Von Willebrand factor regulates physiological and pathological angiogenesis through vascular endothelial growth factor receptor-2 signalling

Starke RD[1], Chillo O[2], Pagel JI[2], Elder MJ[1], Laffan MA[3], Deindl E[2] and Randi AM[1]

[1]Vascular Science, NHLI, Faculty of Medicine, Imperial College London, London, UK; [2]Walter-Brendel-Centre of Experimental Medicine Ludwig-Maximilians-University, Munich, Germany; [3]Haematology Dept, Faculty of Medicine, Imperial College London, London, UK

Von Willebrand Factor (VWF) is a multimeric glycoprotein, which mediates platelet adhesion to damaged endothelium and stabilises coagulation factor VIII. VWF is synthesized by endothelial cells (EC) and stored in Weibel-Palade bodies (WPB), which also contain regulators of angiogenesis and inflammation. A qualitative or quantitative deficiency of VWF causes Von Willebrand disease (VWD), the most common congenital bleeding disorder, which can be associated with vascular lesions (angiodysplasia) causing severe intractable gastrointestinal bleeding. Angiodysplasia is characterized by a fragile vascular network with disrupted architecture, increased permeability and susceptibility to rupture. The pathogenesis has been linked to dysregulated angiogenesis. We have shown that VWF regulates angiogenesis through pathways involving VEGFR2 signalling and the integrin $\alpha v\beta 3$ (Starke et al., Blood 2011; 117:1071–1080). Here we investigate the role of VWF in two *in vivo* models of angiogenesis and arteriogenesis, and provide new evidence on the angiogenic signalling pathways regulated by VWF in EC.

To investigate the role of VWF in the response to ischemia, we used the murine model of hindlimb ischaemia and VWF-deficient mice (Denis et al., Proc. Natl. Acad. Sci. U.S.A 2001; 98:4072–4077). The femoral artery was ligated (or sham-operated) in littermate control or VWF-deficient mice and blood flow was measured in the paws by Laser Doppler analysis at different time points. At day 3 postligation, VWF deficient mice showed a significant decrease in blood flow compared to controls ($P < 0.05$). In the lower leg (gastrocnemius [GN]), H&E and CD31 staining showed increased angiogenesis ($P < 0.05$) and tissue damage ($P < 0.05$) in VWF-deficient mice compared to controls. Quantitative RT-PCR analysis showed reduced β3 integrin levels in VWF-deficient mice compared to controls, in line with our previous *in vitro* findings. In the adductor muscle, VWF deficient mice showed reduced leukocyte infiltrate and vascular proliferation, suggesting decreased arteriogenesis in the absence of VWF. These results confirm that VWF controls angiogenesis and provide the first evidence that VWF is involved in restoring blood flow by regulating arteriogenesis.

Next we evaluated the role of VWF in physiological angiogenesis in the mouse post-natal retina model. Retinas from VWF-deficient mice or littermate controls were isolated at day 6 post-partum and stained for isolectin B4 and VWF. VWF was expressed in all EC, with higher expression nearer the vascular front, where tip cells lead the angiogenic sprout. In VWF-deficient retinas, vascularisation was increased, as measured by increase in vascular density near the optic nerve region and increase in the number of endothelial tip cells at the vascular front. These data support the evidence for VWF's role in regulating tip cell formation and sprouting angiogenesis.

We also carried out *in vitro* studies on the mechanism of VWF regulation of angiogenesis. Using VWF-specific siRNA in human umbilical vein EC, we show that VWF regulates EC proliferation through a pathway involving VEGF receptor-2 and ERK phosphorylation.

In conclusion, our data provide further evidence that VWF regulates both developmental and pathological angiogenesis, and add new insight into the pathways involved. These findings may help to identify novel targets for the treatment of angiodysplasia in patients with VWD.

