.

Aims: First we aimed to identify differences in markers of platelet activation and thrombin generation (TG) among patients with ITP, thrombocytopenia induced by chemotherapy (cTP) and healthy

children and second, to correlate this to clinical symptoms and bleeding score results.

Methods: In a prospective study we investigated venous blood samples of 20 patients (median age 6.5 years, range) with newly diagnosed acute ITP, before and after treatment with IVIg. In addition we studied 20 chronic ITP patients. Severity of bleeding symptoms was assessed according to a paediatric bleeding score for ITP (Buchanan et al., 2002, *J Pediatr*; 141:683–8). Eleven children with oncologic disease and cTP and 18 healthy children served as controls. Platelets were identified as CD42-positive events by flow cytometry and analysed for exposure of CD62 (P-selectin), CD63 and PAC1 using fluorochrome labelled monoclonal antibodies, to identify activation of platelets before and after thrombin-stimulation. TG was measured by a chromogenic assay.

Results: Median bleeding score at presentation was 2–3 in acute ITP and decreased to 1–2.5 in patients with chronic ITP. All acute ITP patients were treated with max. Three doses of IVIg (0.4–0.8 g/kg/dose) and increased the platelet count above 30,000/mL. Platelets of ITP patients showed a higher expression of CD63 than platelets of other thrombocytopenic patients, even before thrombin stimulation (27.21 ± 5.35%; thrombopenic controls 9.29 ± 1.7%). After thrombin stimulation, expression of all activation markers CD63, CD62 and PAC1 rose significantly. Both, patients with ITP and cTP, showed reduced thrombin-stimulated expression of CD63, CD62 and PAC1 compared to healthy controls. IVIg improved platelet activation after thrombin-stimulation to values seen in healthy controls. TG was reduced in acute-, chronic ITP and in cTP patients. In children with acute ITP, TG normalized after IVIg, even without normalization of platelet counts. The lowest TG was seen in cTP patients, that was even lower than in acute ITP ($P < 0.05$). A higher bleeding-score did not correlate with lower TGA or lower platelet activation. A weak correlation ($r = 0.38$, $P < 0.01$) was found between platelet counts and TG.

Summary: Platelets of ITP patients are partly activated, more than platelets of patients with chemotherapy-induced thrombocytopenia. Hence this activation is not correlated to increased TG. While the lowest TG is seen in cTP, in children with acute ITP, platelet activation and low TG can be increased by IVIg to values similar to healthy children.

PB 1.26-3

A clinical pilot study to compare T2MR and VerifyNow P2Y12 platelet activity measurements in cardiovascular patients

Vinagre YM[1], Niroula R[1], Chhabra L[1], Massefski W[2] and Lowery TJ[2]

[1]Saint Vincent Hospital, Worcester, MA; [2]T2 Biosystems, Lexington, MA, USA

Background: Platelets play a critical role in well-regulated hemostasis, and the definition of adequate regulation can change with the clinical state of the patient. The challenges of developing clinically relevant and timely surrogates to monitor platelet function are well established. Light transmission aggregometry (LTA) is the only established method that correlates to clinical outcomes, but LTA requires expert technical skills to run, may require a variety of agonist conditions to get a true measure of the state of the patient, and the data can be difficult to interpret. More recent measures of platelet function that rely on highly-specific single activator tests, such as ADP, can monitor the pharmacodynamics of specific platelet receptor inhibitors, but such tests do not predict adverse clinical outcomes related to platelet dysfunction. We will present preliminary clinical results to demonstrate that a new T2MR detection method may correlate with ADP-induced platelet activity and clotting in interventional cardiovascular patients 90% of the time.

Aims: T2 Biosystems has developed a simple, novel method to monitor platelet function using a portable T2 magnetic resonance (T2MR) device and small volume samples. The methodology enables use of all standard platelet activators and inhibitors. Here we used an ADP activator cocktail to make a global T2MR hemostasis function test sensitive to P2Y12 inhibition by measuring platelet activity in the biological context of fibrin clot formation and platelet mediated clot retraction.

Method: In our prospective, non-blinded, single centered pilot study, 30 patients who presented with chest pain and underwent a diagnostic or interventional cardiac catheterization were enrolled over a 6 month period. The VerifyNow P2Y12 test was run at the discretion of the ordering cardiologist, with the T2MR ADP assay run in parallel. Test results were reported as either active or inactive platelet function. The VerifyNow P2Y12 test was interpreted as platelet-inhibited (VN−) for PRU < 213, and platelet-active (VN+) for PRU > 213. The T2MR platelet function test was interpreted as platelet-inhibited (T2MR−) if the second hemostasis peak in the T2 signal profile fell below 5% of the total T2 signal, and platelet-active (T2MR+) if this signal was > 5%.

Results: In a retrospective analysis of T2MR and VerifyNow test data and associated patient clinical records, we found that 75% of cases ($N = 17$ T2MR+/VN+ and $N = 6$ T2MR−/VN−) were in agreement, with no significant adverse hemostatic events noted. Of the $N = 7$ cases in which the test results did not agree, examination of patient clinical records revealed that all ($N = 3$) of the T2MR+/VN− patients showed normal clotting or had no adverse events, although the incidence of rethrombosis is expected to be low. On the other hand, all ($N = 4$) of the T2MR−/VN+ patients were either on prasugrel ($N = 2$) or showed evidence of post-operative bleeding ($N = 2$), consistent with the T2MR signature indicating low clotting potential.

Summary: These preliminary clinical results suggest that the T2MR ADP test has the potential to predict the hemostatic state of ADP-induced platelet activity and clotting in interventional cardiovascular patients.

PB 1.26-4

Markers of activation haemostasis in patients with psychosis influence of an antipsychotic treatment: findings from the ANTRE study

Malý R, Masopust J, Andrýs C, Ba~ant J, Krejsková V and Hosák L

University Hospital, Hradec Králové, Czech Republic

Background: Patients with schizophrenia have an increased risk of venous thromboembolism (VTE), and this might be associated with the use of antipsychotics.

Aims: The primary goal of the present study was to replicate our previous finding of increased coagulation and thrombocytes activity in drug-naïve psychotic patients in comparison with healthy controls and ascertain whether the blood levels of thrombogenesis markers further increase over the course of a consecutive two-years antipsychotic treatment.

Methods: We investigated the plasma levels of markers indicating activation of coagulation (D-dimers and factor VIII) and platelets (soluble P-selectin, sP-selectin) in an antipsychotic-naive group of 27 men and 18 women with acute psychosis (27.7 ± 8.0 years, range 18–52), and 45 healthy volunteers matched for age and gender. In the patient group, we repeated these assessments after 3 and 12 months and again after 2 years of antipsychotic treatment.

Results: D-dimers (median 0.37 vs. 0.20 mg/L; $P < 0.0001$), factor VIII (median 142% vs. 116%; $P = 0.016$) and sP-selectin (median 155.4 vs. 112.4 ng/mL; $P < 0.0001$) plasma levels were significantly increased in the group of patients with acute psychosis prior to treatment compared with healthy volunteers. The plasma levels of sP-selectin varied significantly ($P = 0.016$) in the course of the 1-year antipsychotic treatment. The plasma levels of D-dimers and factor VIII significantly decreased during 1 year ($P = 0.016$ resp. $P = 0.046$.

Conclusions: We found increased markers of activation of haemostasis in patients with acute psychosis as well as in chronic stage. Our results

could explain possible pathological mechanisms of VTE in schizophrenia patients independently to antipsychotic treatment.

PB 1.26-5

Evaluation of aspirin use on platelet function in essential thrombocythemia and polycythemia vera patients

Panova-Noeva M[1], Marchetti M[2], Russo L[2], Finazzi G[2], Rambaldi A[2], Ten Cate H[3] and Falanga A[2]

[1]Medical Faculty, Skopje, Macedonia; [2]Ospedali Riuniti di Bergamo, Bergamo, Italy; [3]Maastricht University, Maastricht, The Netherlands

Background: Essential Thrombocythemia (ET) and Polycythemia Vera (PV) are two myeloproliferative neoplasms (MPN) characterized by a hypercoagulable state and an increased rate of thrombotic complications. The treatment choice of these diseases is highly dependent on the patient thrombotic risk. Antiplatelet prophylaxis with low dose aspirin is effective in reducing the thrombosis rate in PV patients, while alleviates vasomotor (microvascular) disturbances, and prevents pregnancy-associated complications in patients with ET, particularly those carrying the JAK2V617F mutation. Although low dose aspirin is now largely utilized for thromboprophylaxis in both low and high risk ET and PV patients, however there are subjects on aspirin who show platelet activation and persistent thromboxane biosynthesis.
Aim: To characterize the effect of aspirin on platelet adhesive and procoagulant function in ET and PV patients.
Methods: In this study the PFA-100 assay in whole blood and the thrombin generation (TG) assay in platelet rich plasma (PRP) were performed in a group of 46 ET and 38 PV patients to evaluate the effect of aspirin on platelet adhesive and procoagulant properties.
Results: PFA-100 collagen-epinephrine closure time was significantly ($P < 0.01$) prolonged in patients compared to healthy controls. However, the PFA-100 showed flow obstruction in 20% of patients after collagen-adenosine diphosphate and in 15% of patients after collagen-epinephrine trigger, the majority of them while on aspirin. Higher platelet count and immature platelet fraction were associated with shorter collagen-adenosine diphosphate closure time ($R = -0.5$, $P < 0.05$ for both). The results from the TG assay showed significantly increased TG in PRP from patients compared to controls. Among patients on aspirin, JAK2V617F positive patients had higher TG compared to JAK2V617F negative patients. Within JAK2V617F positive patients, significant correlations between platelet and/or immature platelet count and TG ($R = 0.3$, $P < 0.05$ for both) were found.
Summary/Conclusions: This study demonstrates that PFA-100 and TG assays are potentially relevant methods for monitoring aspirin effectiveness in MPN patients. Elevated immature platelet parameters are suggested important factors influencing increased platelet adhesive and procoagulant properties. New prospective studies are warranted to evaluate the usefulness of PFA-100 and TG assay in identifying MPN patients at high risk for thrombosis.

PB 1.26-6

Inhibition of MRP4 down regulates platelet activation and prevents pre-clinical arterial thrombosis

Decouture B[1], Bachelot-Loza C[1], Belleville T[1], Dizier B[1], Gouin-Thibault I[1], Coqueran B[2], Lompré AM[3], Hulot JS[3] and Gaussem P[1]

[1]UMR_S765; [2]EA4475; [3]UMR_S956, Paris, France

Background: Platelet activation needs to be tightly regulated to prevent excessive platelet activity. In physiological conditions, major cytosolic inhibitors of platelet activation are cyclic nucleotides, cGMP and cAMP. Cytosolic rates of these second messengers result from an equilibrium between their synthesis, their degradation by phosphodiesterases and their relocation. Consequently, molecules that reduce the rate of cytosolic nucleotides, such as ADP stored in dense granules, act as platelet agonists. Indeed, following granule secretion, ADP binds to P2Y12 receptor, resulting in an inhibition of adenylate cyclase and of cAMP generation. Any mechanism involved either directly on cytosolic cyclic nucleotide level or on granular ADP may interfere with platelet activity. Recent studies pointed to the role of MRP4, a transporter of cyclic nucleotides and of ADP, specifically located on dense granule membrane in platelets, as a good candidate to control these mechanisms.
Aim: We evaluated *in vivo* and *in vitro* the role of MRP4 in the modulation of platelet functions using a MPR4−/− mouse model.
Methods: The total knock-out mice MRP4 (MRP4−/−), originally derived in the laboratory of J. Schuetz (St. Jude Hosp, TN, USA) on a FVB background, were compared to FVB wild-type (WT) mice. *In vitro* tests included platelet adhesion in flow conditions and washed platelet aggregation. *In vivo* tests performed were bleeding time (tail cut) and carotid arterial thrombosis (15% FeCl3 patch).
Results: Whole blood platelets from the two animal groups showed a similar initial adhesion on collagen in flow conditions, but aggregates were reduced in number and size after 3 min for MPR4−/− compared to WT. MRP4−/− washed platelet aggregation was impaired in the presence of low PAR4ap concentration (50 μM), with mean maximal aggregation at 16% compared to 53% in WT ($P < 0.01$). No differences were denoted at high PAR4ap concentration (100 μM) that induces activation poorly dependent of secreted ADP. Similar results were obtained in WT platelets in the presence of the MRP4 inhibitor MK571. A defect in platelet function related to an impaired ADP storage in MRP4−/− was further confirmed by secretion-independent aggregations performed in response to ADP, which were similar in the two animal groups.
The defect in platelet function was confirmed *in vivo* by a prolonged bleeding time in MRP4−/− (330 s) compared to WT mice (152 s; $P < 0.01$), in line with a greater volume of elapsed blood, estimated by hemoglobin assay (3253 vs. 327 mg for MRP4−/− and WT, respectively; $P < 0.001$). Arterial thrombosis experiments showed a significant longer occlusion time in MRP4−/− vs. WT mice (926 vs. 663 s; $P < 0.001$), suggesting that MRP4 inhibition protects against thrombosis.
Conclusion: These results show an impaired platelet function in MRP4−/− mice, part of which is likely to be related to an impaired ADP storage in dense granules. Our findings support previous studies, suggesting MRP4 as a new target for an antiplatelet agent. Ongoing work is conducted to evaluate the role of MRP4 in cAMP compartmentation in platelets.

PB1.27 – Platelets and Cancer

PB 1.27-1

Resistance to aspirin in myeloproliferative neoplasms: is it a reality? Evaluation of low dose aspirin resistance in a pilot study including 54 patients

Ajzenberg N[1], Faille D[2], Cung A[2], Huisse MG[2], Chomienne C[3], Jandrot-Perrus M[4] and Dosquet C[3]

[1]AP-HP INSERM; [2]Inserm U698, Bichat Hospital; [3]Inserm U940, Saint Louis Hospital; [4]U698 Bichat Hospital, Paris, France

Background: myeloproproliferative neoplasms (MPN) are associated with an increased risk of arterial and venous thrombosis varying from 2.6% per year to 4.9% according to the studies. Low dose of aspirin is recommended in primary and secondary prophylaxis of thrombosis in polycythemia vera. In the prospective ECLAP cohort (Marchioloi R et al, J Clin Oncol 2005), low dose aspirin is associated to a reduced incidence of cardiovascular events by 28%. However evaluation of biological efficacy of low dose aspirin is still questionable as incidence of biological resistance ranges from 1% to 65% depending on the method used and the delay after the ingestion.

Aim of the Study: To determine aspirin resistance by light transmission aggregometry in well-characterized MPN patients under low dose aspirin (75 mg/day), 24 h after the last ingestion of aspirin
Methods: we prospectively enrolled 54 patients with MPN identified in Saint Louis Hospital, Paris (Dr C Dosquet and Pr C Chomienne). All of them were under aspirin 75 mg/day. Resistance to aspirin was performed on platelet rich plasma by platelet aggregation induced by arachidonic acid 1.33 mM and tested 24 h after the last dose. Resistance to aspirin was defined by a maximal platelet aggregation over 20%.
Results: Only seven out of 54 patients were resistant to aspirin (AsaR). An increased daily dose of 100 mg during 7 days at least overcame this biological resistance in six out of seven patients. The other 47 patients in whom aspirin was efficient were noted as the AsaS group. Clinical characteristics could be summarized as follows: Polycythemia Vera was diagnosed in 29 and in 15 patients of the Asa S and of the Asa R group, respectively and Essential Thrombocythemia in five patients of the AsaS group and in two patients of the Asa R group. JAK2V617F mutation was present in 64% of the AsaS group and in 86% of the AsaR group. Platelet count was 331 ± 172G/L in the AsaS group and 378 ± 201G/L in the AsaR group
Interestingly, 71% of patients resistant to aspirin had a thrombotic event in the arterial circulation or microcirculation but not in venous area compared to only 34% of patients responder to aspirin (Asa S). Moreover, even though platelet count was slightly increased in the Asa R group compared to Asa S patients, it did not reach significance. The only patient resistant to 100 mg aspirin had no history of thrombosis and a normal platelet count at 316 G/L. Bleeding tendency consisted in ecchymosis, epistaxis and gingivorragia and was more frequent in Asa S patients (12/47) than in Asa R patient (1/7).
Conclusion: Increasing the dose of aspirin from 75 to 100 mg once daily seems enough to overcome aspirin resistance when tested in standardized conditions. Only one patient over 54 (1.8%) was still resistant to aspirin with 100 mg once a day. Moreover biological resistance to aspirin was associated to past history of arterial thrombosis in most of the patients. These results need to be confirmed in a larger study.

PB 1.27-2

Intraplatelet angiogenesis regulators more relevant than serum carcino embryonic antigen (CEA) to colorectal cancer (CRC)?

Bauters A, Beugnet-henaut C, Vaast B and Zerbib PF
University hospital of lille, Lille, France

Background: Serum CEA is the most widely used marker for CRC recurrence following curative resection, although the accuracy of CEA monitoring during the follow-up period of surgical resection is not always consistent. Furthermore normal serum CEA levels may be associated with early stages of tumor progression or with non-CEA producing tumor. The post-operative monitoring of CEA is useless for patients with normal pre-operative serum CEA. There is no biological marker to detect recurrence following curative surgery for these patients. Very early in the course of cancer development, variable concentrations of angiogenesis regulators can be taken up, internalized and concentrated in platelet alpha granules for a timely delivery to tumors through specific activation. This suggests an avenue for developping biomarkers to diagnose and monitor CRC. Prior to validate intraplatelet angiogenesis regulators (IPAR) as markers for CRC recurrence in patients with normal CEA, we must confirm the clinical significance of pre-operative IPAR and check platelet activation in these patients before surgery.
Aims: We compared concentration of two major angiogenesis regulatory proteins (VEGF, PDGF) in platelets of CRC patients with normal serum CEA to those of normal controls. We assessed platelet activation through plasmatic p-selectin concentration.
Methods: Blood sample from 43 patients with newly diagnosed CRC were analyzed for CEA before surgery, 31 patients (72%) presented with norman serum CEA (< 10 μ/L). Platelet contents of VEGF and PDGF, and plasma p-selectin were measured for these 31 patients and 31 controls free of CRC. Analyte concentrations were measured with quantitative sandwich enzym immunoassays (R&D system). VEGF and PDGF levels were adjusted to the number of platelets in the pellets by dividing the amount of analyte by the actin quantity. Variables with skewed distribution were log-transformed before being used as continuous variables in statistical analysis. Normal controls were younger than patients (mean age = 47.3 + 1.9 vs. 63.7 + 1.9 respectively), age was entered in a multivariate model.
The study was approved by the medical ethics committee, and informed consent was obtained from patients and controls.
Results: Thirty-one CRC patients stage I (n = 4), II (n = 7), III (n = 4), IV (n = 16) and normal serum CEA were compared to 31 controls. Before surgery CRC patients presented with significantly higher platelet VEGF and PDGF concentrations compared to controls (1.05 + 0.10 vs. 0.43 + 0.06; P = 0.022 and 2.5 + 0.09 vs. 2.07 + 0.04; P = 0.019 respectively). Platelet activation was higher for patients compared to controls (77.34 + 5.03 vs. 58.67 + 2.66; P = 0.036). Platelet counts were not different between patients and controls. We did not observe any difference in analyte concentrations according to the CRC stage.
Conclusion: We confirmed platelet activation in CRC. Pre-operative intraplatelet VEGF and PDGF seem to be more sensitive than CEA to CRC. these results provide further insights into CRC monitoring especially for patients with normal serum CEA prior to surgical resection. Next step will be to confirm these findings on a larger study and to mesure the effect of surgical resection on these parameters.