AS 01.2

Sign and shape: correlation of clinical findings and clot ultrastructure in arterial thrombi

Kovacs A[1], Tenekedjiev K[2], Wohner N[1], Szabó L[3], Sótonyi P[1], Szelid Z[1], Nagy A[1], Szabó G[1], Merkely B[1] and Kolev K[1]

[1]Semmelweis University, Budapest, Hungary; [2]N. Vaptsarov Naval Academy, Varna, Bulgaria; [3]Hungarian Academy of Sciences, Budapest, Hungary

Background: Thrombus architecture is an important determinant of thrombus stability and affects the outcome of preventive and therapeutic interventions in acute myocardial infarction, stroke and peripheral arterial disease, but it is hardly accessible for evaluation in the everyday clinical practice. Here we address the potential correlations between routinely available clinical data and structure of thrombi removed with percutaneous coronary intervention (PCI) or thrombendarterectomy of large arteries.

Methods: Thrombus samples removed by PCI-thrombus aspiration following acute myocardial infarction ($n = 101$) or surgical open repair ($n = 50$) in a heterogeneous group of patients (age range 36–98 years, male-female ratio 6:4) were processed in two parallel ways: glutaraldehyde-fixation for scanning electron microscopy or freezing at −80 °C for cryosections and indirect immunostaining for fibrin and platelet receptor GpIIb/IIIa. Ten to fifteen images were taken of each thrombus with both microscopic techniques, and then analyzed morphometrically to determine fibrin fiber diameter, relative occupancy by fibrin, platelet, red blood cells (RBC), white blood cells (WBC). The correlation between the measured ultrastructural characteristics and selected clinical parameters (age, sex, location of vascular lesion, blood cell counts, haematocrit, C-reactive protein (CRP) in plasma, ECG findings, anti-platelet medication, accompanying diseases) was assessed using multiple hypothesis testing and regression analysis.

Results: Fibrin content of peripheral thrombi showed positive correlation with CRP and male sex ($P = 0.014$ and $P = 0.04$, respectively), but no such dependence was observed in coronary thrombi. Platelet content of thrombi correlated stronger with the hematocrit ($P = 3 \times 10^{-12}$, $R^2 = 0.75$ coronary; $P = 0.02$, $R^2 = 0.238$ peripheral) than with the platelet count in blood ($P = 2 \times 10^{-4}$, $R^2 = 0.20$). Aspirin premedication reduced the role of local factors seen as increased dependence of thrombus platelet content on systemic platelet count ($P = 4 \times 10^{-7}$, $R^2 = 0.54$) and stronger dependence of fibrin structure on RBC count in blood. Fiber diameter of peripheral thrombi decreased at higher RBC counts ($P = 0.009$, $R^2 = 0.16$) and the dependence was significantly stronger in the aspirin-treated group ($P = 0.003$, $R^2 = 0.29$). No such effect was found for clopidogrel. Sorting thrombi by their vessel of origin revealed a marked difference in fibrin-platelet ratio with lower values in the coronaries than in the ilio-femoro-popliteal arterial region ($P < 0.023$ by Kuiper's test for various combinations of subgroups). In line with this observation, platelet content was significantly higher in left anterior descending coronary thrombi than in the ilio-femoral subgroup ($P = 0.037$). In terms of platelet content and fibrin-platelet ratio coronary thrombi were similar to those of aortic origin. Neither the registered ECG findings, nor the accompanying diseases proved to be important determinants of thrombus structure on their own, but complex regression models revealed effects of combination of factors. For example, age at operation and CRP value had an additive effect on WBC content of thrombi in patients with atherosclerosis ($P = 0.003$, $R^2 = 1$) or hypertonia ($P = 0.03$, $R^2 = 0.95$).

Conclusion: The fibrin and platelet content of arterial thrombi as well as their fibrin structure are differentially affected at different vascular

locations and by systemic blood cell counts. Conventional anti-platelet drugs differ in their impact on thrombus structure. Improved individually tailored strategies for prevention of acute thrombotic events could be developed on the basis of these findings.