PB 1.27-4

Immune thrombocytopenia in patients with chronic lymphocytic leukemia treated with 2 – CdA-based regiments or chlorambucil

Trelinski J[1], Blonski J[1], Robak T[1], Chojnowski K[1] and Polish Adult Leukemia Group[2]
[1]Department of Hematology, MedicalUniversity of Lodz, Lodz, Poland; [2]PALG, Gliwice, Poland

Background: The relationship between treatment of Chronic lymphocytic leukemia (CLL) with cladribine (2 – CdA) or chlorambucil and immune thrombocytopenia (IT) have not been yet determined.
Methods: We retrospectively analyzed records of 777 patients treated in two randomized PALG (Polish Acute Leukemia Group) CLL programs with these agents.
Results: Immune thrombocytopenia occurred in 55 of 777 (7.1%) patients. No significant differences in IT prevalence was seen between patients on chlorambucil or 2-CdA – based regiments (P = 0.33). IT developed at a median time of 0.499 years (0.06–4.8) from the start of CLL therapy. This time was significantly longer in patients treated with chlorambucil (2.03 years, 95% CI: 0.06–4.22) in relation to patients treated with 2-CdA- based regiments (0.52 years, 95% CI: 0.34–0.69, P = 0.049). Overall survival (OS) of patients with IT and those without IT were not statistically different (2.65 vs. 3.2 years, P = 0.23) but the severity of bleeding was more pronounced in 2- CdA group. Response to IT therapy was 35%, 54% and 75% for steroids, chemotherapy and splenectomy respectively.
Conclusions: In this study we demonstrated unexpectedly high percentage of IT prevalence in patients with CLL requiring chemotherapy. Although no marked differences were seen in IT frequency in patients treated with 2 – CdA-based regiments compared to chlorambucil regimen the clinical course of haemorrhagic diathesis was more severe in 2 – CdA group. Also time that elapsed from study screening to IT diagnosis was significantly shorter in 2-CdA group than in chlorambucil group suggesting causative relation. The appearance of IT did not influence the median time of OS.

PB 1.27-5

Crosstalk between platelets and inflammation in nasopharyngeal carcinoma

Komala AS[1], Rachman A[1] and Harsal A[2]

[1]*Faculty of Medicine University of Indonesia;* [2]*Dharmais National Cancer Centre, Jakarta, Indonesia*

Background: Nasopharyngeal carcinoma (NPC) is an unique malignancy because of its geographical and ethnic patterns. South China and South East Asia have the highest incidence, while in Indonesia its incidence is about 5.66 cases per 100,000 populations per year. Complex interactions between tumor cells and circulating platelets play an important role in cancer growth and dissemination. Soluble Platelet-Selectin (sP-selectin) is a marker of *in vivo* platelet activation. Inflammation, marked by elevated Interleukin-6 (IL-6) concentrations, can have 'cross-talk' with platelets resulting in thrombosis. Thus we investigated the level of sP-selectin and platelet count in nasopharnyngeal carcinoma and whether they had correlation with IL-6.

Aims: Studying the 'cross-talk' between platelets and inflammation in nasophyarngeal carcinoma.

Methods: This was a cross sectional study including patients with newly diagnosed nasopharyngeal carcinoma at Cipto Mangunkusumo Hospital, Jakarta, Indonesia in period of May to November 2012. Soluble P-selectin levels in various stages of NPC were measured using a human sP-selectin Immunoassay (R&D Systems) following the manufacturer's instructions. Interleukin-6 concentrations were measured using a human IL-6 ELISA (Bender MedSystems). Platelets of every patients were counted by ABX Micros 60. SPSS version 13 software was used in this study.

Results: From 53 patients of NPC, 17 patients had distant metastatic sites. The mean age was 44.2 years with ratio of men to women was 3.4:1. The most prevalence histopathology was undifferentiated carcinoma (84.9%). The mean platelets count was 340,924/μL. Eleven percent of the patients had elevated platelet count (> 450,000/μL). The median level of sP-selectin was 46.6 ng/mL (inter quartile range: 42.07–58.67) while the median level of IL-6 was 17.02 pg/mL (inter quartile range: 10.45–25.31). The median level of sP-selectin was statistically significantly higher among patients with metastatic NPC than non-metastatic NPC (59.5 vs. 44.7; $P < 0.001$). Statistically, the platelet count in metastatic NPC was not different with non-metastatic NPC ($P = 0.717$). In metastatic NPC, IL-6 had correlation with platelet count ($r = 0.514$; $P = 0.035$) and sP-selectin ($r = 0.562$; $P = 0.019$). Platelet count also had correlation with sP-selectin ($r = 0.556$; $P = 0.02$). In non-metastatic NPC, IL-6 didn't correlate with platelet count ($P = 0.637$) or sP-selectin ($P = 0.751$) and there was no correlation between platelet count and sP-selectin ($P = 0.724$).

Conclusion: In metastatic nasopharyngeal carcinoma, there was an increased level of platelet activation than in non-metastatic NPC. Inflammation had significant contribution to platelet activation and platelet count in metastatic nasopharyngeal carcinoma.

PB 1.27-6

Role of thrombopoietin signalling in murine B-cell lymphoma

Josefsson EC, Lebois M, Cannon P, Moujalled D, Rutgersson A, Faraj F, Roberts A, Kile BT, Mason K and Alexander S

The Walter & Eliza Hall Institute of Medical Research, Parkville, Vic., Australia

Platelets have been linked to promotion of metastasis, and in some cases to supporting the tumor vasculature in solid tumors. However, the role of platelets in liquid tumors, such as lymphoma and leukemia, is largely unknown. Thrombopoietin mimetic drugs were recently approved and are currently in clinical trials for use in chemotherapy-induced thrombocytopenia. It is therefore important to better understand the roles of thrombopoietin and platelets in cancer, including hematopoietic malignancies.

We set out to investigate if changes in platelet number and signaling via thrombopoietin, the primary regulator of platelet production, would influence myc driven B-cell lymphoma progression. To test this, *Eμ-Myc* transgenic mice, a well-established model of human Burkitt's lymphoma, were mated with *Mpl−/−* mice that have severe reductions in platelets, megakaryocytes and megakaryocyte progenitor cells due to lack of thrombopoietin signaling through Mpl. In addition, we mated *Eμ-Myc* mice with *TpoTg*transgenic mice which over-express thrombopoietin leading to increased megakaryopoiesis and high platelet numbers. As previously described, *Mpl−/−* mice exhibit platelet counts approximately 10% of wild type levels, whereas *TpoTg* mice have 3.5 times higher platelet counts compared to wild type mice.

In transgenic mice Myc over-expression is under the control of the immunoglobulin heavy chain gene enhancer (*Eμ*). The central mechanism of *Eμ-Myc* induced tumorigenesis is early expansion of immature pro-B/pre-B cells, which further progress to a malignant state. We monitored differences in survival and the rate of tumor initiation by measuring pre-B cells in 4–5 week-old pre-malignant mice.

Remarkably, *Mpl−/− Eμ-Myc* mice had reduced survival as well as earlier onset of lymphomagenesis, based on increased splenic pre-B cell numbers and blood lymphocyte counts in 4–5 week-old mice compared to *Eμ-Myc* control mice. Conversely, our data indicate that elevated thrombopoietin signaling is protective.

Results of tumor transplant experiments of established *Eμ-Myc* tumors into *Mpl−/−* or wild-type mice, point to similar survival rates. This suggests that changes in platelet number do not influence the rate of lymphomagenesis after it has been initiated. Rather, thrombopoietin signaling through Mpl could be of relevance for the rate of tumor onset. In addition to regulating platelet counts, thrombopoietin is known to affect hematopoietic stem cell (HSC) number and quiescence. Mpl receptor deficient mice have increased cycling of HSCs. We propose that changes in HSC cycling or an altered environment arising from abnormal platelet number could be the mechanism(s) behind differences in tumor initiation and survival. Such studies currently are underway.

Our study shows that changes in platelet number and/or signaling via thrombopoietin influence tumor onset and survival in murine B-cell lymphoma.

PB1.28 – Platelets and Cancer

PB 1.28

Procoagulant microparticles in cancer patients: prognostic value

Vila V, Martinez-Sales V, Fleitas T and Reynés G

Hospital Universitario y Politécnico La Fe, Valencia, Spain

Background: Microparticles (MPs) are small vesicles (100 nm–1 μm) which directly bud from the plasma membrane of different cells, including blood, endothelial and tumor cells. The procoagulant MP levels increase in cancer patients. Nevertheless, the potential prognostic value of MPs in cancer remains unclear.

The aim of this study was to evaluate the potential prognostic value of MPs and MP-mediated procoagulant activity in cancer patients.

Material and Methods: We studied: (i) 60 patients with non-small cell lung cancer (NSCLC) stages IIIB and IV before first line, platinum-based chemotherapy +/2 bevacizumab, and after the third cycle of treatment; (ii) 22 patients, newly diagnosed, with histologically proven glioblastoma (GB) who received radiotherapy plus concomitant metronomic temozolomide treatment at a daily dose of 75 mg/m^2 before the start of radiochemotherapy and during the last week of this treatment. Sixty healthy subjects were evaluated as controls. Total MPs were quantified by flow cytometry by labeling with FITC-AnnexinV. Samples were acquired for 120 s at high flow rate. Plasma procoagu-

lant activity was assayed by the automated calibrated thrombogram as the endogenous thrombin generation measurements (TG, nM thrombin) and by the clotting time due to procoagulant phospholipids (PPLCT).
Results: The results of the current study show that the MP count (36,210 ± 34,494 vs. 11,088 ± 5814 MPs/120 s; $P < 0.0001$) and ETG levels (209 ± 86 vs. 158 ± 59 nMol thrombin, $P < 0.01$) are elevated in patients with NSCLC in comparison with healthy controls. Chemotherapy did not change the levels of these markers. MP levels positively correlated with TG levels, both before (Spearman $r = 0.60$, $P < 0.001$) and after treatment (Spearman $r = 0.68$, $P < 0.001$). We have also found an association between high MP levels, both before and after treatment, and survival. In GB patients the mean pretreatment levels of MPs were significantly higher than healthy controls (48,210 ± 47,700 vs. 11,088 ± 5814 MPs/120 s; $P < 0.001$). MPs and TG decreased, and PPLCT increased significantly after treatment. MP levels positively correlated with both pre- and post treatment levels of TG (Spearman $r = 0.74$, $P < 0.01$), and inversely correlated with pretreatment levels of PPLCT (Spearman $r = -0.86$, $P < 0.01$). It is also shown that a TG level greater than the 25th percentile in patients, after treatment with radiotherapy and concomitant temozolomide, is associated with a shorter survival.
Conclusion: Our findings provide new data on the prognostic value of MPs in patients with NSCLC and GB. The role of MPs as potential biomarkers in patients with cancer, treated with conventional chemotherapy or targeted therapies, warrant further study, since a better understanding of their role can open new perspectives in the fields of diagnosis and treatment.

PB 1.28-1
Effects of ultraviolet radiation on platelet shape

Terada C, Okazaki H, Satake M and Tadokoro K
Japanese Red Cross Society Central Blood Institute, Tokyo, Japan

Background: The adoption of pathogen reduction technology (PRT) has been considered for the implementation of safer platelet transfusion. PRT treatment involves ultraviolet (UV) radiation in a wide wavelength range; however, the effects of UV radiation at different wavelengths on platelets have not been fully clarified.
Aim: In this study, we evaluated the effects of UV radiation with UV of different wavelengths on the platelet shape.
Methods: An apheresis platelet concentrate was diluted with SSP+ additive solution (Macopharma) and used as a measurement sample (residual plasma rate, 30%). Changes in the platelet shape were monitored in real-time during the radiation of the sample with UV of 300–370 nm wavelengths (0–0.15 J/cm^2) using a 90° scattered light. The change in the amplitude of the signal (*amp*) obtained by frequency analysis of the change in the intensity of scattered light was used as an index of platelet shape change. The level of generation of reactive oxygen species (ROS) in platelets upon UV radiation was measured using hydroxyphenyl fluorescein (HPF).
Results: For UV with wavelengths shorter than 330 nm, *amp*, which indicates the percentage of discoid platelets, decreased with the dose of UV radiation. The extent of the decrease in *amp* increased with decreasing wavelength at the same dose of UV radiation. For UV with wavelengths longer than 330 nm, *amp* remained unchanged with increasing UV radiation dose. For UV with a wavelength of 300 nm, generation of ROS in the platelets was observed depending on the dose of UV radiation. There was a good correlation between the platelet shape change and the level of ROS generation ($r = 0.90$, $P = 0.04$). The platelet shape change and the generation of ROS in the platelets as a result of UV radiation at a wavelength of 300 nm were significantly suppressed ($P < 0.05$) in the presence of ascorbic acid (2.5 mM), an antioxidant.
Conclusions: UV radiation at wavelengths shorter than 330 nm induced a platelet shape change depending on the dose of UV radiation. It was suggested that the generation of ROS in the platelets is related to the platelet shape change upon UV radiation.

PB 1.28-2
Reversible blockade of GPIIb-IIIa reduces platelet storage lesions

Jennings LK, White M, Cholera S and Tyagi A
University of TN Health Science Ctr, Memphis, TN, USA

Background: The storage-related decline in platelet function and viability is collectively referred to as platelet storage lesions or PSLs. It has been suggested that PSLs actually begin when the automated forces of product processing delivers the first assault on the platelets prior to storage. During storage platelets begin to lose the ability to aggregate, as well as matrix adhesion capabilities. Platelet activation markers, soluble CD40 ligand (sCD40L) and CD62 accumulate on the platelet membrane surface or in the plasma environment over time. Finally, modifications in the expression of platelet-specific membrane proteins GPIb and GPIIb-IIIa and structural changes to the platelet cytoskeleton have been associated with platelet storage.
Aims: This study focused on a novel mechanistic approach that tested the hypothesis that GPIIb-IIIa blockade by a reversible agent, eptifibatide (EPT), may improve platelet functionality over storage time.
Methods: Platelet aggregation in response to 5 μg/mL collagen and to 20 μM ADP was measured as well as EPT occupancy and CD62 expression during blood bank storage of platelet products either treated with EPT or saline (SAL) control. pH and glucose was also monitored over storage time.
Results: Day 1 testing demonstrated that the platelet products were functional and that the added EPT saturated the GPIIb-IIIa receptors. At Day 3 of storage and after removal of the inhibitory effect of EPT, platelet aggregation response to collagen and ADP of the EPT-treated product had a discernible shape change and typical aggregation profile. However, the SAL control product had no evidence of shape change and only a minimal aggregation response. On Day 1, CD62 binding to the platelet product in the absence of exogenous agonist demonstrated little activation. By Day 3, CD62 MFI in the SAL treated product was 9-fold higher whereas in the EPT treated product, the MFI was increased < 4-fold. Furthermore, with ADP or TRAP activation, the MFI in the SAL treated product was slightly increased by 1.0- to 1.2- fold, respectively, indicating 'exhausted platelets'. In contrast, the EPT product had a more robust reactivity and the MFI increased by 2.5- to 5-fold, respectively, upon activation by ADP or TRAP. Other readouts showed that pH decreased from 7.5 to 6.5 and glucose was POS at day 3 in the SAL group compared to a constant pH 7.0 and NEG glucose for the EPT group.
Summary/Conclusion: Our data suggest that this novel treatment mitigates key characteristics of PSL and may be a viable, new approach for improving platelet post-transfusion survival and function. Reversible blockade of GPIIb-IIIa has the potential to reduce platelet storage lesions and lessen adverse events associated with platelet transfusion in patients that require platelet products. These data also suggest that EPT treatment may inhibit transitions in pH and have some benefit in reducing effects of early bacterial contamination.

PB 1.28-3

Sonorheometry assessment of aspirin effects on platelet contributions to blood clot stiffness *ex vivo* in patients undergoing cardiopulmonary bypass procedures

Lawrence MB[1], Lin-Schmidt X[1], Viola F[2], Ailawadi G[1] and Walker WF[2]

[1]*University of Virginia;* [2]*HemoSonics, LLC, Charlottesville, VA, USA*

Background: Platelets contribute significantly to blood clot stiffness and their decreased function may underlie bleeding following cardiopulmonary bypass (CPB) supported cardiac surgery. Few quantitative measures exist to guide transfusion of platelets during and immediately following CPB, leading to a shotgun approach to the delivery of multiple hemostasis-promoting products to the patient. Sonorheometry (SR) is a novel ultrasound-based technology that rapidly quantifies hemostasis from a blood sample by measuring *ex vivo* clot stiffness (*S*) during surgery using acoustic radiation force.

Aims: To assess platelet contributions to *ex vivo* CPB patient clot stiffness and correlate clot stiffness with pre-surgical aspirin therapy and intraoperative transfusion risk.

Methods: Forty patients were enrolled following informed consent (University of Virginia IRB approved study no. 14050) in a prospective pilot study to assess the utility of SR testing during surgeries involving cardiopulmonary bypass (CPB). The subset of subjects on aspirin therapy (81–325 mg/day) stopped ingestion 1–3 days prior to surgery. During surgery, patient blood samples (2 mL each) taken from the A-line were divided with one sample treated with abciximab and the other serving as a control. Samples were activated by kaolin (5 mg/sample) and changes in blood clot stiffness (*S*) were measured by SR. Blood was sampled immediately before surgery and 10 min after protamine infusion after the end of CPB. The blood sample was held in a custom ultrasound transducer holder at 37 °C. The anesthesiologist and the surgical team were blinded to the results of SR testing.

Results: A differential measure named the Platelet Activity Index (*PAI*) was defined by measuring *S* with and without the platelet IIb/IIIa integrin inhibitor, abciximab. *PAI* measured prior to CPB (*PAIpreCPB*) was 34% lower in subjects who were on prior aspirin therapy than those not on aspirin therapy ($P < 0.028$). *PAI* determined immediately after CPB (*PAIpostCPB*) was 33% lower in subjects on prior aspirin therapy ($P < 0.010$). Patients not on aspirin therapy had a 27% chance of receiving a transfusion. Patients on aspirin therapy had a 77% chance of receiving a transfusion. ROC analysis of platelet-based transfusions showed a correlation of *PAIpreCPB* measures with the surgical team's decision (AUC = 0.73, $P < 0.01$). Similarly, *PAIpostCPB* measures also correlated with the surgical team's transfusion decision (AUC = 0.71, $P < 0.018$). Furthermore, *PAI* was significantly lower for transfused subjects than for non-transfused subjects ($P < 0.003$).

Conclusions: In a prospective, small-scale pilot study, CPB patients on aspirin therapy had lower platelet contributions to *ex vivo* blood clot stiffness than CPB patients not on aspirin therapy and a higher occurrence of intraoperative platelet transfusions, suggesting the existence of residual impairment of platelet function due to aspirin treatment. SR assessment of platelet activity may help predict platelet transfusion needs and lead to more selective usage of platelets during surgery. This study was conducted following the guidelines of the Declaration of Helsinki.

PB 1.28-4

Use of high-sensitivity flow cytometry for the characterization of a lyophilized platelet-derived hemostatic agent

Gerrits AJ[1], Barnard R[1], Fitzpatrick MG[2], Berny-Lang MA[1], Michelson AD[1] and Frelinger AL III[1]

[1]*Boston Children's Hospital, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA;* [2]*Cellphire, Inc, Rockville, MD, USA*

Background: Uncontrolled bleeding is the leading cause of potentially preventable death among trauma patients in the pre-hospital civilian and military setting. Lyophilized platelets have been proposed as a therapeutic agent for pre-hospital management of hemorrhages. Characterization of the particles present in lyophilized platelet-derived hemostatic agents is essential for understanding the mechanism(s) underlying clinical benefit, to standardize production of the agent, and thus, to achieve reproducible clinical outcomes.

Aims: To develop a method to reproducibly quantify particles in discreet ranges between 300 nm and 15 μm, and immunophenotypically characterize particles in lyophilized platelet-derived hemostatic agents within each range.

Methods: Unstained or CD41a−, CD42b− and annexin V-stained samples were analyzed using the high sensitivity Beckman Coulter Gallios flow cytometer. To detect the smallest particles, forward light scatter (FSC) was collected in wide-angle mode with a threshold of zero and the photomultiplier tube (PMT) amplification was set to a gain of 2.0 and 500 V. To detect larger particles, FSC was collected in narrow mode and the PMT amplification was set to a gain of 1.0 and 350 V. Results of the median FSC-Area of bead standards were used to establish limits of regions corresponding to the following calibrated plastic microsphere sizes: 0.294–0.482, 0.482–0.9, 0.9–2.53, 2.53–5.037, 5.037–7.83, 7.83–14.73, and > 14.73 μm.

Results: Intra- and inter-day variability was determined for regions 0.482–0.9 and 0.9–2.53 μm by repeated measurements of a single sample. Intraday coefficients of variation (CV)s for these regions were 0.80% and 1.08%, respectively, while the interday CVs were 1.06% and 3.78%, respectively. Particles in human lyophilized platelet preparations showed a bimodal distribution of sizes by ungated analysis of wide-angle light scatter, with peaks just below the 0.294 μm and the 0.9 μm marker. Percentages of events in specific regions were: < 0.294 μm: 20–27%, 0.294–0.482 μm: 20–27%, 0.482–0.9 μm: 22–30%, 0.9–2.53 μm: 12–15%, 2.53–5.037 μm: 9–11% and > 5.037 μm: 3%. Due to the high sensitivity of the Gallios, a large number of particles < 0.482 μm were detected in ungated samples. However, these particles were negative for CD41a and CD42b and thus were eliminated when samples were gated on the basis of positivity for these markers. Percentages in the specific regions for CD41a+/CD42b+ events were: < 0.294 μm: 0.1%, 0.294–0.482 μm: 0.1–0.2%, 0.482–0.9 μm: 30–34%, 0.9–2.53 μm: 32–35%, 2.53–5.037 μm: 26–27% and > 5.037 μm: 7–9%. Analysis by narrow-angle light scatter of particles of both ungated and CD41a+/CD42b+ gated samples showed 17–23% of particles in size ranges > 5.037 μm. Samples were > 73% positive for annexin V in regions > 0.482 μm, compared to an isotype.

Summary/Conclusions: Results demonstrate reproducible quantification and immunophenotypic characterization of platelet derived particles across a wide range of sizes (< 0.294–> 14.73 μm). Characterization and standardization of the size and procoagulant phenotype of lyophilized human platelets is important for achieving reproducible clinical efficacy.

PB 1.28-5

Refrigerated storage of platelet products for transfusion in dogs

Segawa K, Fujimoto A, Kato T, Neo S, Hisasue M and Tsuchiya R
Azabu University, Sgamihara-shi, Kanagawa, Japan

Background: Platelet products for transfusion are normally stored at room temperature, and the storage time is limited to only 5 days to prevent the growth of potentially contaminating bacteria. Although refrigerated storage would likely reduce the growth of most bacteria, thus prolonging the storage, the *in vivo* survival time of human platelets after transfusion is known to significantly decrease due to refrigeration.
Aims: Preventing the rapid clearance of refrigerated platelets is challenging, and it is difficult or unethical to examine the effects of modifications to the storage protocols in human volunteers. Therefore, we examined the effects of refrigeration of platelet products in dogs to determine whether dogs could be used as an alternative to humans.
Methods: Canine platelet rich plasma in polyolefin containers was stored for 7 days at room temperature (22 °C) or at 4 °C with continuous agitation on a flat bed shaker. Samples were taken aseptically 1 and 7 days after storage, and the *in vitro* characteristics were assessed. The *in vivo* recovery and survival of the autologous platelet products that had been stored for 7 days were also assessed using a biotinylation method.
Results: The aggregability induced by collagen and ADP were better maintained in the refrigerated platelet products than in the platelets stored at room temperature on day 7 (22 °C: collagen, 36.7 ± 20.8%; ADP, 14.8 ± 12.9%; 4 °C: collagen, 72.3 ± 21.2%; ADP, 55.9 ± 29.5%). Significant differences were also found in the platelet counts, pH, glucose concentration, lactate concentration and the extent of shape change. No significant differences were found in the mean platelet volume, hypotonic shock response or lactate dehydrogenase activity. On the other hand, although the *in vivo* recovery was not significantly different, the survival time after transfusion of refrigerated platelet products was obviously shorter than that of room temperature stored platelet products (22 °C: 5.2 ± 0.6 days, 4 °C: within 2 days).
Summary/Conclusions: These results indicate that the effects of refrigeration on canine platelet products, especially the rapid clearance after transfusion, were similar to those in humans. Therefore, dogs may be considered a valuable preclinical model for assessing the effects of different modifications on refrigerated platelets in order to extend their storage life.

PB 1.28-6

Pneumatic tube transport affects platelet function measured by multiplate electrode aggregometry

Simon T, Forsling I, Eintrei J, Söderblom L and Antovic JP
Karolinska Sjukhuset, Stockholm, Sweden

Platelet activation and aggregation is an essential component of many thromboticevents. Multiple electrode aggregometry (MEA) is used to measure platelet function. Pneumatic tube transport systems (PTS) for delivery of patient samples to a centrallaboratory are often used to reduce turnaround time for vital analyses. We evaluated theeffects of PTS transport on platelet function as measured by MEA. Duplicate samples were collected from 32 healthy individuals, eight patients from anintensive care unit, four patients from a coagulation clinic and 14 patients from acardiovascular unit treated with aspirin, clopidogrel or both. One sample was sent usingthe PTS and the other was carried by personnel to the lab. Platelet function was measuredby means of a Multiplate® analyzer (Roche, Mannheim, Germany) using adenosinediphosphate (ADP test), arachidonic acid (ASPI test), collagen (COL test), ristocetin (RISTO test) and thrombin-receptor activating peptide-6 (TRAP test) as aggregationagonists. Samples transported using PTS showed a reduction of AUC-values of up to a 100% ofthe average as compared to samples carried by personnel and a majority showedreductions of AUC-values greater than 20% of the average. Bias ± 95% limits ofagreement for the ADP test were 26 ± 56% of the average. Bias ± 95% limits of agreementfor the ASPI test were 16 ± 58% of the average. Bias ± 95% limits of agreement for theCOL test were 20 ± 54% of the average. Bias ± 95% limits of agreement for the RISTOwere 14 ± 79% of the average. Bias ± 95% limits of agreement for the TRAP test were19 ± 45% of the average. We conclude that PTS transport affect platelet activity as measured by MEA. Weadvise against clinical decisions regarding platelet function on the basis of samples sentby PTS in our hospital settings.

PB1.29 – Megakaryocytes and Thrombopoiesis – I

PB 1.29-1

Purinergic signalling regulates human megakaryocytes function by inducing store-operated Ca^{2+} entry

Di Buduo CA[1], Moccia F[2], Battiston M[3], De Marco L[3], Mazzucato M[3], Cattaneo M[4], Tanzi F[2] and Balduini A[1]
[1]IRCCS San Matteo Foundation, University of Pavia; [2]University of Pavia, Pavia; [3]Centro di Riferimento Oncologico, Aviano; [4]Azienda Ospedaliera San Paolo, University of Milan, Milan, Italy

Background: During differentiation megakaryocytes migrate from the osteoblastic niche to the vascular niche of the bone marrow, where they convert the bulk of their cytoplasm into multiple long processes called proplatelets that assemble nascent platelets at their tips. Despite the well-defined mechanisms that drive proplatelet formation and architecture, less is known about the signals that trigger platelet production. Different findings highlighted the importance of autocrine signals, together with environmental factors, in the regulation of megakaryocyte behavior, however the exact mechanisms by which all these factors coordinate to promote platelet release are unknown. We previously showed that megakaryocytes, and not platelets, express the purinergic receptor $P2Y_{13}$ which interacts with constitutively released adenosine diphosphate (ADP) leading to proplatelet formation. ADP-dependent platelet activation relies on the increase in cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$), accomplished by store-operated Ca^{2+} entry. Despite this knowledge whether or not this mechanism plays a role in platelet production is not known.
Aims: Store operated Ca^{2+} Entry (SOCE) has been described to be required in different human cell types to promote interaction with extracellular matrix components. The aim of this study is to demonstrate the role of ADP-induced SOCE activation in regulating Mk behavior within extracellular matrix environment.
Methods: In this project we took advantage of an *in vitro* human model to obtain megakaryocyte from human cord blood-derived progenitor cells. We employed Ca^{2+} imaging to investigate the expression and functionality of SOCE in fully differentiated megakaryocytes by either pharmacological (i.e. cyclopiazonic acid) or physiological (i.e. ADP) stimulation.
Results: We demonstrated that ADP binding to $P2Y_{13}$ elicits a rapid increase in $[Ca^{2+}]_i$, followed by a plateau, which is lowered in Ca^{2+}-free solution, thereby suggesting the involvement of store-operated Ca^{2+} entry. Therefore, we provided the first evidence that megakaryocytes express the major candidates to mediate store-operated Ca^{2+} entry, STIM1 and Orai1, which were functionally activated upon depletion of the intracellular Ca^{2+} pool. The mechanism was inhibited by a phospholipase C inhibitor (U-73122), an inositol-3-phosphate receptor inhibitor (2-APB), or a specific store-operated Ca^{2+} entry blocker (BTP-2). Finally, studies on the effects of these compounds on megakaryocytes behavior revealed that Ca^{2+} entry form extracellular media is primarily involved in the regulation of cytoskeleton rearrangement responsible for cell adhesion and motility on extracellular

matrix components. Conversely, only Ca^{2+} mobilization form intracellular stores is required to activate signaling cascades that trigger proplatelet formation.

Summary/Conclusions: These findings provide the first evidence that ADP utilizes store-operated Ca^{2+} entry to regulate human megakaryocyte functions and open new perspectives in the evaluation of the signals that control platelet release *in vivo*.

PB 1.29-2

Establishment of conditions for *in vitro* and *in vivo* production of genetically modified human megakaryocytes and platelets

Thijs T[1], Broos K[1], Maes W[1], Vandenbulcke A[1], Fang J[2], Wilcox A[2], Vanhoorelbeke K[1] and Deckmyn H[1]

[1]KU Leuven Kulak, Kortrijk, Belgium; [2]Medical College of Wisconsin, Milwaukee, WI, USA

Background: In recent years, large-scale 'platelet-omics' studies and transcriptome screenings in healthy volunteers and patients suffering from thrombotic events have discovered a large number of differentially expressed platelet genes and proteins, whose function is largely unknown. Efficient methods for genetic manipulation and subsequent functional characterization of human megakaryocytes (MK) and platelets are however currently lacking due to a low number of human platelets produced *in vitro* and the need for a large number (35×10^6) of $CD34^+$ hematopoietic stem and progenitor cells (HSPC) for transplantation in immunodeficient mice and human platelet production *in vivo*.

Aims: We aimed to develop a method that allows efficient platelet-specific genetic modification of HSPC in combination with *in vitro* and *in vivo* production of human MK and platelets.

Methods: We initially tested three different cytokine cocktails (TSF16, TSF and TPO containing different concentrations of TPO, SCF, Flt-3-Ligand, IL-6 and IL-1β, for their ability to support *in vitro* differentiation. Differentiation of HSPC towards the megakaryocytic lineage was assessed by flow cytometry by determining expression of CD34, β_3 (CD61) and GPIbα (CD42b) and by light and transmission electron microscopy after 7 and 14 days. The best performing cytokine cocktail was then used for lentiviral transduction of HSPC with a vector containing the GFP gene under control of the α_{IIb} promoter (lenti-α_{IIb}-GFP-WPT), after which the percentage of GFP^+ MK was again assessed by flow cytometry. Finally, HSPC were prestimulated, transduced and transplanted in sublethally irradiated NOD/SCID/IL2R$\gamma^{-/-}$ (NSG) mice and the production of human GFP^+ platelets was assessed up to 6 weeks post-transplantation.

Results: In all three media tested, differentiation of HSPC was observed as an increase in the number of β_3^+ and GPIbα$^+$ cells concomitant with a decrease in the number of $CD34^+$ cells. Culturing of HSPC in TSF16 medium resulted in the highest number of β_3^+ ($69.7 \pm 5.5\%$; $n = 3$) and GPIbα$^+$ ($41.1 \pm 17.7\%$; $n = 3$) cells after 14 days. Successful differentiation of HSPC in this medium was furthermore confirmed by the detection of proplatelet-forming MK using light and electron microscopy. Following overnight prestimulation in TSF16 medium, lentiviral transduction of HSPC with lenti-α_{IIb}-GFP-WPT for 2×2 h at MOI 2.5 resulted in $29.7 \pm 5.0\%$ ($n = 3$) of α_{IIb}^+ cells successfully expressing GFP after 7 days of *in vitro* culture in TSF16 medium. Finally, we transplanted 5×10^6 lentivirally transduced HSPC into a sublethally irradiated NSG mouse. This resulted in the detection of GFP^+ human platelets in murine peripheral blood for up to 6 weeks post-transplantation.

Conclusion: We here report on the establishment of conditions that permit efficient lentiviral transduction of HSPC in combination with *in vitro* production of transgenic proplatelet-forming MK as well as *in vivo* production of transgenic human platelets in the circulation of NSG mice. Furthermore, our optimized protocol permits a sevenfold reduction in the number of cells needed for transplantation, compared to previously reported data. These results show that overexpression or knockdown of a gene of interest in human MK and platelets is feasible, thus paving the way to study genetically modified human platelets in mouse models.

PB 1.29-3

Protein synthesis in the late stages of megakaryocyte maturation triggers proplatelet formation

Machlus KR[1], Thon J[1], Campbell RA[2], Weyrich AS[2] and Italiano JE[1]

[1]Harvard Medical School and Brigham and Women's Hospital, Boston, MA; [2]University of Utah, Salt Lake City, UT, USA

Background: Platelets are essential for hemostasis, and thrombocytopenia (platelet counts $< 150 \times 10^9$/L) is a major clinical problem. Megakaryocytes (MKs) generate platelets by extending long, branching processes, designated proplatelets, into sinusoidal blood vessels.

Aims: While the mechanism of platelet production has been studied extensively, very little is known about what initiates and regulates proplatelet formation. We aim to identify and study proteins and corresponding signaling pathways that initiate proplatelet formation.

Methods: We used the IncuCyte high content live-cell kinetic imaging system to monitor proplatelet formation in cultured primary megakaryocytes differentiated from murine hematopoietic stem cells. Kinetic analysis of proplatelet formation over 24 h revealed maximum proplatelet formation after 8 h. Puromycin treatment was used to inhibit protein synthesis. Polysome profiling was used as a global measure of protein synthesis. To identify what proteins are dynamically changing during proplatelet formation, we compared the proteome of round vs. proplatelet-producing megakaryocytes by two-dimensional differential interference gel electrophoresis (2D DIGE).

Results: Inhibition of protein synthesis with puromycin significantly decreased proplatelet formation from $54 \pm 4.0\%$ to $17 \pm 3.8\%$, and significantly reduced the amount of proplatelets and platelets released. These data suggest proteins synthesized immediately preceding proplatelet formation are necessary for the transition from round to proplatelet-producing MKs. Polysome profiling of round MKs immediately preceding proplatelet formation revealed enrichment in the polysome fraction, showing protein synthesis is strikingly active during this time; the polysome fraction was significantly reduced following proplatelet formation. Interestingly, proteomic analysis between round and proplatelet-producing MKs revealed only a small number of differences, suggesting regulation of a subset of proteins is sufficient to drive proplatelet production.

We focused on one protein identified in the both 2D DIGE and polysome profiling analysis that was up-regulated in proplatelet-producing MKs, myristoylated, alanine-rich, C kinase substrate (MARCKS). Differential expression of MARCKS in MKs was confirmed by western blot and immunofluorescence. MARCKS is a protein kinase C (PKC) substrate that binds PIP_2 and crosslinks F-actin in its dephosphorylated form at the plasma membrane. To examine the role of the PKC pathway and MARCKS in proplatelet formation, we treated MKs with the PKC inhibitor and activator Ro 32-0432 and PMA, respectively. Ro 32-0432 treatment dose-dependently augmented proplatelet production up to 48%, while treatment of MKs with the PKC activator PMA dose-dependently inhibited proplatelet formation up to 84%, suggesting that MARCKS must be dephosphorylated to promote proplatelet formation. This is supported by western blots of MKs at different stages of development; MARCKS total protein increases over 3-fold in proplatelet producing MKs while there is a 1.8 fold decrease in phospho-MARCKS.

Conclusions: Our preliminary data suggest that the dynamic cytoskeletal process of proplatelet formation requires protein synthesis. We propose that MARCKS is enriched and dephosphorylated in round MKs, where it binds to and localizes PIP2 throughout the demarcation mem-

brane system, facilitating signaling necessary to initiate proplatelet formation. In the future, targeting MARCKS directly may be a viable therapeutic option to drive proplatelet production and initiate 'autotransfusion' of platelets from existing bone marrow megakaryocytes.

PB 1.29-4

Human pre-adipocytes differentiate into megakaryocytes and platelets using endogenous thrombopoietin

Matsubara Y[1], Ono-Uruga Y[1], Matsubara Y[1], Tanaka T[2], Goda N[2], Okamoto S[1], Ikeda Y[2] and Murata M[1]

[1]Keio University School of Medicine; [2]Waseda University, Tokyo, Japan

The regulation of megakaryopoiesis and thrombopoiesis is poorly understood. Better understanding of the mechanism may help us establishing novel strategy for *in vitro* production of sufficient number of platelets. We previously reported that pre-adipocytes differentiate into megakaryocytes (MKs) leading to platelet production. Pre-adipocytes exhibited the gene expression relevant to megakaryopoiesis and thrombopoiesis, such as p45NF-E2, GATA-2, thrombopoietin (TPO), and its receptor c-mpl. Among them, there is little expression of TPO in hematopoietic stem cells. TPO is the primary cytokine for megakaryopoiesis and thrombopoiesis, and recombinant TPO has been used to generate enriched populations of MKs using *in vitro* differentiation systems. The present study was undertaken to examine whether pre-adipocytes express endogenous TPO and c-mpl of sufficient magnitude to drive megakaryopoiesis. We used primary human pre-adipocytes (Cell Applications, Inc.). Cells were cultured either in MK lineage induction (MKLI) medium composed of IMDM, supplemented with L-glutamine, BSA, low-density lipoprotein cholesterol, iron-saturated transferrin, insulin, 2-beta-mercaptoethanol, and nucleotides, or in the maintenance medium, as a control medium, composed of DMEM supplemented with FBS and non-essential amino acids. The gene expression of TPO during MK differentiation using MKLI medium was examined by quantitative real-time PCR with premade primers (Applied Biosystems), and the threshold value of TPO normalized with GAPDH was 16.5 ± 0.8 on Day 0, 15.9 ± 0.6 on Day 5, 16.0 ± 0.5 on Day 8, unmeasurable level on Day 12, and unmeasurable level on Day 14. The protein levels of TPO measured by ELISA assay (Human TPO Quantikine, R&D) in the supernatant from 10^6 pre-adipocytes cultured in 2 mL MKLI medium were negligible on Day 0 and 28 ± 14 pg/mL on Day 8. No measureable TPO was observed in supernatants from pre-adipocytes on Days 0 and 8 cultured in the maintenance medium. These observations indicated that TPO was released into the supernatants when the culture medium switched from maintenance medium to MKLI medium. We examined MK differentiation from pre-adipocytes in MKLI medium in the absence (TPO-) or presence of exogenously added recombinant TPO, 50 ng/mL (TPO+). The frequency of human CD41-postive/CD42b-positive pre-adipocyte-derived cells in culture after 14 days was approximately 15% in TPO (-). Similar result was observed in TPO (+). The DNA ploidy, as assessed by propidium iodide staining, was from 2 to 16 N in TPO (+/−). The effects of the anti-c-mpl blocking antibody AMM2 (10 μg/mL) on MK production were performed on mouse pre-adipocytes which were also shown to differentiate into platelets. We observed 10-fold more CD41-positive cells in the absence of AMM2 than in its presence. For a platelet function, binding of Alexa Fluor 488-labeled fibrinogen to human pre-adipocyte-derived platelet-sized CD42b-positive cells in the presence of stimulation (5 U/mL thrombin) was increased to be approximately 20% as compared with the binding in its absence in TPO (+/−). Taken together, these findings indicate that pre-adipocytes differentiate into MKs and platelets using endogenous TPO. Although the precise molecular mechanism of TPO production during differentiation of pre-adipocytes into MK remains to be elucidated, our findings suggest the pre-adipocytes are reasonable cell candidate in production of platelets for clinical use.