AS 01.3

Joint association of elevated factor VIII and low protein C with stroke and coronary heart disease: the reasons for geographic and racial differences in stroke (REGARDS) study

Zakai A[1], Judd S[2], Kissela B[3], Howard G[2], Safford M[2] and Cushman M[1]

[1]University of Vermont, Burlington, VT; [2]University of Alabama at Birmingham, Birmingham, AL; [3]University of Cincinnati, Cincinnati, OH, USA

Background: Low protein C (PC) and high factor VIII (FVIII) have been inconsistently associated with risk of stroke and coronary heart disease (CHD) in observational studies. We hypothesized that high FVIII and low PC are associated with increased risk of incident stroke and CHD. Further, as PC inactivates FVIII, we also hypothesized that the association of high FVIII with stroke and CHD will be stronger in those with low PC.
Aims: To study the associations of high FVIII and low PC on stroke and CHD risk in the REasons for Geographic and Racial Differences in Stroke (REGARDS) study.
Methods: REGARDS recruited 30,239 black and white US participants ≥ 45 years old between 2003 and 2007. FVIII and PC were measured in a case-cohort sample of 646 stroke cases, 746 CHD cases (defined as incident nonfatal myocardial infarction or fatal CHD), and a 1104 person cohort random sample with follow up for 4.5 years. High FVIII was defined as the top 20% and low PC as the bottom 5% of the biomarker distribution in the cohort random sample. The hazard ratio (HR) for high FVIII in the presence or absence of low PC was estimated using Cox proportional hazards models. We adjusted for Framingham stroke risk factors for the stroke outcome (age, sex, race, systolic blood pressure, anti-hypertensive medication use, diabetes, smoking, heart disease, atrial fibrillation, and left ventricular hypertrophy) and Framingham CHD risk factors for the CHD outcome (age, sex, race, systolic blood pressure, anti-hypertensive medication use, diabetes, smoking, total and high density lipoprotein cholesterol, and lipid-lowering medication use).
Results: FVIII and PC were not correlated ($R^2 = -0.01$, $P = 0.77$). High FVIII was associated with increased risk of both stroke (HR 1.42; 95% CI 1.02, 1.99) and CHD (HR 1.78; 95% CI 1.21, 2.61). Low PC was non-significantly associated with increased risk of both stroke (HR 1.65; 95% CI 0.95, 2.84) and CHD (HR 1.74; 95% CI 0.94, 3.20). For stroke, there was no evidence for an interaction between high FVIII and low PC (p for interaction 0.70). For CHD however, the adjusted HR for high FVIII was significantly greater in those with a low PC (HR 5.11; 95% CI 1.62, 16.20) than normal PC (HR 1.59; 95% CI 1.07, 2.39; *P*-interaction = 0.06).
Summary/Conclusion: High FVIII was associated with both CHD and stroke risk, while low PC was non-significantly associated with increased stroke and CHD risk. The association of high FVIII with CHD was higher in participants with low PC, but was not different for stroke. These data demonstrate that risks conferred by adverse levels of one biomarker may be augmented by levels of another biomarker. These findings suggest that there may be differences in the role of hemostasis in stroke and CHD pathophysiology.