PB 1.29-5

Expression and functionality of toll-like receptor 3 in the megakaryocytic lineage

D'Atri LP[1], Etulain J[1], Rivadeneyra L[1], Lapponi MJ[1], Fondevila C[2] and Schattner M[1]

[1]Institute of Experimental Medicine; [2]Bazterrica Clinic, Buenos Aires, Argentina

Background: Beyond having a key role in hemostasis, platelets and megakaryocytes also regulate the immune and inflammatory response, partially due to the expression of Toll-like receptors (TLRs) a family of proteins, which recognize molecular components of pathogens. Among the TLRs, TLR3 recognizes double-stranded (ds) RNA associated with viral infection, and induces the activation of the transcription nuclear factor-κB (NF-κB) and the production of type I interferons (IFN-I). We have previously demonstrated that Junin virus (JV), an arenavirus causative of Argentine hemorrhagic fever, or Poly (I:C), a synthetic dsRNA, ligand of TLR3, impair thrombopoiesis by decreasing release of *in vitro* generated-platelets. Moreover, JV or Poly (I:C) increase the expression of functional IFN-I receptor and induce the synthesis/release of IFN-I in early progenitors and mature megakaryocytes. Although we have shown TLR3 expression in megakaryocytes by RT-PCR, its expression and functionality in the megakaryocytic linage has not yet been studied.

Aims: To study the expression and functionality of TLR3 in the megakaryocytic lineage.

Methods: TLR3 expression was determined in human hematopoietic progenitors cells ($CD34^+$), $CD34^+$-derived megakaryocytes and peripheral blood platelets by RT-PCR, immunofluorescence and flow cytometry (FC). The TLR3 signaling pathways were evaluated by western blot. Platelet functionality was assayed by lumiaggregometry and FC. IFN-β release was determined by ELISA.

Results: We found that TLR3 is expressed throughout the entire megakaryocytic lineage at both, mRNA and protein level ($CD34^+$cells: 95 ± 2, megakaryocytes: 76.5 ± 5.2, platelets: 21.5 ± 1.8% of positive cells FC, $n = 3$). Treatment of megakaryocytes with two synthetic dsRNA such as Poly(I:C) or Poly(A:U) (100 μg/mL), resulted in the activation of NF-kB pathway, evidenced by the degradation of its inhibitor I-κB and phosphorylation of the p65 subunit, as well as in phosphorylation of Akt, Erk1/2 and p38 MAPK, known downstream pathways of TLRs. Moreover, megakaryocyte activation by both dsRNA decreased platelet production *in-vitro* (Poly(I:C): 78.8 ± 2.9; Poly(A:U): 81.8 ± 3.5% of control $n = 4$, $P < 0.05$) and triggered IFN-β gene expression and release that were abolished by inhibition of PI3K/Akt pathway with Ly294002 (C:0; Poly(I:C): 770 ± 21; Poly(A:U): 650 ± 27; Ly+Poly(I:C): 0; Ly+Poly (A:U):0 pg/mL, $n = 2$).

Similar to megakaryocytes, TLR3 agonists induce the activation of NF-κB, Akt and Erk1/2 pathways in platelets. Although both TLR3 ligands did not induce platelet aggregation or degranulation, they potentiate the aggregation mediated by suboptimal concentrations of classical platelet agonists such as ADP (2.3 ± 0.8 fold of control), collagen (1.8 ± 0.8), arachidonic acid (1.3 ± 0.2) and thrombin (1.8 ± 0.5; $n = 4$, $P < 0.05$ for each agonist). This effect was correlated with an increased integrin-αIIbβ3 activation determined by fibrinogen binding (C: 2 ± 0.6; Thr: 50 ± 9.2*, Poly(I:C)+Thr: 87 ± 2.8*, Poly(A:U)+Thr: 84 ± 4.2*% of binding, $n = 4$, $^*P < 0.05$ vs. control), and inhibited by blockade of the Akt pathway (Poly(I:C)+Thr: 164.8 ± 14.2; Poly(A:U)+Thr: 148.3 ± 15.1; Ly+Poly(I:C)+Thr: 98.3 ± 4.9*; Ly+Poly(A:U)+Thr: 101.7 ± 8.2*% of Thrombin, $n = 4$, $^*P < 0.05$).

The potentiation effect was also observed in the ATP release ($n = 4$ $P < 0.05$), but not in P-selectin membrane exposure.

Summary/Conclusions: Our findings indicate that functional TLR3 is expressed through the megakaryocytic lineage and suggest a potential role of this receptor in the megakaryo/thrombopoiesis alterations observed in viral infections.

PB 1.29-6

Evidence for non-hematopoietic Cre activity in Pf4-Cre mice

Pertuy F[1], Strassel C[1], Eckly A[1], Freund J-N[2], Duluc I[2], Gachet C[1], Lanza F[1] and Léon C[1]

[1]UMR_S949, INSERM, Université de Strasbourg, EFS-Alsace; [2]UMR_S1113, INSERM, Faculté de Médecine, Université de Strasbourg, Strasbourg, France

Background: Transgenic mice expressing Cre recombinase under the control of the Platelet factor 4 (Pf4) promoter are a powerful tool for genetic modifications in the platelet lineage. However, there has been recent indication of Pf4-Cre activity in hematopoietic progenitor and stem cells (Calaminus *et al*., *PloS one* 2012). In addition, our recent observation of tumors in descending colon in Pf4-Cre^{+} APC$^{flx/flx}$ (Adenomatous Polyposis Coli) mice suggests that the Pf4 promoter may even be functional in non-hematopoietic tissues.
Aims: The aim of our study was to evaluate expression of Pf4-Cre in several mouse organs and tissues.
Methods: PF4-Cre mice (C57BL/6-Tg(Cxcl4-cre)Q3Rsko/J) (Tiedt *et al*., *Blood* 2007) were crossed with a reporter mouse (B6.129(Cg)-*Gt(ROSA)26Sor^{tm4(ACTB-tdTomato,-EGFP)Luo}*/J) constitutively expressing the membrane-targeted tdTomato in all tissues. Following Cre-mediated recombination, the TdTomato gene is excised, allowing expression of the downstream eGFP cassette. Recombination was investigated in adult mouse organs or E14-15 whole embryos by confocal fluorescence microscopy and electron microscopy immunolabeling using anti-GFP antibody.
Results: As expected, all platelets exhibited recombination. Bone marrow and spleen also exhibited numerous recombined cells, some of which being identified by confocal microscopy as megakaryocytes. Electron microscopy immunolabeling of the bone marrow showed that these cells included stage I to stage III megakaryocytes, with a growing intensity according to cell maturity. The Pf4-Cre transgene thus appears to be expressed in the earliest detectable megakaryocytes. In addition, clusters of small recombined cells were also observed, which may be either megakaryocyte progenitors, or hematopoietic stem cells as previously suggested (Calaminus *et al*., *PloS one* 2012). A similar recombination of megakaryocytes and small cell clusters were present in fetal liver of E14-15 embryos. Recombined GFP-positive individual cells were also observed in whole embryo and adult tissues (heart, liver, lungs, pancreas, kidney, stomach, proximal intestine, caecum, colon, rectum), as infiltrating cells between tissue-specific cells. Some of these were macrophages as indicated by MOMA2- or F4/80-positive labeling. More surprisingly, we also observed eGFP expression in epithelial cells from both descending colon and rectum, but not in small intestine or ascending colon. This recombination displayed a mosaic pattern, and in most cases, only part of the gland was eGFP-positive, suggesting expression of Cre in some but not all stem cells. This expression of Cre in mouse colon and rectum may be at the origin of the tumor development in Pf4-Cre^{+} APC$^{flx/flx}$ mouse.
Conclusion: These data show that early recombination occurs in the megakaryocytic-lineage in PF4-Cre mice allowing to draw conclusion on genes important for megakaryocyte and platelet biology. In addition, we provide evidence that recombination may occur in other tissues that could result in unexpected phenotypes. Thus, care must be taken in interpretation of the data when performing integrated studies in whole animals.

PB 1.30-1

Increased circulating microparticles and endothelial cells in patients with psoriasis

Martínez-Sales V, Vila V, Ricart JMJ, Vayá A, Todolí J, Núñez C, Ballester C, Contreras T and Reganon E

Hospital Universitario y Politécnico la Fe, Valencia, Spain

Introduction: Psoriasis is a chronic pathology characterized by increased inflammation that can be associated with changes in the vascular endothelium.
Aim: We quantified the levels of circulating microparticles (MPs) and endothelial cells (CECs) in patients with psoriasis in order to analyze their relationship with endothelial and inflammation markers, subclinical atherosclerosis and microcirculation.
Patients and Methods: We studied 20 patients with psoriasis and 20 controls. Circulating markers of endothelial damage (MPs, CECs and von Willebrand factor, [vWF]) and inflammation (E-selectin, [E-sel]; Interleukin-6, [IL6] and C-reactive protein, [CRP]) were determined. Total MPs were quantified by flow cytometry by labeling with FITC-AnnexinV in an EPICS XL-cytometer. CECs were measured by an immunomagnetic technique and immunofluorescence microscopy. Subclinical atherosclerosis was assessed by carotid ultrasound to obtain intima-media thickness (IMT). Microcirculation was evaluated by nailfold capillaroscopy.
Results: CEC, MP, vWF, CRP and E-sel levels were significantly elevated in patients when compared with controls ($P < 0.05$). Ninety-four and 53% of patients had CEC and MP levels, respectively, higher than 99th percentile in controls. Forty-seven percent of patients simultaneously showed increased CEC and MP levels. MPs correlated with all inflammatory markers ($r = 0.68$–0.76, $P < 0.01$) and with IMT: mean IMT ($r = 0.76$, $P < 0.01$) and max IMT ($r = 0.60$, $P < 0.05$). CECs correlated with vWF ($r = 0.49$, $P < 0.05$) and with the number of capillaries per mm per mm ($r = 0.56$, $P < 0.05$).
Conclusion: Psoriasis patients show elevated CECs and MPs, as a sign of endothelial dysfunction which correlates with inflammation as well as some capillaroscopy findings and subclinical atherosclerosis.

PB 1.30-2

Chemotherapy and anti-angiogenic drugs affect composition and coagulant phenotype of cell-derived vesicles in cancer patients

Kleinjan A[1], Verhoeff J[1], Berckmans R[1], Kunst P[1], Van Doormaal F[1], Di Nisio M[2], Richel D[1], Kamphuisen PW[3], Büller HR[1] and Nieuwland R[1]

[1]Academic Medical Center, Amsterdam, The Netherlands; [2]G.D'Annunzio University, Chieti, Italy; [3]University Medical Center Groningen, Groningen, The Netherlands

Background: The relationship between chemotherapy and circulating microparticles in patients with cancer is complex. First, release of cancer cell-derived microparticles may contribute to resistance of cancer cells to chemotherapy. Second, chemotherapy and angiogenesis inhibiting agents promote a prothrombotic state in cancer, and microparticles have been shown to exhibit both pro- and anticoagulant features.
Aim: The aim of the present exploratory study was to determine the effects of therapy on the composition and coagulant activity of circulating vesicles.
Methods: Blood was collected from 11 patients with glioma and 5 patients with lung cancer, at respectively 4 and 6 different time points before and after start of two different chemotherapy regimens. Age and sex matched healthy subjects ($n = 11$) were included for the glioma

patients. In glioma patients, temozolamide was combined with bevacizumab, an anti-angiogenic agent. Patients with stage IIIB or IV lung cancer were treated with either cisplatin and gemcitabine, or with daily radiotherapy and cetuximab. Procoagulant activity was studied in a fibrin generation test. For some experiments, the coagulant activity of exosomes and other small types of vesicles in plasma was determined by removing microparticles by centrifugation. Numbers of endothelial and tumour-derived microparticles were determined by flow cytometry.

Results: Treatment did not affect the overall procoagulant activity of vesicles in cancer patients ($P = 0.39$). Plasma of three patients had a detectable coagulant activity in the exosome fraction before therapy, compared to plasma from six patients after chemotherapy. Levels of endothelial microparticles ($CD62E^+$) tended to increase in the glioma ($P = 0.18$), but not in lung cancer patients ($P = 0.41$). Baseline levels of microparticles exposing vascular endothelial growth factor receptor-1 (VEGFR-1) were increased in cancer patients compared to healthy subjects ($P = 0.012$), and VEGFR-1-exposing microparticles decreased by 85% after anti-angiogenic therapy in glioma patients ($P = 0.021$). Finally, overall, no differences could be observed in the levels of mucine-exposing microparticles, except in two lung cancer patients which showed a clear increase two days after chemotherapy.

Summary/Conclusion: In this small explorative study, chemotherapy and anti-angiogenic therapy lead to specific changes in the composition of circulating vesicles, especially with regard to endothelial- and tumour-derived microparticles. These changes are markedly different between the two patients groups and even between subjects within one group, suggesting that such microparticles may be associated with prognosis or response to treatment. At baseline, the procoagulant activity was mainly associated with microparticles, whereas after chemotherapy also a part of the procoagulant activity is associated with smaller vesicles (exosomes) in some patients, suggesting a role for such vesicles in the prothrombotic state after chemotherapy.

PB 1.30-3

The role of breast cancer cell microparticles in thrombogenicity, angiogenesis and apoptosis following chemotherapy

Aharon A[1], Ben-shaul S[1], Stern H[2], Barsela G[1], Loven D[3] and Brenner B[1]

[1]Rambam Health Care Campus; [2]Bruce Rappaport Faculty of Medicine, Technion, Haifa; [3]Haemek Medical Center, Afula, Israel

Background: Chemotherapy administered at the maximal tolerated dose (MTD) induces death of tumor cells and disruption of tumor blood vessels, as well as an increased incidence of thrombosis. MTD chemotherapy is followed by increased levels of microparticles (MPs) – vesicles of approximately 1 μm that are shed from cells membrane upon activation or apoptosis. Previous studies demonstrated that plasma of breast cancer patients with large tumor masses or distant metastases contains significantly more MPs than that of healthy subjects. MPs bearing tissue factor (TF) – the main activator of the coagulation cascade – play a role in pathogenesis of the pro-thrombotic state in cancer patients. In addition, MTD chemotherapy is followed by rebound angiogenesis facilitating tumor re-growth. We assume that post-chemotherapy tumor-MPs are involved in cancer thrombogenicity, angiogenesis and tumor invasion.

Study Aims: (i) Isolation and characterization of MPs obtained from breast cancer patients prior to and during chemotherapy administration and from human breast cancer cell lines in the presence or absence of chemotherapy drugs. (ii) Evaluation of the thrombogenic, angiogenic, invasive and apoptotic effects of these MPs on breast cancer cell lines and endothelial cells.

Methods: MPs were isolated from blood samples of the two groups during chemotherapy: (i) Patients after surgical removal of small tumors (chemotherapy is given as adjuvant treatment); (ii) Patients after biopsy only (chemotherapy is given as neo-adjuvant (pre-surgery) treatment). In addition, MPs were isolated from breast cancer cell lines: MCF-7 human breast adenocarcinoma and estrogen receptor (ER) positive and MDA231, ER negative, following exposure to starvation or chemotherapy. MPs of all types were characterized by cell origin, thrombogenic and angiogenic protein profile. MPs structure was evaluated by electron microscopy. In addition, MPs apoptotic effects on endothelial and breast cancer cell lines were assessed by the Tunnel assay and their angiogenic effects were evaluated by migration assay, and time laps microscopy.

Results: Breast cancer cell lines stimulation led to increased levels of cell apoptosis and release of MPs. Breast cancer MPs adhered to endothelial cells penetrated into the cells, affected cell hemostasis and distracted cells gap junctions. MDA231-MPs assessed after high-dose chemotherapy, showed increase in procoagulant activity and higher level of VEGF-receptor-1 compared to MPs obtained after low-dose chemotherapy. MDA231-MPs isolated following starvation adhered to endothelial cells, penetrated into the cells and affected cell angiogenesis by inducing tube formation, while MPs assessed after low-dose chemotherapy inhibited tube formation. Patients' MP TF/TFPI ratio, reflecting MPs thrombogenicity, increased during chemotherapy mainly as a result of decrease in the coagulation inhibitor TFPI on MPs surface.

Summary: We suggest that MPs of breast cancer patients may reflect the physiologic state and efficacy of the treatment and affect the hemostatic balance and angiogenesis. This research may clarify the role of tumor MPs in hypercoagulable states and angiogenic rebound associated with chemotherapy.

PB 1.30-4

Microparticle characterization in patients with acute leukemia at diagnosis and after induction therapy

Tsoran-Rosenthal I, Brenner B and Aharon A

Rambam Health Care Campus, Haifa, Israel

Background: Microparticles (MPs) are membrane vesicles shed from various cells that may express antigens reflecting their cellular origin. Tissue factor (TF)-bearing MPs play a major role in the pathogenesis of the prothrombotic state observed in patients with malignancies. Acute myeloid leukemia (AML) is characterized by rapid growth of abnormal blast cells that accumulate in the bone marrow and interfere with production of normal blood cells. AML patients can develop venous thromboembolism despite thrombocytopenia. We hypothesize that circulating MPs may serve as a biomarker, capable to reflect the change in blood cells population and predict thrombogenic states in AML patients at diagnosis and in remission.

Methods: Blood samples were collected from healthy controls and patients with newly diagnosed AML at three time points: diagnosis, 2 weeks after treatment initiation and at remission achievement.

Microparticle cell origins were characterized by specific fluorescent antibodies and analyzed by FACS. The fluorescent antibodies included: CD41 (platelet glycoprotein complex), CD 62P (P-selectin expressed on activated platelets); CD62E and CD144 (endothelial markers), CD11 (leukocyte marker), CD14 (monocyte marker) and Annexin V (for MPs expressing negative phospholipids on their surface). To distinguish MP from cancer cells, MPs were labeled by CD34, CD117, CD33, and HLA-DR (for leukemic blast cells).