AS 02 – Assays for Antithrombotic Drugs

AS 02

Assays for antithrombotic drugs

Chandler W

The Methodist Hospital, Houston, TX, USA

The first generation of antithrombotic drugs, warfarin and heparin, require continuous monitoring of drug levels using the PT/INR for warfarin and PTT or anti-Xa activity for heparin. Second generation antithrombotic drugs like low molecular weight heparin (LMWH) and pentasaccharides do not require routine monitoring, they are measured only when questions arise associated renal function, overdose, bleeding, elimination of the drug prior to surgery, or patients not approved for use. Levels of LMWH and pentasaccharides are measured using anti-Xa activity assays. The latest oral antithrombotic drugs to be introduced, dabigatran (direct thrombin inhibitor), and rivaroxaban and apixaban (anti-Xa inhibitors), do not require routine monitoring. Treatment is based on fixed doses with changes in dose associated with reduced renal function, patient weight and age in some cases. Monitoring of these medications may be needed in some clinical situations, including changes in renal function, concern about overdose in patients that are bleeding or thrombosis while on the drug, elimination of the drug prior to surgery, adherence to therapy, and patients not approved for use (e.g. children, pregnancy). Important considerations related to monitoring these new drugs include (i) therapeutic ranges, (ii) calibrators, (iii) assay to be used and (iv) assay availability, stat vs. routine. A major issue with monitoring of these new drugs is establishing a therapeutic range, regardless of the assay used for monitoring. These drugs were approved for use without monitoring, there are no approved therapeutic ranges based on clinical trial data. Levels in patients taking the drugs can be estimated from pharmacodynamic studies, but these are not official ranges, and the levels vary substantially during the day. Timing of when the sample is taken (peak vs. trough) is important for interpreting results. A second issue is calibrators for these assays. Dabigatran assays must be calibrated with the active form dabigatran and not the inactive parent drug dabigatran etexilate. Rivaroxiban and apixaban assays can be calibrated with parent drug and some companies are developing calibrators for future assays. For dabigatran (and older parenteral direct thrombin inhibitors), the standard thrombin time can be used to determine if the drug has cleared from the blood prior to surgery or in bleeding patients, but the assay is too sensitive for monitoring of drug levels in the therapeutic range. Dabigatran can be monitored with a PTT, but the degree of prolongation varies with different reagents and the test overestimates dabigatran levels in many patients. A plasma diluted thrombin time has been developed for monitoring that is rapid, uses standard thrombin time reagents and is more accurate than the PTT. Ecarin clotting times can also be used to monitor dabigatran, but are more expensive and not available in many laboratories. For oral anti-Xa drugs, the PTT is not sensitive enough and while the PT does prolong, the degree of prolongation is highly variable between reagents. The optimum test for oral anti-Xa monitoring is likely to be a modified anti-Xa assay with calibrators specific for the drug being measured.

AS 02.1

Comparison of the HAS-BLED, ATRIA and HEMORR2HAGES scores to the CHADS2 score for bleeding risk in atrial fibrillation patients on warfarin therapy: the MAQI2 experience

Barnes D[1], Gu X[1], Haymart B[1], Kline-Rogers E[1], Almany S[2], Kozlowski J[3], Besley D[4], Krol GD[5], Froehlich JB[1] and Kaatz S[6]

[1]University of Michigan, Ann Arbor; [2]William Beaumont Hospital, Royal Oak; [3]Huron Valley Sinai, Commerce; [4]West Michigan Heart, Grand Rapids; [5]Henry Ford Hospital and Medical Center, Detroit; [6]Hurley Medical Center, Flint, MI, USA

Background: Bleeding risk scores have the potential to impact anticoagulation care decision making in patients with atrial fibrillation (AF). Recent studies have demonstrated bleeding risk increases with increasing $CHADS_2$ score as well. Some clinicians have begun using the $CHADS_2$ score as a quick estimate of bleeding risk for AF patients. However, a comparison of these validated bleeding risk scores to the $CHADS_2$ score has not been performed.

Aims: To compare the HAS-BLED, ATRIA and $HEMORR_2HAGES$ bleeding risk scores to the $CHADS_2$ score for predicting major bleeding in AF patients on warfarin.

Methods: Two thousand five hundred and seventy-seven AF patients with at least 2 INR values were followed for a mean 1.0 year (SD 0.8) at seven anticoagulation management centers in Michigan, USA. Data was collected by trained abstractors with random audits to ensure accuracy. Demographic and comorbidity data were used to calculate HAS-BLED, ATRIA, $HEMORR_2HAGES$ and $CHADS_2$ scores for each patient. Genetic information was not available for use in $HEMORR_2HAGES$ score calculation. Major bleeding rates with 95% CI, as defined by the ISTH definition, were calculated for each risk score. ROC curves were generated and compared using the c-statistic with 95% CI. Statistical analysis was performed using Chi-squared, Wilcoxon Rank Sum, Log-rank and Fisher's exact tests.

Results: One hundred and sixteen major bleeding events occurred during 2580 patient-years of follow-up. Major bleeding risk occurred more commonly in patients with higher HAS-BLED, ATRIA and $HEMORR_2HAGES$ scores ($P < 0.0001$ for trend) but not with higher $CHADS_2$ scores ($P = 0.08$ for trend). Patients with low (0), moderate (1–2) and high (3+) bleeding risk according to the HAS-BLED score experienced 1.9 (0.05–10.4), 1.6 (0.9–2.7) and 6.2 (5.1–7.6) major bleeds per 100 patient-years, respectively. Patients with low (0–3), moderate (4) and high (5+) bleeding risk according to the ATRIA score experienced 2.3 (1.7–3.2), 7.4 (4.6–11.3) and 9.0 (6.8–11.7) major bleeds per 100 patient-years, respectively. Patients with low (0–1), moderate (2–3) and high (4+) bleeding risk according to the $HEMORR_2HAGES$ score experienced 1.6 (0.7–3.2), 3.6 (2.7–4.8) and 8.6 (6.5–11.1) major bleeds per 100 patient-years, respectively. Patients with low (0–1), moderate (2) and high (3+) risk $CHADS_2$ scores experienced 3.3 (2.2–4.7), 4.8 (3.5–6.4) and 5.6 (4.0–7.6) major bleeds per 100 patient-years, respectively. Mean TTR was 54.6% for those with major bleeding and 59.5% for those without major bleeding ($P = 0.0018$). The c-statistic was 0.72 (0.67–0.77) for HAS-BLED, 0.69 (0.64–0.74) for ATRIA, 0.69 (0.64–0.73) for $HEMORR_2HAGES$ and 0.59 (0.54–0.64) for $CHADS_2$. The c-statistic was not significantly different between HAS-BLED, ATRIA and $HEMORR_2HAGES$ ($P = 0.053$–0.72 for direct comparisons). HAS-BLED, ATRIA and $HEMORR_2HAGES$ each had significantly higher c-statistics than the $CHADS_2$ score ($P < 0.0001$ for each direct comparison).

Conclusion: In our observational cohort of AF patients, the HAS-BLED, ATRIA and $HEMORR_2HAGES$ bleeding risk scores performed equally well to predict major bleeding events. The $CHADS_2$ score's predictive value for major bleeding was significantly less than the HAS-BLED, ATRIA or $HEMORR_2HAGES$ scores. Use of the $CHADS_2$ score in place of a formalized and validated score, such as HAS-BLED, ATRIA or $HEMORR_2HAGES$, to predict major bleeding risk is not advised.

AS 02.2

Effects of dabigatran on routine tests of haemostasis as determined with a full range of reagents: results of a UK NEQAS exercise

Kitchen S[1], Jennings I[1], Kitchen D[1], Woods T[1], Lowe A[2] and Walker I[1]

[1]UK NEQAS Blood Coagulation; [2]Royal Hallamshire Hospital, Sheffield, UK

Background: Dabigatran is known to influence the results of some routine tests of haemostasis. Published studies include data on only a few reagents and methods. Some guidelines (Baglin et al. BJH 2012:159:427–9) recommend that laboratories should be aware of the sensitivity of their methods to the presence of dabigatran. Data are needed on the full range of reagents in routine use worldwide.

Aims: To assess the effects of a range of dabigatran concentrations including likely peak trough and accumulation levels on prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin time (TT) and Clauss fibrinogen (Fib) results.