In FACS analysis used to determine the pro- and anti-coagulant potential of microparticles in the study groups, each sample of MPs was labeled with fluorescent antibodies against TF, TF pathway inhibitor (TFPI) and markers of the protein C anticoagulant pathway – endothelial protein C receptor (EPCR). The TF/TFPI ratio, potentially contributing to detection of the hypercoagulable state was calculated.

Results: Twenty AML patients were enrolled in the study; 13 patients achieved remission following induction therapy. The average MP count in patients at diagnosis was higher than in controls and than

that observed at two other points of treatment (at nadir and remission), although the difference did not reach statistical significance. Conversely, the level of Annexin V expression was significantly higher in controls compared to patients at three time points of sampling.
The platelet marker CD41 was significantly higher in controls compared to the rates of patients at diagnosis (33.7% vs. 5.9%; $P < 0.05$), without changes in platelet activation markers. The endothelial marker CD144 appeared to be higher in patients' MP at diagnosis compared to controls (16.4% vs. 4.48%; $P < 0.05$). The blast cells marker CD34 was significantly elevated in patients at diagnosis compared to controls (3.15% vs. 0.0; $P < 0.001$) and to patients in remission (3.15% vs. 0.0; $P < 0.05$). TF expression was similar in controls and patients at three time points tested; however, the TFPI level was higher in controls' MPs compared to patients, without changes in MPs EPCR.
Conclusion: In AML patients, the MPs number was higher at diagnosis and reduced after treatment. MPs of AML patients at diagnosis express markers of blast cells and may serve as a biomarker for disease and remission. Increase in endothelial MP level at AML diagnosis may indicate vascular injury, which could result in TFPI reduction and lead to the hypercoagulable state.

PB 1.30-5
Anticoagulant activity of MP in patients with atherosclerosis of the vessels of the lower extremities

Matvienko O, Namestnikov Y, Golovina O and Saltykova N
Russian Research Institute of Hematology and Transfusiology, Saint-Petersburg, Russian Federation

Background: Activation of blood cells and endothelium at atherosclerotic diseases leads to microparticles (MP) release. MP contributes to the development of hypercoagulability due to expression tissue factor (TF) and procoagulant phospholipids (PPL) on their surface. It is known that endothelial MP are enriched with the molecules such as tissue factor pathway inhibitor (TFPI), thrombomodulin, endothelial protein C receptor and may have anticoagulant activity.
Aim: to determine if thrombin generation caused by PPL of MP is limited by anticoagulant activity of MP in patients with atherosclerosis of the vessels of the lower extremities.
Methods: This research included 29 patients (10 females and 19 males) at the age from 44 to 77 with atherosclerosis of the vessels of the lower extremities. Reference blood samples were obtained from 30 healthy controls. Thrombin generation was measured in platelet-free plasma with Calibrated Automated Thrombinogram Assay method (CAT). "PRP-reagent", containing rTF, (1 pM) and 'FluCa–kit' (Thrombinoscope BV, The Netherlands) were used as triggers. Following parameters were derived: endogenous thrombin potential (ETP, nM-min), peak thrombin activity (Peak, nM), rate of thrombin generation (R, nM/min) lag-time (LT, min) and time to peak (TTP, min). Data were described by non-parametric methods using the median (Me), 50% confidence interval (CI) and Mann-Whitney U test (Statistica 6.0). $P < 0.05$ was considered sighnificant.
Results: There were not any differences in ETP, Peak and R in patients as compared with controls (ETP: Me-508.00, CI: 372.50–623.50 vs. Me-471.84, CI: 384.25–564.00, $P > 0.05$; Peak: Me-16.89, CI: 11.66–21.68 vs. Me: 18.40, CI: 12.29–20.26, $P > 0.05$; R: Me-1.48, CI: 1.05–2.01 vs. Me-1.59, CI: 1.19–2.01, $P > 0.05$). LT and TTP were longer significantly in patients than in controls (LT: Me-11.33, CI: 10.50–13.83, vs. Me-8.93, CI: 8.28–9.53, $P < 0.0001$; TTP: Me-23.08, CI: 21.17–26.25 vs. Me-19.90, CI: 18.68–20.97, $P < 0.0001$). We suppose that TFPI expressed on the MP surfaces may be a reason for LT prolongation and limitation of thrombin generation in patients with atherosclerosis of the vessels of the lower extremities.
Conclusion: Anticoagulant activity of MP balances the procoagulant properties of PPL MP in patients with atherosclerosis of the vessels of the lower extremities. The nature of the anticoagulant activity is needed in further investigation.

PB 1.30-6
Granulysin and other inflammatory mediator induced procoagulant response in patients with Stevens Johnson syndrome/toxic epidermal necrolysis

Iqbal O, Malais J, Mata C, Kahn D, Cunanan J, Lin A, Mosier M, Bouchard C, Hoppensteadt D and Fareed J
Loyola University Medical Center, Maywood, IL, USA

Background: Stevens Johnson syndrome and toxic epidermal necrolysis (SJS/TEN) are life-threatening adverse drug reactions characterized by blisters and skin necrosis often accompanied by ocular inflammatory manifestations. Currently, there is no effective treatment. Although granulysin and tumor necrosis factor-α have been reported to be highly expressed in the skin lesions, a systemic procoagulant response has not been reported. Because of the massive inflammatory state, it was projected that these patients may manifest a procoagulant response.
Materials and Methods: Following institutional review board approval of the clinical study, blood samples and swabs from ocular, oral mucosal and skin lesions were obtained from SJS/TEN confirmed patients ($n = 3$) and from patients ($n = 5$) with systemic dermatologic conditions and associated skin sloughing, in whom the diagnosis was biopsy confirmed negative, and were considered as abnormal controls. Samples from normal healthy volunteers ($n = 6$) served as normal controls. The citrated blood samples were centrifuged to obtain platelet poor plasma which was aliquoted and kept frozen at −70 °C. The plasma samples were thawed and analyzed to determine thrombin antithrombin complex (TAT., Dade-Behring®, Marburg, Germany), prothrombin fragment F 1.2 (F 1.2, Dade-Behring®, Marburg, Germany), plasminogen activator inhibitor-1 (PAI-1, Diagnostica Stago®, Parsippany, NJ), using ELISA kits and ZYMUPHEN platelet microparticle activity (MP) (Hyphen® BioMed (Neuville-Sur Oise, France), HEMOCLOT protein C and Stachrom antithrombin (Diagnostica Stago, Parsippany, NJ) using functional assays per manufacturer's instructions. The swabs collected were immediately frozen at −70 °C and thawed and the exudates were isolated following the addition of 0.25 mL of saline to each swab and double centrifugation. The exudates and plasma samples were analyzed using a SELDI-TOF, mass spectrometric technique for unique biomarkers.
Results: Analyses of the plasma samples revealed that, there was a marked increase in the TAT (6.3 ± 5.9 μg/mL), F1.2 (430.4 ± 202.4 pM), MP (13.1 ± 9.3 nM) and protein C levels ($90.5 \pm 63.4\%$) levels, a decrease in PAI-1 (53.3 ± 18.8 ng/mL) and antithrombin levels ($80.7 \pm 42.4\%$) compared to normal human plasma, confirming a procoagulant response. Mass spectrometric analysis of the swabs revealed the presence of unique biomarker peaks in some of the patients samples. The recombinant human granulysin exhibits a molecular weight of 15.4 kDa. In the protein chip array, it exhibited two major peaks at 14.2 and 15.6 kDa. In contrast to the controls, the skin and oral mucosal exudates showed distinct peaks in the same molecular weight range as that of granulysin. The ocular discharges did not exhibit any peaks in this range.
Conclusion: Since unique peaks were noted in the ocular, oral mucosal and skin discharges similar to granulysin, the observed peaks maybe related to this mediator. Analysis of plasma samples revealed a procoagulant state as demonstrated by the increase in the thrombin generation markers, protein C and MP, and decrease in the fibrinolytic inhibitor PAI-1. Additional clinical validation of these findings will provide guidance to risk stratification and development of novel therapeutic options including the specific antagonist to such mediators as granulysin and TNF-α.

PB1.31 – Endothelial Function

PB 1.31-1

Procoagulant activity at the margins of TNFa treated endothelial cells leads to pericellular fibrin deposition and anti-streptococcal function in flowing plasma

Gilbert GE[1], Novakovic VA[1], Lu J[1], Shi J[1], Ahn B[2] and Lam WA[2]
[1]*VA Boston/Harvard Medical School, West Roxbury, MA;* [2]*Emory U School of Medicine & Georgia Inst. Technology, Atlanta, GA, USA*

Background: Inflammation causes endothelial cells to relax junctions with neighboring cells, to thicken the cell body, and to extend filopodia. We recently reported localized procoagulant activity on filopodia, related to focal phosphatidylserine exposure and high curvature. We asked whether this pattern would lead to pericellular fibrin deposition without clotting of bulk plasma.
Aims: Our aims were (i) to determine whether TNFa treated endothelial cells generate pericellular fibrin while maintaining anticoagulant function toward bulk plasma (ii) To determine which coagulant pathways regulate pericellular fibrin deposition and (iii) to determine the extent to which the pericellular procoagulant response contributes to innate immunity against group A streptococci.
Methods: Human umbilical vein endothelial cells were cultured to confluency in 30 mm microtiter dishes and in an 'endothelialized' microfluidic coated with fibronectin. Recalcified plasma or fresh plasma treated with corn trypsin inhibitor ± 0.1 μ/mL heparin was overlaid on cells and perfused through the microfluidic at shear rates of 10–100/s. Fibrin was detected with fluorescein-labeled mAb 59D8, specific for the beta chain of fibrin, or by adding fluorescent fibrinogen to the plasma. The quantity of fibrin was measured in the presence of specific inhibitors. *Streptococci pyogenes* strain 700294 from ATCC was grown according to standard techniques.
Results: Plasma did not clot over endothelial cells but did clot over control gelatin-coated coverslips. Confocal microscopy showed fibrin strands between TNFα-treated endothelial cells that were largely absent from untreated cells. Corn trypsin inhibitor-treated plasma infused at sheer rates of 10–100/s led to deposition of fibrin margins demarcating TNFα treated endothelial cells without deposition on or around untreated cells. Thus, the inflammatory response of TNFα-treated HUVEC's leads to pericellular fibrin deposition without clotting of bulk plasma. Fibrin was diminished by an anti-tissue factor mAb and by hirudin. Fibrin was increased by an anti-tissue factor pathway inhibitor mAb but not by corn trypsin inhibitor, anti-activated protein C mAb, anti-thrombomodulin mAb, or anti-factor VIII mAb. Thus, focal fibrin deposition is mediated by the extrinsic coagulation pathway.
Streptococcus pyogenes, was added to plasma at a concentration of 10^3 cfu/mL. The concentration of viable bacteria decreased > 90% in 1 h at 37 °C in the presence of TNFα treated endothelial cells. Addition of hirudin enabled Streptococci to grow at the same rate as in citrated plasma alone or re-calcified plasma incubated over quiescent endothelial cells. Confocal microscopy indicated that streptococci decorated the fibrin strands in the inter-endothelial space but not the intercellular matrix or the endothelial cell bodies.
Summary: TNFα treated HUVECs demonstrate pericellular procoagulant activity via the extrinsic coagulation pathway while maintaining cell-centered anticoagulant function. Pericellular fibrin contributes to innate immune response against streptococci pyogenes in the absence of phagocytes or platelets. This suggests a role of pericellular procoagulant activity in innate immunity. We are currently investigating the range of bacteria that may be influenced by this arm of innate immunity and the efficiency of this mechanism as a function of vessel dimensions and sheer rate.

PB 1.31-2

Effects of antiretroviral treatment on endothelial dysfunction and regeneration in HIV-positive patients: 1-year of follow-up

Cesari F[1], Rogolino A[1], Martinelli C[1], Carocci A[1], Corsi P[1], Gensini G[2], Abbate R[3] and Gori AM[1]
[1]*Azienda Ospedaliero-Universitaria Careggi, University of Florence;* [2]*Don Carlo Gnocchi Foundation;* [3]*University of Florence, Florence, Italy*

Background: To evaluate the effect of antiretroviral therapy (ART) on the markers of endothelial dysfunction and regeneration, such as circulating endothelial cells (CECs) and endothelial progenitor cells (EPCs) in a population of HIV naïve positive patients.
Methods: Sixteen HIV+ patients naïve for antiretroviral drugs (M15, F 1) with a median age of 42 (22–65) years and 16 age- and sex-matched control subjects were enrolled in the study. Ten of 16 HIV positive patients were treated with ART therapy for 1 year. Circulating CECs were defined as CD146+/CD31+/CD45−/CD61−, while EPCswere defined as CD34+KDR+, CD133+KDR+ and CD34+CD133+KDR+.
Results: Before antiretroviral treatment HIV positive subjects showed a significant higher number of CECs and a significant lower number of EPCs with respect to the controls [CD146+/CD31+/CD45−/CD61− 8 (3–23) cells/10^6events vs. 3 (0–13) cells/10^6events $P = 0.021$; CD34+/KDR+ 7 (0–23) cells/10^6events vs. 16 (3–40)cells/10^6events, $P = 0.047$; CD133+/KDR+ 7 (0–23) cells/10^6events vs. 13 (7–43) cells/10^6events $P = 0.043$]. After 1 year, 8/10 (80%) patients in ART showed a marked decrease in CECs number and 6/10 (60%) in EPCs number, whereas in patients who did not receive antiretroviral therapy the numbers of CECs and EPCs decreased in 3/6 (50%) and 5/6 (83.3%) respectively. After 1-year of follow-up HIV+ patients who received antiretroviral therapy showed lower number of CECs with respect to HIV+ patients who did not receive the treatment [CD146+/CD31+/CD45−/CD61 2 (0–15) cells/10^6events vs. 10 (0–37) cells/10^6events $P < 0.05$], whereas EPCs number was similar in both groups.
Conclusions: Our data demonstrate the presence of an endothelial dysfunction, as documented by low EPCs and high CECs number, in naïve HIV positive patients with respect to a control population. Moreover present results suggest that ART is associated with an improvement of the markers of endothelial dysfunction.

PB 1.31-3

Regulation of endothelial cell proliferation and survival by collagen receptors

Kim SKP, Pugh N, Bihan D, Hamaia SW and Farndale RW
University of Cambridge, Cambridge, UK

Background: Collagen has been identified as a suitable biomaterial to be used in tissue engineering, a medical therapy that involves implanting a 3D scaffold seeded with cells *in vivo*. Vascularisation of an implant is a prerequisite for success. Various types of collagen promote or inhibit endothelial cell proliferation; however the distinct segments of collagen that supports endothelial cell proliferation and survival are yet to be identified.
Aims: To identify critical collagen segments that support and enhance endothelial cell proliferation and survival using the collagen Toolkits and other triple-helical peptides, to specifically target collagen receptors on HUVECs (human umbilical vein endothelial cells).
Methods: Twelve-well plates were coated with collagenous ligands and HUVECs were allowed to adhere and proliferate. Changes in the cell numbers were detected at various time points, evaluated by CellTracker, Hoechst 33342 and propidium iodide staining. At each end-point, simultaneous labeling with fluorescent Annexin V and propidium iodide were used to resolve cells undergoing necrosis and apoptosis.

Additionally, rapid real-time live cell monitoring was performed using Acea xCELLigence cell-index analyser.

Results: We identified a direct relationship between collagen-receptor affinity and endothelial cell proliferation and survival. Significant elevation of proliferation and prolonged survival was observed on endothelial cells cultured on high affinity collagenous ligands. Co-staining with Annexin V and propidium iodide revealed high affinity peptide such as GFOGER prevented necrosis and delayed apoptosis of HUVECs.

Conclusion: Neovascularisation is a critical step in wound healing and tissue repair. The response of endothelial cells to collagen is therefore of great importance in tissue engineering. We have identified collagen peptides that encourage endothelial cell proliferation and are central to delaying cell death using receptor specific ligands. This finding may offer vast improvements in tissue engineering where, as necessary, such ligands can be used as biomaterials to decorate 3D scaffolds.

PB 1.31-4

A role of cilostazol in Alzheimer's disease treatment: induction of LRP1 expression in endothelial cells

Yano Y, Takeshima C, Kawashita E, Kanno Y and Matsuno H

Doshisha Women's Collage of Liberal Arts, Kyo-tanabe, Japan

Background: Alzheimer's disease (AD) is a type of progressive neurodegenerative disease exhibiting the clinical cardinal symptoms of the impaired memory and cognitive function, observed with the extracellular deposition of beta-amyloid peptide (Aβ), neurofibrillary tangle due to the abnormal phosphosphorylation of tau protein, and neuronal cell death in the brain of AD patients. Vascular endothelial cells play a major role in controlling the Aβ level in the brain via low density lipoprotein receptor related protein 1 (LRP1) and receptor for advanced glycation end products (RAGE). In addition, the destruction of tight junction in the blood brain barrier is observed in AD. Hence, protecting function of vascular endothelial cells could exhibit preventive/improving effect in medical treatment for AD.

Cilostazol is an inhibitor of phosphodiesterase III (PDE3), which is a degrading enzyme of cAMP and the cGMP, and has a protective effect on endothelial functions.

Aim: This study clarified the therapeutic effect and mechanism of Cilostazol in AD.

Methods: Cilostazol was administered to amyloid precursor protein Swedish transgenic (APPswe) mice, and then learning and memory function was evaluated using a Morris Water Maze (MWM) test. The Aβ and LRP1 levels in the brain were detected by immunohistochemistry and Western blotting.

Using bEnd3 cells, vascular endothelium cell, the signaling pathway involved in the Cilostazol-induced LRP1 expression was analysed by western blotting.

Results: Memory and learning function was improved, and the intracerebral Aβ level was significantly declined due to the cilostazol administered. Cilostazol increased the expression of LRP1 in vascular endothelial cells, accelerated the clearance of intracerebral Aβ. The activation of JNK, ERK and Akt was inhibited by Aβ, but recovered by Cilostazol. Pharmacological analysis revealed Akt was involved in the Cilostazol-induced LRP1 expression. In addition, the cGMP pathway, but not cAMP pathway, mediated the induction of LRP1.

Conclusion: Cilostazol increases the expression of LRP1 in vascular endothelial cells through the cGMP and Akt pathway, thereby reducing the intracerebral Aβ level and improving learning and memory function in AD.

PB 1.31-5

Closely spaced thiols in integrin are involved in adhesion of endothelial cells

Ponamarczuk H, Popielarski M, Sobierajska K, Stasiak M and Swiatkowska M

Medical University in Lodz, Lodz, Poland

Activation of integrins, transmembrane receptors that mediate cell adhesion and migration, is accompanied by a series of conformational rearrangements resulting in changes in affinity and avidity. Several observations indicate that conformational changes induced by ligand interaction with integrins lead to exchange of disulfide bonds within the integrin molecule, which stabilizes the altered conformation. Closely spaced thiols in proteins that interconvert between the dithiol form and disulfide bonds are called vicinal thiols. The purpose for this study was to examine whether vicinal thiols are involved in adhesion process of endothelial cell. The manganese ions are know to affect the thiol-disulfide balance and activate integrin to maximal affinity. In the present study, we attempt to explain whether activation of integrins in endothelial cells by Mn^{+2} might involve vicinal thiols. Human umbilical vein endothelial celle (HUVEC) were cultured in medium 200 supplemented with low-serum growth supplement. Labeling of sulfhydryl groups was performed using the poorly membrane-permeable maleimide reagent (MPB). Protein labeled with MPB were precipitated using avidin-Sepharose, electrophoresed and transferred on nitrocellulose. Biotinylated proteins were detected using streptavidin-horseradish peroxidase with chemiluminescent substrate. In some experiments, the MPB-labeled cells were used for immunoprecipitation performed with monoclonal or polyclonal antibody to αvβ3 integrin. For cell adhesion assay the plates were coated with fibrinogen, fibronectin or vitronectin. In some cases the cell were pretreated with phenylarsine oxide (PAO) and added to the plate. The binding of vitronectin or LM609 antibody to endothelial cells activated by manganese ion were evaluated by flow cytometry method. The studies ith membrane-impermeable reagent 3-N-maleimidylpropionyl biotin (MPB) demonstrate that exposure of endothelial cells to Mn^{+2} results in the appearance of surface protein thiol groups, which can found in αvβ3 integrin. Phenylarsine (PAO), a reagent that binds vicinal thiols inhibit adhesion of endothelial cells activated by $Mn^{+2.}$ Additionally, PAO inhibit sulfhydryl labeling of thiols in αvβ3 molecule. The αvβ3 contains vicinal thiols that provide sites for redox regulation of function of this integrin. Closely spaced thiols are involved in activation of αvβ3 integrin during adhesion of endothelial cells.

PB 1.31-6

Cocaine induces oxidative stress and decreased nitric oxide production in human endothelial cells: beneficial effect of atorvastatin

Pereira J[1], Sáez C[1], Pereira-Flores K[1], Ebensperger R[2], Massardo T[3] and Mezzano D[1]

[1]Department of Hematology-Oncology Catholic University of Chile; [2]Department of Chemistry Catholic University of Chile; [3]Nuclear Medicine Section, Santiago, Chile

Background: Cocaine abuse is associated with an increased risk of cardiac and cerebrovascular events. The underlying mechanisms leading to these complications are not fully understood although accelerated atherosclerosis is a prominent finding. We have recently demonstrated that chronic cocaine use is associated with endothelial dysfunction (Sáez et al. Thromb Res 2011; 128: 18) and RhoA/Rho kinase (ROCK) pathway activation (Blood 2012; 120:2177), a key event in the onset and progression of atherosclerosis. Several experimental studies have showed that activation of the Rho kinase pathway is related to an increase in oxidative stress. On the other hand, ROCK also mediates the down-regulation of endothelial nitric oxide (NO) synthase (eNOS) with decreased vascular NO bioavailability, the hall-

mark of endothelial dysfunction. Inhibition of Rho function by statins increases NO production.

Aim: The main aims of these studies were: (i) to test the hypothesis that cocaine-induced activation of ROCK in endothelial cells is associated with oxidative stress and decreased NO synthesis and (ii) to investigate the effect of atorvastatin on these effects *in vitro*.

Methods: Human umbilical vein endothelial cells (HUVECs) were cultured under standard conditions and supplemented for 5 h with plasma from chronic cocaine users, normal plasma, cocaine (10 μM) or vehicle. After media removal, HUVECs were lysed for determination of ROCK activity by western blot assessing the levels of phosphorylated to total myosin light chain phosphatase 1 (MYPT1-P/T). The production of NO and ROS generation were determined by fluorometric assay using DAF-2DA (5 μM) or DCF-DA (100 μM), respectively and the results expressed as arbitrary fluorescence units (AFU). Experiments were conducted in the presence or absence of atorvastatin (10 μM).

Results: HUVECs supplemented with plasma from chronic cocaine users showed: (i) an increase in ROCK activity by 25% (*P*: 0.039) and (ii) a significant decrease in NO production (*P*: 0.029). Exposure of cells to cocaine 10 μM resulted in: (i) a significant increase in ROCK activity by 95% (*P*: 0.04); (ii) an increment in ROS production as compared with vehicle treated cells (8.0 ± 0.3 vs. 2.72 ± 0.9 AFU, respectively; *P*: 0.0035) and (iii) a significant decrease in NO production with respect to cells exposed to vehicle (0.1 ± 0.04 vs. 0.3 ± 0.01 AFU, respectively; *P*: 0.017). Atorvastatin (10 μM) reduced significantly ROCK activity (*P*: < 0.01) and increased NO production (*P*: 0.048) in cells incubated with plasma from cocaine users. In cells exposed to cocaine, atorvastatin inhibited ROCK activity (*P*: 0.039); increased significantly NO production (*P*: 0.03) and showed no effect on ROS generation (8.0 ± 0.32 vs. 5.8 ± 1.8; *P*: 0.6).

Conclusions: Our results show that oxidative stress and impairment in NO production may play a key role in cocaine-associated endothelial dysfunction. The lack of effect of atorvastatin on the production of ROS by cocaine, suggest that their production probably involves mechanisms upstream of Rho/Rho kinase signaling pathway. However, the significant improvement in NO generation induced by atorvastatin may constitute a new therapeutic tool to prevent or ameliorate ischemic complications as part of the comprehensive management of cocaine addiction. (Fondecyt 110418).

PB1.32 – Atherosclerosis: Mouse Models

PB 1.32-1

Liver X receptor (LXR) agonist T0901317 induces regression of early and advanced atherosclerotic lesions under normolipidemic conditions in mice

Van Der Stoep M[1], Li Z[1], Calpe-Berdiel L[1], Van Der Sluis RJ[1], McKinnon HJ[2], Smit MJ[2], Van Berkel TJC[1], Van Eck M[1], Hoekstra M[1] and Korporaal SJA[3]

[1]Leiden Academic Centre for Drug Research, Leiden, The Netherlands; [2]Merck Research Laboratories, Newhouse, UK; [3]University Medical Center Utrecht, Utrecht, The Netherlands

Background: Ligand-mediated activation of the liver X receptor (LXR) induces changes in gene expression, aimed at limiting build-up of pathogenic levels of cholesterol. LXR agonists have been shown to inhibit the initiation and progression of atherosclerosis. However, a key goal in the treatment of cardiovascular diseases is the regression of pre-existing atherosclerotic lesions.

Aim: In the current study, we evaluated the potential of LXR agonist T0901317 to regress both early fatty streak lesions and advanced collagen-rich atherosclerotic lesions.

Methods: Experiments were performed with C57BL/6 wild-type (WT) mice, LDL receptor (LDLr) knockout (KO) mice and apolipoprotein E (apoE) KO mice. C57BL/6 mice were fed with semi-synthetic cholate-containing cholesterol-enriched atherogenic diet containing 15% (w/w) cocoa butter, 1% (w/w) cholesterol, and 0.5% cholate for 16 weeks to induce atherosclerotic lesion development. LDLr KO mice were fed with semi-synthetic Western-type diet (WTD) containing 15% (w/w) fat and 0.25% (w/w) cholesterol for 6 weeks to induce atherosclerotic lesion development. ApoE KO mice were fed with WTD for 3 days or 3 weeks to induce the formation of initial or advanced atherosclerotic lesions respectively, and were subsequently transplanted with WT bone marrow (BM) to restore plasma apoE levels and normalize plasma lipid levels. After the formation of atherosclerotic lesions in all studies, diet was switched to regular cholesterol-free chow diet containing 4.3% (w/w) fat for 3 weeks (LDLr KO or WT mice) or 6 weeks (apoE KO mice), with or without supplementation of T0901317 (10 mg/kg/day).

Results: In LDL receptor knockout mice, T0901317 dramatically worsened plasma lipoprotein profiles and failed to induce lesion regression. In contrast, in wild-type C57BL/6 mice, chow diet in combination with T0901317 improved plasma lipoprotein levels and induced lesion regression (−43%, $P < 0.05$). BM apoE reconstitution in apoE KO mice dramatically improved plasma lipoprotein profiles and resulted in a marked regression of initial (−45%, $P < 0.001$) and advanced lesions (−23%, $P < 0.01$) Regression was associated with a dramatic decrease in the absolute macrophage content (−84%, $P < 0.001$) Treatment with T0901317 further decreased size of early (−71%, $P < 0.001$ vs. baseline; −48%, $P < 0.01$ vs. chow diet alone) and more advanced lesions (−36%, $P < 0.001$ and −17%, $P = 0.06$ respectively).

Conclusion: Our study shows that normal apoB-lipoprotein clearance is crucial to achieve lesion regression through LXR activation. Lesion regression induced by T0901317 is mainly the result of the disappearance of macrophages from atherosclerotic lesions ultimately leading to a highly significant reduction of the size of both early and advanced atherosclerotic lesions.

PB 1.32-2

Replacement of Apob peptide sequence with C5ar peptide sequence in a recombinant vaccine construct significantly increases the atheroprotective effect of immunization in Apobtm2SgyLdlrtm1Her/J mouse

Lu X[1], Xia M[1], Chen D[2], Endresz V[3], Faludi I[3], Szabo A[3], Mundkur L[1] and Kakkar V[1]

[1]Thrombosis Research Institute; [2]King's College London, London, UK; [3]University of Szeged, Szeged, Hungary

Background: Apolipoprotein B-100 (ApoB-100) is a major constituent of LDL and immune responses against ApoB-100 peptide sequences have been shown to reduce the development of atherosclerosis in $ApoE^{-/-}$ mice or $Apob^{tm2Sgy}Ldlr^{tm1Her}$/J mice (Schiopu A, et al Circulation. 2004; 110:2047–2052; Schiopu A, et al. J Am Coll Cardiol. 2007; 50:2313–2318; Lu X, et al. Atherosclerosis. 2010; 212:472–480) while immunization of mice with an N-terminal peptide has been shown to reduce atherosclerotic lesion formation through the induction of a specific Treg-cell response and blocking monocyte differentiation into macrophages (Lu X, et al. Arterioscler Thromb Vasc Biol. 2012;32:2358–2371).

Aim: To compare the effect of immunization with either C5aR peptide epitope or ApoB peptide epitope in a same recombinant construct on atherosclerotic lesion reduction in $Apob^{tm2Sgy}Ldlr^{tm1Her}$/J mice.

Methods: Six-week-old $Apob^{tm2Sgy}Ldlr^{tm1Her}$/J mice were immunized using a repetitive immunization multiple-sites strategy with GST-tagged recombinant constructs containing either C5aR epitope or ApoB epitope in a same protein scaffold. Mice were fed a high-fat diet for 10-week period. Lesions were evaluated histologically; local and systemic immune responses were analyzed by immunohistochemistry

of aorta samples and cytokine measurements in plasma samples and splenocyte supernatants.
Results: High levels of ApoB and C5aR antibodies were detectable 2 weeks after the first immunization with either ApoB epitope-containing or C5aR epitope-containing construct, respectively. Histological analyses demonstrated that mice immunized with C5aR epitope-containing construct showed significantly less lesion occupied area in the aorta sinus than that of mice immunized with ApoB epitope-containing construct (12% vs. 17% $P < 0.05$) when compared to the lesion occupied area in control group (38%). These results were further supported by significant differences in respect of the cellular and humoral immune responses between test animals.
Conclusions: Replacement of ApoB peptide sequence with C5aR peptide sequence in a recombinant construct may provide new antigenic and structural features which are favorable for its immunogenicity, thus leading to significantly reduced atherosclerotic lesion formation when used as an immunizing antigen. This approach offers a novel strategy for developing anti-atherosclerotic agents.

PB 1.32-3
Immune response and gene profiling at different stages of atherosclerotic plaque progression using mouse model

Vrushali VD, Lakshmi LM and Vijay VK
Thrombosis Research Institute, Bangalore, India

Background: Atherosclerosis progression can be divided into several stages starting from early fatty streak formation to the matured plaque. The disease is complex in nature and involves expression of several genes during the development of the disease. We used ApoB/LDLr$^{-/-}$ to study the gene expression in different stages of lesion progression. The study was focused on MicroRNAs (small non-coding RNA's) that act as negative regulators of gene expression by inhibiting the translation or promoting the degradation of target mRNAs. Because individual microRNAs are responsible for regulation of the expression of multiple target genes with related functions, modulating the expression of a single microRNA instead of a single gene can actually influence an entire gene network.
Aim: To study the peripheral immune markers, progression of disease and gene profiling at different stages of plaque development in mice
Methods: Atherosclerosis was induced in groups of Apob^{tm2Sgy} Ldlr^{tm1Her}/J mice by feeding them with diet rich in cholesterol. Mice fed with normal chow diet were taken as control. Global gene expression was performed with RNA extracted from ascending aorta with atherosclerotic lesion at 4, 8, 14 and 20-week time points. Samples were hybridized in Agilent 8 × 60K mouse gene expression array slides and scanned. Genes that were twofold differentially regulated in high fat diet (HFD) samples in comparison to 'Chow' was obtained from Volcano plot. Significant Gene ontology categories and KEGG pathways were dysregulated using the software. Hierarchical clustering of differentially regulated genes was done for both entities and samples using Pearson uncentered algorithm with average linkage rule.
Results: The cDNA microarray analysis revealed a total of 62 miRNA genes which showed differential expression in high fat diet compared to the chow diet fed mice. Among these let-7/98, miR-1/206, miR-10, miR-125/351, miR-128, miR-129/129-5p, miR-137, miR-138, miR-141/200a, miR-149, miR-182, miR-185/882, miR-200bc/429, miR-203, miR-205, miR-208/208ab, miR-214/761, miR-218, miR-221/222, miR-23ab, miR-26ab/1297, miR-27ab, miR-28/28-5p/708, miR-33/33ab, miR-335/335-5p, miR-342/342-3p, miR-384/384-3p, miR-495/1192, miR-499/499-5p, miR-539 were significantly upregulated in mice fed with high fat diet compared to chow diet. It is interesting to note that most abundant miRNAs (with respect to the maximum number of targets) expressed in the murine aorta belong to the miR-340/340-5p and miR-218 (14%), the miR-19 (13%), the miR-196ab (11%) and let- 7/98 (8%) of all the total miRNAs. To validate the results, RT-PCR analysis of the samples was being done. We believe that further elucidation of the role of these miRNAs will help us to understand the disease progression leading to new therapeutic and preventive strategies.
Conclusions: This data opens up the possibility of identifying miRNA's as therapeutic target for prevention of atherosclerosis

PB 1.32-4
Oral administration of recombinant multi antigenic construct expressing three peptides induces tolerance to individual peptides and prevents development of atherosclerosis in mice

A Mundkur L, Sheena P, Ponnusamy T, Rao N, Biradar S, Varma M, Lu X and Kakkar V
Thrombosis research Institute, Bangalore, India

Background: Atherosclerosis is a chronic inflammatory disease of the arterial wall characterized by accumulation of lipids and immune inflammatory cells. Inflammation mediated by a pathogenic T-cell response to self antigens like modified low density lipoproteins (LDL) and heat shock proteins (HSP) as well as exogenous antigens from pathogens, have been implicated in the initiation of an autoimmune response during atherogenesis. Induction of regulatory immune response to these antigens has shown protection against disease development. We believe that each of these self antigens has a distinct role to play in the pathogenesis of atherosclerosis and using multiple antigens would be more effective for a immune therapy against the disease than either of the individual antigens. We have earlier reported that a recombinant construct expressing multiple antigens can control atherosclerosis in mice.
Aim: The objective of the present study was to evaluate whether oral administration of a multi antigenic construct expressing epitopes from apolipoprotein B 100 (ApoB), heat shock protein (HSP60) and Chlamydia pneumonia outer membrane protein (Cpn), can induce immunological tolerance to individual peptides and prevent atherosclerosis development in mouse model.
Methods: ApoB, HSP60 and Cpn peptides were cloned and expressed as part of the dendroaspin protein scaffold. Groups of Apob^{tm2Sgy} Ldlr^{tm1Her}/J mice were given five oral doses of recombinant multi antigenic construct on alternate days. Mice were fed with high-fat diet for 10 weeks to induce development of atherosclerosis. Antigen specific tolerance was studied by Treg functional assay with individual peptides. Quantification of atherosclerotic lesions was carried out in the aortic sinus sections stained with Elastic van Geison. Immunohistochemical analyses were carried out by indirect immunofluorescence. Flow cytometry was used to study the specific immune cells in the lymphoid organs and aorta. ELISA was carried out to study antibody response to peptides
Results: oral administration of recombinant multi antigenic construct was found to induce antigen specific tolerance to ApoB, HSP60 and Cpn peptides as seen by reduction in effector cell proliferation in the presence of Treg cells isolated from splenocytes of tolerized mice. Regulatory T cells were found to increase in the lymphoid organs and the aorta of treated animals compared to control. Antibodies specific for the peptides were not detected in the serum of treated animals confirming immunological tolerance. Tolerance to the peptides resulted in 47.1% ($P = 0.002$) reduction in the development of atherosclerotic lesion in the aortic sinus compared to control. Protection against atherosclerosis was associated with decrease in macrophages infiltration (58.6%,$P = 0.03$) and increase in collagen content and IL10 in the developing lesion.
Conclusions: Our results suggest that oral administration of multi antigenic construct expressing ApoB, HSP60 and Cpn peptides induces tolerance to individual peptides and can prevent development atherosclerosis by reducing inflammatory mediators in the plaque.

PB 1.32-5

Immunization with a linear peptide derived from tissue factor and protease activated receptor-1 significantly reduces the development of atherosclerotic lesion in Apobtm2SgyLdlrtm1Her/J mice

Lu X[1], Xia M[1], Endresz V[2], Chen D[3], Goodwin C[1], Faludi I[2], Szabo A[2], Mundkur L[1] and Kakkar V[1]

[1]Thrombosis Research Institute, London, UK; [2]University of Szeged, Szeged, Hungary; [3]King's College London, London, UK

Background: Tissue factor (TF), an important protein in coagulation pathway, has been shown to be abundantly expressed in macrophages and the lipid rich core in atherosclerotic plaques and plays a pivotal role in thrombus formation associated with plaque rupture. The Thrombin signaling mediator protease activated receptor-1 (PAR-1) associated coagulation pathway which can be cleaved by thrombin, play critical roles in hemostasis and thrombosis, as well as in inflammatory, proliferative responses triggered by vascular injury and atherosclerosis. Stimulation of PAR1 in atherosclerotic plaques has been implicated in smooth muscle cell proliferation and exaggerated vasoconstrictory response.
Aim: To assess whether immunizing $Apob^{tm2Sgy}Ldlr^{tm1Her}$/J mice with the peptide epitopes derived from either TF or PAR-1 is effective in reducing atherosclerotic lesions.
Methods: Six-week-old $Apob^{tm2Sgy}Ldlr^{tm1Her}$/J (ApoB100 only, $LDLr^{-/-}$) mice were immunized using a repetitive immunization multiple-sites strategy with KLH-conjugated peptides derived from TF and PAR-1, respectively.
Results: Mice immunized with the peptide epitope derived from TF, PAR-1 and PAR-2 showed a greater reduction in lesion size compared to control mice immunized with KLH only, showing 26.5% ($P = 0.001$) and 27.4% ($P < 0.001$) for TF peptide- and PAR-1 peptide-immunized mice, respectively and these results were also in agreement with those in descending aortas compared with that in control showing significant decrease in lesion area in descending aortas (35.8% for TF and 42.2% for PAR-1). This effect on lesion reduction was associated with a shift in the cellular composition of plaques towards decreased inflammatory cell and increased regulatory T-cell content and increased production of anti-inflammatory cytokines and decreased secretion of proinflammatory cytokines demonstrated in plasma and in supernatant of stimulated spleen cells.
Conclusions: The immune response against epitopes derived from TF and PAR-1 has an effect in reducing atherosclerotic lesion formation.