Methods: The same pooled normal plasma was spiked with 0, 50, 200, 500 and 1000 ng/mL dabigatran (a kind gift of Boehringer Ingelheim), lyophilised in 1 mL aliquots, lyophilised and despatched to all centres registered with UK National External Quality Assessment Scheme (NEQAS) for Blood Coagulation for any combination of PT, APTT, TT and Fib. Results were grouped according to reagent used and the median ratio calculated (test/mid point of normal range).

Results: Results were received from 570 centres (~60%UKand 40% nonUK) who used 17–25 different reagent sets, the majority performed PT APTT and Fib, and 290 returned TT results. 168 centres reported that patients in their centre had received dabigatran therapy, 162 had not and 201 centres did not know. The sample containing no dabigatran had normal overall median PT, APTT, TT and Fib results. PT reagent median ratios: 50 ng/mL – most reagent medians essentially normal at < 1.2 (with 2 medians around 1.3); 200 ng/mL – median ratios ranged from 1.22 to 1.67; 500 ng/mL 1.51–2.42; 1000 ng/mL – range 2.63–6.65. APTT reagent median ratios: 50 ng/mL – all reagent median ratios prolonged (range 1.3–1.69); 200 ng/mL – range 1.78–2.46; 500 ng/mL – range 2.36–3.46; 1000 ng/mL – range 3.32–4.73. TT results: At 50 ng/mL ~25% of centres were unable to detect a measurable clotting time, with a median TT ratio of 7.03 and reagent medians for the commonly used reagents ranging from 5.3 to 11.9; 200 ng/mL – only 10% of centres could record a clotting time.

Fib results: Clauss fibrinogen results were unaffected by 200 ng/mL dabigatran for most methods. At 500 ng/mL there was underestimation by up to ~20% except for one method (in which test plasma is not prediluted in contrast to most other techniques) with ~60% underestimation. At 1000 ng/mL there was 50–80% underestimation in three methods, though most had < 20% underestimation.

Conclusions: All PT and APTT reagents were affected by dabigatran. PT was less affected by low levels and showed more variability in reagent sensitivity. TT was unclottable even at 50 ng/mL in 75% of centres, and in most centres at higher drug concentrations. Fibrinogen was underestimated by up to 20% in most assays but some methods were markedly affected at higher concentrations.

AS 02.3

How to monitor Dabigatran- when needed: comparison of coagulation laboratory methods an Dabigatran concentrations in plasma

Antovic JP[1], Skeppholm M[2], Eintrei J[1], Eriksson-Boija E[1], Söderblom L[1], Rönquist Y[1], Beck O[1], Norberg E-M[1], Hjemdahl P[1] and Malström RE[1]

[1]Karolinska University Hospital & Institutet; [2]Karolinska Institutet & Danderyd Hospital, Stockholm, Sweden

Dabigatran (Pradaxa®, Boehringer Ingelheim) is an oral direct thrombin inhibitor for which routine laboratory monitoring is currently not recommended. However, there are situations in which measurements of the drug and its effect are desirable (e.g. preparation for surgery; major bleeds, to check compliance and/or effect). Direct measurement of dabigatran plasma concentrations may be considered the method of choice. However, this is not widely available and standardized coagulation assays may be used by the routine 24/7 laboratory instead. We have compared some coagulation tests with dabigatran measurements in plasma.

Methods: Plasma samples were obtained from 70 patients treated with dabigatran. Plasma concentrations were measured using liquid chromatography coupled with mass-spectrometry (LC-MS/MS) and were compared with new methods for indirect determination of dabigatran concentrations (Hemoclot thrombin inhibitors [HTI], Hyphen) and Ecarin clotting assay (ECA; Stago), as well as with PT-INR (Owren reagent SPA+, Stago) and APTT (Silica reagent, Automate, Stago) and the endogenous thrombin potential (ETP; Siemens).