Aging- and activation-induced platelet microparticles suppress apoptosis in monocytic cells and differentially signal to proinflammatory mediator release

Heemskerk JWM[1], Vasina M[2], Cauwenberghs S[3], Staudt M[2], Feijge MAH[1], Weber C[4], Koenen R[1] and Heemskerk JWM[1]

[1]Maastricht University, Maastricht, The Netherlands; [2]Univeristy Hospital Aachen, Aachen, Germany; [3]Katholieke Universiteit Leuven, Leuven, Belgium; [4]Univeristy of Munich, Munich, Germany

Background and Aim: Platelet microparticles (PM) are the most abundant cell-derived microparticles in the blood, and accumulate in thrombo-inflammatory diseases. Platelets produce PM upon aging via an apoptosis-like process and by activation with strong agonists. We previously showed that long-term treatment of monocytic cells with apoptosis-induced PM (PM_{ap}) promotes differentiation towards resident macrophages. Here we investigated shorter term effects of various types of PM on monocyte signalling and function.
Methods and Results: Flow cytometry and scanning electron microscopy revealed that PM formed upon platelet aging (PM_{ap}) or ultrasonication (PM_{sonic}) expressed activated αIIbβ3 integrins and tended to assemble into aggregates. In contrast, PM formed upon platelet activation with thrombin (PM_{thr}) or Ca^{2+} ionophore (PM_{iono}) had mostly non-activated αIIbβ3 and little aggregate formation, but had increased CD63 expression. PM from activated and sonicated platelets expressed phosphatidylserine at their surface, while only the latter were enriched in the receptors CD40L and CX3CR1. All PM types expressed P-selectin, interacted with monocytic cells via this receptor, and were internalised into these cells. All PM types promoted actin cytoskeletal rearrangements and hydrogen peroxide production by monocytic cells. Markedly, both aging- and activation-induced PM types stimulated the phosphoinositide 3-kinase/Akt pathway, suppressing apoptosis induced by several agonists, in a P-selectin-dependent manner. On the other hand, the PM types differentially influenced monocyte signalling in eliciting Ca^{2+} fluxes (particularly PM_{ap}) and in releasing secondary mediators (complement factor C5a with PM_{ap}, and pro-inflammatory tumour necrosis factor-α with PM_{thr}).
Conclusions: In spite of their common anti-apoptotic potential via Akt activation, the aging- and activation-induced PM cause different Ca^{2+} signalling and mediator release events in monocytic cells. By implication, both aging and activated platelets may modulate monocyte function by forming different PM types.

PB1.33 – ADAMTS13: Clinical – I

PB 1.33-1

Quantitative PCR assay demonstrated exon deletions of ADAMTS13 in two unrelated patients with Upshaw-Schulman syndrome

Eura Y[1], Kokame K[1], Takafuta T[2], Tanaka R[3], Kobayashi H[4], Ishida F[5], Hisanaga S[6], Matsumoto M[7], Fujimura Y[7] and Miyata T[1]

[1]National Cerebral and Cardiovascular Center, Suita, Osaka; [2]Nishi-Kobe Medical Center; [3]Hyogo Prefectural Kobe Children's Hospital, Kobe, Hyogo; [4]Nagano Red Cross Hospital; [5]Shinshu University, Matsumoto, Nagano; [6]Koga General Hospital, Miyazaki; [7]Nara Medical University, Kashihara, Nara, Japan

Background: Upshaw-Schulman syndrome (USS), also called hereditary thrombotic thrombocytopenic purpura, is associated with severe deficiency of plasma ADAMTS13 activity with an autosomal recessive trait of inheritance. In most of the patients with USS, homozygous or compound heterozygous mutations are identified in the ADAMTS13 genes. So far, more than 100 causative mutations have been identified worldwide by use of the direct sequencing method.
Aims: We previously analyzed the ADAMTS13 genes of 47 Japanese patients with USS in 41 unrelated families using direct sequencing. Of them, 44 patients in 38 families had homozygous or compound heterozygous mutations in ADAMTS13. As for the remaining patients, however, only one single missense mutation (two patients) or no mutation (one patient) was detected. Then, we intended to find more extensive defects of ADAMTS13 in these three patients.
Methods: The study protocol was approved by the ethical committee of the National Cerebral and Cardiovascular Center, and only subjects who provided written informed consent for genetic analyses were included. Genomic DNAs were prepared from blood cells and subjected to real-time PCR to quantitate the relative copy numbers of each exon in ADAMTS13. PCR primers were designed by the Primer-BLAST online tool (NCBI), and PCRs were performed using Quanti-Fast SYBR Green PCR Kit (QIAGEN). Fluorescent intensities were detected using Mx3000P QPCR System (Agilent Technologies), and each threshold cycle (Ct) was calculated by the MxPro software (Agilent Technologies).

Results: The Ct values implied that exon 8 of ADAMTS13 was heterozygously missing in one patient, who carries the c.1648G>A (p.Gly550Arg) mutation in exon 14. Similarly, exon 27 was heterozygously missing in another patient, who carries the c.841T>A (p.Cys281Ser) mutation in exon 8. Further analysis using PCR mapping and sequencing revealed that the loss of exon 27 was caused by 729-bp deletion ranging from the 36th nucleotide of exon 27 to the 587th nucleotide of intron 27 (c.3751_3892+587del). Assignment of the precise deleted region causing the loss of exon 8 is proceeding with difficulty, because of PCR amplification-resistant sequences around exons 7 and 8. The compound heterozygosity of the missense mutation and exon deletion was confirmed by PCR analysis of the parents' DNA samples. The other patient showed no abnormalities in the exon copy numbers of ADAMTS13.

Summary/Conclusion: The present study identified the patients with USS carrying the allele with exon deletion in ADAMTS13, which, as far as we are aware, has not been previously reported. One patient was compound heterozygous for c.1648G>A (p.Gly550Arg) and exon 8 deletion, and another was for c.841T>A (p.Cys281Ser) and c.3751_3892+587del (exon 27 deletion). Thus, the quantitative PCR assay provides an effective tool to identify the extensive deletion of ADAMTS13 in patients with USS. In our study, one patient did not show any abnormalities in either direct sequencing or quantitative PCR analyses, suggesting that the patient may carry uncommon types of defects in ADAMTS13 such as genetic translocation and inversion.

PB 1.33-2

Kinetics and half-life of plasma ADAMTS13 after plasma infusion in four patients with Upshaw-Schulman syndrome

Yagi H[1], Kato S[2], Konno M[3], Tanaka R[4], Hasegawa Y[5], Kanai R[5], Yamaguchi S[5], Isonishi A[2], Matsumoto M[2] and Fujimura Y[6]

[1]Nara Hospital Kinki University School of Medicine, Ikoma; [2]Department of Blood Transfusion Medicine, Nara Medical University, Kashihara, Nara; [3]Department of Nephrology, Hyogo prefectural Kobe Children's Hospital, Kobe, Hyogo; [4]Department of Pediatrics, Sapporo-Kosei general Hospital, Sapporo, Hokkaido; [5]Department of Pediatrics, Shimane University School of Medicine, Izumo, Shimane; [6]Nara Medical University, Kashihara, Nara, Japan

Introduction: Upshaw-Schulman syndrome (USS) is congenital deficiency of plasma ADAMTS13 activity caused by mutations in *ADAMTS13* gene, and characterized by repeated episodes of thrombocytopenia and hemolytic anemia that quickly respond to infusions of fresh froze plasma (FFP). Here, we investigate the kinetics and half-lives after single FFP infusion on routine infusions in order to estimate precious effect of preventive FFP infusion for USS patients.

Materials and Methods: We collected a series of plasma just before and 2 weeks after FFP infusion. We measured ADAMTS13 activity (:AC) by ADAMTS13-act ELISA, and ADAMTS13 antigen (:AG) by a sandwich ELISA and quantitative western blot analysis previously reported. Recovery values of ADAMTS13 level were calculated from maximum level of ADAMTS13:AC or AG after FFP infusion and volume of FFP infusion. The half-lives of ADAMTS13 levels were calculated from the time of half level decayed from maximum that predicted from the plots of ADAMTS13 level.

Patients: We analyzed four patients with USS (B3, W4, Q3, Q5) belonging to three families. USS-B3 was 20-year-old female with homozygous nonsense mutations of p.Q449*. She received FFP infusion every 2 weeks to maintain her platelet counts over 70×10^9/L. USS-W4 was 15-year-old female with compound heterozygotes for p.G550R and exon 8 deletion. She received FFP infusion upon episodes of thrombocytopenia and hemolytic anemia. USS-Q3 (24-year-old male) and Q5 (19-year-old male) were brothers and their ADAMTS13 gene mutations were compound heterozygotes for p.G227R and p.C908T. They received prophylactic FFP infusion every 2 weeks. The volumes of FFP infused in USS-B3, USS-W4, USS-Q3, and USS-Q5 were 240 mL (4.4 mL/kg), 320 mL (5.6 mL/kg), 160 mL (3.1 mL/kg), and 160 mL (3.3 mL/kg), respectively.

Results: The kinetics of ADAMTS13:AC and:AG showed similar pattern after FFP infusion. The maximum values of ADAMTS13:AC and AG were at 1 h after FFP infusion in USS-B3, W4 and Q3 and at 6 h in USS-Q5. After that, both levels of ADAMTS13:AC and AG gradually decreased. In USS B3 and Q5, both were no longer detected in plasma at 14 days after FFP infusion. The ADAMTS13:AC level at 14 days after FFP infusion of USS W4 was detectable, but severely decreased. In USS-Q3, both level were decreased into undetectable level at 7 days after FFP infusion. In USS-B3, W4, and Q5, platelet counts raised to maximum level at day 7 after FFP infusion. In USS-Q3, the maximum level of platelet was 77×10^9/L at 3 days after FFP infusion. The average of maximum value of ADAMTS13:AC and:AG after FFP infusion were 5.8 ± 1.8 and $5.8 \pm 2.6\%$ (mean $\pm$ 2 SD), respectively. The half-life of ADAMTS13:AC and:AG were 2.8 ± 0.6 and 2.7 ± 1.6 days, and the recovery of ADAMTS13:AC and ADAMTS13:AG after FFP infusion were $71 \pm 9.6\%$ and $70 \pm 15.2\%$, respectively.

Conclusion: We evaluated the efficacy of prophylactic FFP infusion in the patients with USS under remission status. Our results suggested that 5 mL/kg FFP infusion every 2 weeks was reasonable protocol for preventing relapses.

PB 1.33-3

The determination and characterisation of anti-ADAMTS13 autoantibodies

Harahsheh Y, Hughes Q, Tay J, Holmes L, Gilmore G, Thom J and Baker R

Royal Perth Hospital, Perth, WA, Australia

Background: A deficiency of ADAMTS13, a multi-domain, anticoagulant protein, specifically responsible for the cleavage of von Willebrand Factor (VWF), can result in Thrombotic Thrombocytopenic Purpura (TTP). The acquired form results from inhibitory anti-ADAMTS13 autoantibodies directed against the protein's functional or catalytic domains. However, not all antibodies are inhibitory. Current methods designed to identify ADAMTS13 autoantibodies do not discriminate between the inhibitory and non-inhibitory forms.

Aims: This study aims to develop a method for screening patient plasma samples to determine the location of autoantibody binding sites, and their significance in TTP onset.

Methods: The individual domains of the ADAMTS13 protein were selected as antigens in an ELISA that was optimised for screening patient plasma samples. The individual peptide regions were selected from the corresponding sequence of a synthetic cDNA construct of the full ADAMTS13 coding sequence. A standard PCR was optimised using specifically designed primers. The peptides were then produced in a bacterial expression system. Three patient groups took part in the screening process; patients who contained high titres of anti-ADAMTS13 autoantibodies, yet did not develop TTP, stroke patients, and a group of TTP patients. All patient samples had aBethesdaassay performed to identify the presence of an inhibitor.

Results: OurBethesdaassay results demonstrated that all TTP patients contained an inhibitor, all of the healthy control patients who contained anti-ADAMTS13 autoantibodies did not contain an inhibitor. Interestingly the stroke patients exhibited a wide range ofBethesdaresults. From the peptides used in this study, the TTP patient autoantibodies were mainly directed at the catalytic spacer domain, where-as the non-TTP patient plasma samples were directed at the non-catalytic CUB 2 domain.

Summary/Conclusion: The TTP patients screened presented with autoantibodies directed at the spacer domain, further supporting the literature identifying this domain possessing the pathological binding sites. However, the CUB 2 domain may represent a target for the binding of non-inhibitory anti-ADAMTS13 autoantibodies and the pathogenesis, if any, of this subset of antibodies warrants further investigation.

PB 1.33-4

ADAMTS13 activity is a potential biomarker of thrombotic risk in systemic lupus erythematosus

Martin S[1], Reverter JC[1], Tassies D[1], Galan AM[1], Espinosa G[2], Pino M[1], Escolar G[1] and Diaz-Ricart M[1]

[1]Department Hemotherapy-Hemostasis, Hospital Clinic, CDB, IDIBAPS; [2]Department Systemic Autoinmune Diseases, Hospital Clinic, IDIBAPS, Barcelona, Spain

Background/Aim: A severe deficiency of ADAMTS13 activity results in the presence of VWF ultra large multimers with high affinity for platelets, causing thrombotic thrombocytopenic purpura. Other pathological conditions with mild to moderate ADAMTS13 activity levels exhibit a risk for thrombosis. We have explored the ADAMTS13/VWF axis in patients with Systemic Lupus Erythematosus (SLE) and its potential value as a thrombotic marker.

Methods: ADAMTS13 activity, VWF antigen and multimeric structure, and VCAM-1 were measured in plasma from 50 SLE patients. Anti-ADAMTS13 antibodies were evaluated in patients with low ADAMTS13. Parameters of disease activity (SLEDAI) and organ damage (SLICC), thrombotic events, and presence of antiphospholipid syndrome (APS-SLE) and antiphospholipid antibodies were registered.

Results: SLE patients showed reduced ADAMTS13 activity and high VWF levels (66 ± 27% vs. 101 ± 8%, $P < 0.01$, and 325 ± 151% vs. 81 ± 14%, $P < 0.001$, vs. control). ADAMTS-13 activity was below 60% and 40% in 40% and 22% of patients, respectively. VCAM-1 levels were superior in patients plasma than in control samples (range of 564–4991, vs. 596.25 ± 100 ng/mL, $P = 0.03$). ADAMTS13 activity was under 60% in APS-SLE patients and in all patients with thrombotic events. SLEDAI was > 6 in 65% of the cases.

Conclusion: Reduction of ADAMTS13 activity together with increased VWF levels could be ascribed to the chronic inflammatory state in SLE. These results were specially found in patients with higher disease activity index and with antiphospholipid antibodies. Therefore, ADAMTS13 activity, in combination with other laboratory parameters, may be used as prognostic biomarker of thrombotic risk in SLE.

PB 1.33-5

Decreased plasma ADAMTS13 activity during moderate to much consumption of ethanol in healthy volunteers: differences between normal and heterozygous mutant aldehyde dehydrogenase-2 alleles

Uemura M, Fujimoto M, Hayakawa M, Matsuyama T, Kato S, Takaya H, Morioka C, Matsumoto M, Fujimura Y and Fukui H

Nara Medical University, Kashihara, Japan

Background: Deficiency of ADAMTS13 activity (ADAMTS13:AC) results in the accumulation of unusually large von Willebrand factor multimers (UL-VWFM) and platelet thrombi formation. We demonstrated that enhanced production of UL-VWFM over deficient ADAMTS13:AC may contribute to the progression of liver injury and the development of multiorgan failure in patients with severe alcoholic hepatitis (Curr Drug Abuse Rev, 2008;1:188).

Aims: Little information is available on the effects of ethanol on plasma ADAMTS13:AC in healthy subjects. In this study, we determined changes in plasma ADAMTS13:AC following moderate to much consumption of ethanol in healthy volunteers who were either wild-type homozygous or mutant heterozygous for the aldehyde dehydrogenase (ALDH)-2 gene.

Methods: Eleven healthy volunteers homozygous for wild-type ALDH-2 genes (Group I) and nine heterozygous for wild-type and mutant alleles (Group II) were studied. All volunteers were co-workers who usually consumed moderate to much amounts of alcohol, and this study protocol was approved by the Ethics Committee of our university. Blood alcohol concentration (BAC), plasma levels of ADAMTS13:AC and VWF:Ag, and VWFM patterns were determined before and every hour for 5 h after ethanol consumption (60 g) with food (580 KCal). VWFM patterns were analyzed by SDS-0.9% agarose gel electrophoresis.

Results: BAC reached its highest levels 2 h after ethanol consumption in both groups (Group I 22 mM, Group II 24 mM), and thereafter tended to decrease more gradually in Group II than Group I. ADAMTS13:AC decreased by 20% from baseline between 2 and 5 h after ethanol consumption in Group II, whereas it decreased by 10% 4 h after ethanol intake in Group I. The incidence of subjects with > 20% decreases in ADAMTS13:AC was higher in Group II than in Group I (88.9% vs. 27.3%, $P < 0.05$). The largest decrease in ADAMTS13:AC after ethanol consumption was greater in Group II (−33.0 ± 9.0%, $P < 0.01$) than in Group I (−16.2 ± 10.8%, $P < 0.01$). Plasma inhibitor against ADAMTS13:AC was not detected throughout the study. VWF:Ag increased by 30% between 3 and 5 h after alcohol intake in Group II, but remained unchanged in Group I. As a result, the ratio of VWF:AG to ADAMTS13:AC increased by 55–79% between 2 and 5 h after ethanol consumption in Group II, whereas it was almost unchanged in Group I. VWFM patterns were normal in 9 (81.8%) and degraded (18.2%) in Group I, whereas they were normal in 2 (22.2%), degraded in 2 (22.2%), lacking in 2 (22.2%) and unusually-large in 3 (33.3%) in Group II.

Conclusions: Plasma ADAMTS13:AC significantly decreased in healthy volunteers with a mutant allele of the ALDH2 gene after moderate to much consumption of ethanol, resulting in increased levels of VWF:Ag. VWFMs showed lacking and unusually-large patterns in more than half of volunteers with mutant allele gene except normal and degraded patterns observed in those with wild-type genes. These subjects with mutant allele of the ALDH2 gene may be susceptible to platelet hyperaggregability after moderate to much consumption of ethanol.

PB 1.33-6

Levels of the ADAMTS13 metalloprotease and risk of myocardial infarction: review of the literature and meta-analysis

Lotta LA[1], Musallam KM[2], Tuana G[3], Biguzzi E[3], Rossio R[3], Ferrari B[3], Radhakrishnan N[3], Peyvandi F[3] and Rosendaal FR[4]

[1]Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, Milan, Italy; [2]American University of Beirut Medical Center, Beirut, Lebanon; [3]Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico, Milan, Italy; [4]Leiden University Medical Center, Leiden, The Netherlands

Background: The circulating metalloprotease ADAMTS13 exerts an essential antithrombotic function by cleaving the ultralarge platelet-tethering multimers of von Willebrand factor. A severe deficiency in the plasmatic activity of ADAMTS13 causes thrombotic thrombocytopenic purpura, which is often associated with microthrombotic cardiac damage. Recent evidence from studies in humans and experiments in mice suggest that a reduced activity of ADAMTS13 might also be associated with the development of myocardial infarction (MI). A number of studies carried out in recent years investigated the association between plasmatic levels of ADAMTS13 and MI, yielding conflicting results.

Aims: To summarize and pool current evidence on the association between ADAMTS13 plasmatic levels and MI.
Methods: The study was conducted according to the principles of the PRISMA statement. We did not follow a pre-specified review protocol. In order to obtain material for the review, we conducted a Pubmed (URL: http://www.ncbi.nlm.nih.gov/pubmed/) search for articles published after 1980, using 'ADAMTS13' and 'heart' or 'myocardial' or 'coronary' as search terms (updated to September 12th, 2012). Articles were chosen for review based on the following criteria: (i) they concerned plasmatic ADAMTS13 levels in humans; (ii) they reported on controlled studies; (iii) the investigated disease was incident myocardial infarction. Studies were excluded from meta-analysis if they had too small a sample size to allow meaningful calculations (i.e. < 30 MI cases), chose controls from patients referred to the hospital for other diseases/conditions, had no frequency matching for age and sex, or did not provide any information on the distribution of patients and controls in tertiles/quartiles of ADAMTS13 activity. Data on the distribution of cases and controls in the tertiles or quartiles of ADAMTS13 levels were extracted from the reports. Studies suitable for meta-analysis were pooled by the Mantel-Haenzel method and by calculating unweighted mean to account for heterogeneity. The odds ratio for MI and its 95% confidence interval were the summary measures of choice.
Results: Seven case-control studies fulfilled the criteria for inclusion, after examination of 71 candidate manuscripts retrieved from the Pubmed repository. Selected studies most often concerned ADAMTS13 antigen levels rather than activity and measurements were carried out at different time periods from the acute episode. All studies had a case-control design, but yielded heterogeneous results regarding the association of ADAMTS13 with myocardial infarction. These encompassed protective effect, no effect and a risk-increasing effect of low ADAMTS13 levels. Of the seven studies, four could be used to obtain a pooled estimate. The unadjusted odds ratios for MI ranged from 0.62 to 1.27 in the four studies. The Mantel-Haenzel pooled odds ratio was 0.96 (95% confidence interval: 0.72–1.17) and the straight-averaged odds ratio was 1.01 (95% confidence interval: (0.72–1.30).
Summary/Conclusions: The results of this meta-analysis argue against a major influence of plasmatic ADAMTS13 levels on the risk of MI, although the large heterogeneity between studies suggests effects in specific groups.

PB1.34 – Fibrinolytic System: Clinical – I

PB 1.34-1
Increased N-terminal cleavage of alpha-2-antiplasmin in liver cirrhosis

Uitte de Willige S, Malfliet JMC, Janssen HLA, Leebeek FWG and Rijken DC
Erasmus University Medical Center Rotterdam, Rotterdam, The Netherlands

Background: Hepatic failure due to cirrhosis is caused by progressive fibrosis that ultimately results in nodular regeneration with loss of liver function. As the liver is the site of both synthesis and clearance of many proteins involved in hemostasis and fibrinolysis, including alpha-2-antiplasmin (a2AP), altered plasma levels of these factors are often found in chronic liver failure. The main function of a2AP, the inhibition of plasmin, is influenced by the proteolytic modifications the protein undergoes in the circulation. Approximately 35% of circulating a2AP is cleaved at its C-terminus, resulting in a form of a2AP that has lost most of its activity by losing its ability to bind to plasmin (ogen). Non-plasminogen-binding a2AP can still inhibit plasmin, but kinetically very slow. Additionally, a large part of circulating a2AP is N-terminally cleaved between residues Pro12 and Asn13 by the recently identified AntiPlasmin-Cleaving Enzyme (APCE), a soluble, circulating derivative of fibroblast activation protein (FAP). This cleavage turns the native Met-a2AP into Asn-a2AP. FAP is a type II integral membrane protease dominantly expressed in areas of tissue remodeling, e.g. by activated fibroblasts, myofibroblasts and activated hepatic stellate cells.
Aims: In this study we investigated whether liver cirrhosis, characterised by increased expression of FAP and therefore presumably also APCE, resulted in increased N-terminal cleavage of a2AP in the circulation.
Methods: We focused on the active plasminogen-binding form of a2AP, PB-a2AP, and on individuals homozygous for the common R-allele of polymorphism Arg6Trp, as this polymorphism strongly influences N-terminal cleavage of a2AP. New ELISA assays were set up to measure the antigen levels of both total PB-a2AP and N-terminally intact Met-PB-a2AP. With these data we calculated the percentage Met-PB-a2AP, reflecting N-terminal heterogeneity. a2AP antigen levels were measured in the plasma samples of 48 patients with liver cirrhosis with different types of etiology and 20 healthy control individuals. Informed consent was obtained and the study was approved by a recognised medical ethics committee. Patients were classified into three groups of increasing severity according to the Child-Pugh's score.
Results: As many other proteins synthesized in the liver, total PB-a2AP levels (mean ± SD) were reduced in the cirrhosis patients (30.0 ± 13.0 μg/mL) compared to the total PB-a2AP levels in the control individuals (55.1 ± 8.3 μg/mL; $P < 0.001$). The Met-PB-a2AP levels were also reduced in the cirrhosis patients (4.2 ± 4.0 μg/mL) compared to the Met-PB-a2AP levels in the control individuals (13.0 ± 3.3 μg/mL; $P < 0.001$). Interestingly, we found that, in addition to the reduction in a2AP levels, the percentage of Met-PB-a2AP was reduced in the cirrhosis patients (12.5 ± 6.4%) compared to the percentage of Met-PB-a2AP levels in the control individuals (23.6 ± 4.6%; $P < 0.001$). This indicates increased N-terminal cleavage of a2AP in the cirrhosis patients. All three variables significantly decreased with the severity of the disease.
Conclusions: We found an increase in N-terminal cleavage of a2AP in patients with liver cirrhosis which correlated with the severity of the disease. This may be of pathogenic importance in the frequently observed enhanced fibrinolytic potential of cirrhotic patients.

PB 1.34-2
Feasible mechanisms of fibrinolysis impairment in patients with antiphospholipid syndrome

Aisina RB[1], Reshetnyak TM[2], Mukhametova L[1], Patrushev LI[3], Patrusheva NL[3], Seredavkina N[2], Gulin D[1] and Gershkovich KB[4]
[1]Lomonosov Moscow State University; [2]Scientific Research Institute of Rheumatology of RAMS, Moscow; [3]Shemyakin-Ovchinnikov Institute of Bioorganic Chemistry of RAS; [4]Emanuel Institute of Biochemical Physics of RAS, Moscow, Russian Federation

Background: The pathogenesis of thrombosis in patients with antiphospholipid syndrome (APS) is multifactorial. Numerous ways and mechanisms including an impairment of fibrinolysis by which antiphospholipid antibodies (aPL) may lead to the development of thrombosis in APS have been proposed. Possible mechanisms of aPL effects on activity of the fibrinolytic system are under study for the past years.
Aims: To study the relationship between thromboses, levels of aPL and fibrinolytic system components in APS patients.
Methods: The plasminogen (Pg) level was determined by the kinetic method in 78 patients with APS, 35 of them with systemic lupus erythematosus (SLE + APS) and 43 – with primary APS (PAPS). The PAI-1 antigen level measured by ELISA was assayed in 45 APS patients (21 with SLE + APS and 24 with PAPS). Positivity of aPL (LAC, aCL and $a\beta_2GP1$) was estimated. The thrombotic events were assessed clinically and confirmed by objective methods. A control group included 10 donors without autoimmune diseases and thromboses in anamnesis.

Results: Decrease in fibrinolysis may be caused by low level of Pg or high level of PAI-1 which neutralizes plasminogen activators. In the group of Pg study thromboses were registered in 67 APS patients (32 arterial and 53 venous thromboses, 14 patients had combined thrombi). Among 67 patients low Pg levels (0.37–1.49 μM) were found in 23 (34.3%) with nine arterial and 19 venous thromboses. The low Pg levels in patients with thromboses were associated with high-positive levels both of $a\beta_2$GPI (n = 16) and aCL (n = 9) and Pg levels were lower in patients with SLE+APS than in patients with PAPS.
In the group of PAI-1 study thromboses were registered in 43 (95.5%) APS patients (22 arterial and 33 venous thromboses, 12 patients had combined thrombi), 14 of them had increased (47.1–93.3 ng/mL) and 24 – high (102.0–463.3 ng/mL) levels of PAI-1 antigen which were associated with high-positive levels both of $a\beta_2$GPI (n = 20) and aCL (n = 11). One of possible mechanism of this interrelationship was considered. Patients with SLE + APS had higher PAI-1 levels than patients with PAPS. To test a possible contribution of genetic factors on the development of thrombosis, the genetic variants of PAI-1 in APS patients were determined by the method of polymerase chain reaction. It was found that arterial and, to a greater extent, venous thromboses are associated with the 4G/5G polymorphism of the PAI-1 gene and high plasma level of the inhibitor in 79% of APS patients.
Conclusion: The impairment of fibrinolysis are connected partially with decrease in Pg level and, to a greater extent, with increase in PAI-1 level both of which are associated with high-positive $a\beta_2$GPI and aCL levels at least in one third of APS patients with thromboses. The most of APS patients with thromboses and increased and high PAI-1 levels were carriers of 4G allele of PAI-1 gene. In APS patients venous thromboses occurred more frequently than arterial ones. The impairment of fibrinolysis due to aPL and PAI-1 gene mutation contributes to the development of thrombosis in APS patients.

Topical and conjunctival use of fresh frozen plasma in patients with congenital plasminogen deficiency

Ozdemir N[1], Tuysuz G[1], Turhan AB[2], Iskeleli G[3], Alkin Z[4] and Celkan T[1]

[1]Istanbul University, Cerrahpasa Medical Faculty, Istanbul; [2]Pediatric Hematology Department, Eskisehir Osmangazi University Hospital, Eskisehir; [3]Opthalmology Deptartment, Cerrahpasa Medical Faculty, Istanbul University; [4]Ophthalmology Department, Taksim Training and Research Hospital, Istanbul, Turkey

Background: Plasminogen plays an important role in fibrinolysis as well as wound healing, cell migration, and angiogenesis. Congenital plasminogen deficiency is rare autosomal recessive disorder that leads to development of pseudo-membranes on mucosal surfaces such as eyelids and mouth. Ligneous conjunctivitis is the most common presentation in which fibrin accumulation causes inflammation of conjunctiva and leads to thick, woody (ligneous) growths inside eyelids. The treatment options are few and the prognosis is poor especially in severely affected patients.
Aim: The aim of this report is to present our experience with systemic and conjunctival fresh frozen plasma treatment in our patients with congenital plasminogen deficiency.
Methods: Patients' files were evaluated retrospectively and 11 patients who were followed-up with a diagnosis of plasminogen deficiency were included.
Results: There were six girls and five boys. The most common clinical presentation was ligneous conjuctivitis (n:11) that was present in all patients, followed by ligneous gingivitis (n:5) and hydrocephalus (n:3). Further manifestations were hearing loss (n:2), genitourinary involvement (n:1), hepatomegaly (n: 1), epilepsy (n:1), recurrent respiratory tract infections (n:1) and Dandy-Walker malformation (n: 1). The median age of first clinical manifestation was 7 months (range: 0.5–24 months). All patients were Turkish descent. Most of the patients' parents were consanguineous (n:6). Two girls and two boys were sisters and brothers; in addition to that these four patients were related. Venous thrombosis did not occur in any of the patients. In nine patients eye lesions were surgically removed and in all of them there were relapses on follow-up after surgery. Eight patients were treated by intravenous and conjunctival fresh frozen plasma. One of them had an anaphylactic reaction during plasma infusion so it was discontinued. One girl passed away due to endophtalmitis shorly after presenting to our clinic. None of the patients treated by fresh frozen plasma had a recurrence on follow-up. Three patients have been followed-up for > 3 years now with a prophylactic use of fresh frozen plasma every 10–30 days.
Conclusion: Patients with congenital plasminogen deficiency are symptomatic early in life. Boys usually become symptom-free at 4–5 years of age, however girls suffer throughout adulthood. Our experience showed that the severity of symptoms are not parallel with plasminogen levels and the clinical progress is more severe in girls compared to boys. Hydrocephalus and hearing loss are important clinical manifestations and ophthalmologists treating ligneous conjuctivitis patients should be aware of these systemic complications. Treatment of ligneous conjunctivitis is challenging due to frequent recurrences. Surgical excision should not be performed unless there is proggressive, intractable fibrin deposition. Systemic and topical fresh frozen plasma can be used successfully for preventing recurrences and relieving symptoms. The long-term prophylactic application of fresh frozen plasma seems to prevent recurrences and has a protective effect on the vision. Local conjuctival use of fresh frozen plasma in combination with other eye medications such as cyclosporin and artificial tear drops may relieve the nuisance feeling of 'something in the eyes'.

Effect of genetic PAI-1 polymorphisms 4G/5G, C428T and G429A on PAI-1 activity and clot lysis time

De Lange Z[1], Rijken DC[2], Hoekstra T[3], Conradie K[1], Jerling JC[1] and Pieters M[1]

[1]North-West University, Potchefstroom, South Africa; [2]Erasmus University Medical Centre, Rotterdam; [3]Leiden University Medical Centre, Leiden, The Netherlands

Background: Plasminogen activator inhibitor type-1 (PAI-1) plays an important role in clot lysis and is influenced by both environmental and genetic factors. Data on cardiovascular disease (CVD) risk and genetic factors influencing PAI-1 levels in the black African population, in whom the prevalence of CVD is increasing rapidly is, however, scarce.
Aims: We determined the frequencies of three polymorphisms in the promoter area of the PAI-1 gene and their influence on PAI-1_{act} levels and clot lysis time in a black African population. We also investigated gene-environment interactions and their influence on PAI-1_{act} levels and clot lysis time (CLT) and whether urbanisation influenced these interactions.
Methods: Data from 2010 apparently healthy black men and women (aged 35–65 years) who participated in the South African PURE study were cross-sectionally analysed. Anthropometric and dietary intake data were collected, as well as blood samples for the determination of biochemical factors, including PAI-1_{act} and CLT determined using a turbidimetric assay, and DNA isolation and genotyping.
Results: The 5G homozygous genotype frequency of the 4G/5G polymorphism was 72.5% in this population. PAI-1_{act} was the highest in the 4G/4G group (6.82 U/mL) followed by the 4G/5G group (5.77 U/mL) and then the 5G/5G group (4.77 U/mL) in the urban subgroup, while PAI-1_{act} levels did not differ significantly across genotypes in the rural group. CLT did not differ across 4G/5G genotypes. PAI–1_{act} additionally increased across the 4G/5G genotypes in normal, overweight and obese participants as well as in centrally obese participants,

but not in those with normal waist circumference. CLT differed significantly across the 4G/5G genotypes in centrally obese participants only. The C428T and G429A polymorphisms did not influence PAI-1_{act} or CLT, except for higher PAI-1_{act} in the homozygous wild type group of the G429A SNP.
For the 4G/5G polymorphism we found significant gene-environment interactions for WC, BMI and triglycerides on PAI-1_{act}; and for fibrinogen and fibrinogen gamma prime on CLT. Significant interactions for the C428T polymorphism and PAI-1_{act} were found with triglycerides, total homocysteine, fibrinogen gamma prime and HDL-cholesterol levels, and for CLT with BMI. The G429A polymorphisms showed interactions with LDL-cholesterol, and fibrinogen on PAI-1_{act} and interactions on the determination of CLT with fibrinogen and blood pressure. Some of the gene-environment interactions also differed significantly between the rural and urban subgroups.
Summary/Conclusions: The high prevalence of the 5G allele may contribute to the low PAI-1_{act} levels seen in this population. The 4G/5G polymorphism significantly influenced PAI-1_{act} levels in urban but not rural participants. The influence of the 4G/5G polymorphism on PAI-1_{act} is apparent in normal, overweight and obese participants and those who are centrally obese. The C428T and G429A SNPs do not seem to play an important role in PAI-1 transcription, probably owing to these SNPs not being present within a known transcription site. The 4G/5G, C428T and G429A polymorphisms showed significant interactions with various CVD risk factors in determining PAI-1_{act} and CLT. Many of these interactions were, however, affected by urbanisation as differences were observed between rural and urban participants.

PB 1.34-5
The hyperfibrinolytic phenotype induced by short-term venous stasis is not triggered by activation of the clotting cascade or thrombin formation

Rühl H, Müller J, Wäschenbach J, Oldenburg J and Pötzsch B
University Hospital Bonn, Bonn, Germany

Background: Venous stasis is a major factor in the development of venous thrombosis. The venous occlusion (VO) test is used to simulate this pathomechanism by induction of short term venous stasis. Recently, we have shown that a procoagulant response is not induced by the VO test in healthy individuals.
Aims: To study if the VO test induces such a procoagulant shift in the presence of endothelial cell dysfunction or inherited thrombophilia we extended our study to patients with arteriosclerosis or hereditary thrombophilic risk factors.
Methods: The study population consisted of three groups: healthy individuals (n = 25, 14 females, mean age, range: 32, 20–58 years); patients with arteriosclerotic coronary artery disease confirmed by coronary angiography (n = 15, one female, 65, 48–77 years); and thrombophilic patients (n = 19, 13 females, 43, 18–64 years) with antithrombin deficiency (n = 2), protein C or S deficiency (n = 6), homozygous FV Leiden (n = 8) or FII G20210A mutation (n = 3). The study was approved by the local ethics committee and all patients gave written informed consent. Blood samples were taken before, during VO (12 min after start) at the stasis arm and the contralateral arm, and 15 min after VO. Blood samples were analyzed for plasma levels of free thrombin and activated protein C (APC), both measured using highly sensitive oligonucleotide-enzyme capture assays showing lower limits of quantification of thrombin and of APC of 0.039 and 0.116 ng/mL, respectively. In addition, tissue-type plasminogen activator (t-PA), plasmin-α2-antiplasmin-(PAP)-complexes, and thrombin-antithrombin-(TAT)-complexes were determined. All determinations were corrected for changes in hematocrit.
Results: In all three cohorts the majority of samples taken during VO showed thrombin and APC levels below the LLOQ. Thrombin levels above the LLOQ during VO were observed only in one patient in the arteriosclerosis group (7.468 ng/mL) and one patient with homozygous FV Leiden mutation (1.738 ng/mL). Consistent with previous reports the VO test induced a fibrinolytic response, indicated by a significant increase ($P < 0.05$) in plasma levels of t-PA from 1.5 ± 3.1 ng/mL (mean ± SD) to 8.2 ± 7.6 ng/mL in healthy probands, 2.0 ± 1.1–11.2 ± 4.7 ng/mL in arteriosclerotic patients, and 1.7 ± 0.9–11.4 ± 6.6 ng/mL in patients with thrombophilia. Plasma levels of PAP-complexes also increased significantly from 657 ± 476 to 1730 ± 1085 ng/mL in healthy probands, 609 ± 166–1562 ± 913 ng/mL in patients with arteriosclerosis; and 614 ± 371–1642 ± 975 ng/mL in thrombophilic patients. TAT-complexes did not change significantly in all three cohorts.
Summary/Conclusion: Activation of the clotting cascade is not triggered by short term venous stasis even in the presence of additional thrombotic risk factors such as endothelial dysfunction or inherited thrombophilia. Furthermore, our results indicate that the fibrinolytic response induced by the VO test is caused by mechanisms independent from coagulation activation and thrombin formation.

PB 1.34-6
Nicotinic acid/laropiprant modulates fibrinolytic system in patients with elevated levels of Lipoprotein(a)

Lami D[1], Cioni G[1], Cellai AP[2], Sticchi E[1], Saracini C[1], Antonucci E[1], Alessandrello Liotta A[2], Rogolino A[2], Marcucci R[1] and Abbate R[1]
[1]*University of Florence;* [2]*AOU-Careggi, Florence, Italy*

Background: Hyperlipidemia can be effectively treated either by niacin or HMG-CoA reductase inhibitor. In addition, elevated levels of Lipoprotein (a) may be, at least in part, reduced by nicotinic acid. Scarce data are available on the role of nicotinic acid/laropiprant on fibrinolysis.
Aims: To asses the behaviour of the fibrinolitic system in patients with elevated levels of Lipoprotein (a) treated with with nicotinic acid/laropiprant.