Results: Dabigatran concentrations by LC-MS/MS varied considerably between patients (0–586 ng/mL, median 45, 95% CI 48–111). Correlations between directly measured and estimated concentrations were excellent for both HTI and ECA (R^2 = 0.97 and 0.96 respectively, $P < 0.0001$), and the same was true for HTI vs. ECA (R^2 = 0.94). The lowest calibrator point for HTI was 30 ng/mL (with dilution to 15 ng/mL the CV was > 30% at those low values), while ECA had null calibration. There were significant correlations between dabigatran levels and both APTT (R^2 = 0.58) and ETP (R^2 = 0.69). However, APTT was within the normal range (< 40 s) even with dabigatran levels of 60 ng/mL, and ETP decreased below 80% only at dabigatran concentrations above 150 ng/mL. There was no correlation between dabigatran concentration and PT-INR; the only abnormal PT-INR value was observed with a dabigatran concentration of 500 ng/mL.

Interpretation: This is the first comparison of the plasma concentrations of dabigatran and coagulation assays in samples obtained from patients treated in real clinical settings. It seems that both the HTI and ECA assays may be used to estimate the intensity of dabigatran anticoagulation and drug levels in clinical samples. However, the interpretation of low values should be cautious, especially for HTI. The Owren PT reagent is insensitive to dabigatran, and ETP is not useful. The APTT assay used in our laboratory is relatively insensitive to dabigatran and normal APTT results may be observed even if dabigatran concentration is slightly above 60 ng/mL. The APTT could be useful for the assessment of peak effects shortly after taking the drug or in connection with bleeding associated with high concentrations of dabigatran. In conclusion, determinations of plasma concentrations of dabigatran by LC-MS/MS is the gold standard when monitoring of dabigatran is needed. If this is not available, HTI and ECA are the assays of choice. However, neither of those assays can be used to monitor low levels or infer the total absence of dabigatran.

AS 03 – Platelet Interactions

AS 03.1

Investigation on the role of protein S in platelets

Calzavarini S[1], Saller F[2], Bologna L[1], Burnier L[3], Brisset A[1], Fernández JA[3], Griffin JH[3], Hackeng TM[4] and Angelillo-Scherrer A[1]

[1]University Hospital of Lausanne (CHUV), Lausanne, Switzerland; [2]University Paris-Sud-XI, Paris, France; [3]The Scripps Research Institute, La Jolla, CA, USA; [4]Cardiovascular Research Institute Maastricht (CARIM), University Maastricht, Maastricht, the Netherlands

Background: Anticoagulant protein S (PS) is essential for maintaining the haemostatic balance. In humans, although most of the PS in plasma is thought to be mainly synthesized by hepatocytes, the PS gene (*ProS*) is also expressed by several other cell types, including megakaryocytes (MK). Notably, about 2.5% of PS in circulating blood is stored in platelets and released upon stimulation. So far, little is known about the functionality and importance of platelet PS. Our previous characterization of PS deficiency in mouse models has shown similarities with the human phenotypes as heterozygous PS-deficient mice had increased susceptibility to thrombosis and homozygous PS deficiency was incompatible with life.

Aims: To explore the functional roles of PS secreted from platelets.

Methods: Mice carrying a conditional *ProS* knockout allele in the MK lineage, were established using the *Pf4* promoter as Cre driver ($ProS^{Lox/Lox}Pf4Cre^{+}$). The characterization of the resulting phenotype was performed by evaluating the thrombotic risk *in vivo*, as well as platelet function by using the Platelet Function Analyzer-200 and light transmission aggregometry (collagen and ADP were used as agonist). In addition, PS cofactor activity for tissue factor pathway inhibitor α (TFPI α) was measured by a Factor Xa amidolytic activity assay.

Result: $ProS^{Lox/Lox}$ $Pf4Cre^{+}$ mice did not have detectable PS levels in platelet lysates (n = 5) but did have normal levels in plasma (88.9 ± 4.6%, n = 19), as assessed by antigenic assays. Analysis of complete blood counts established that these animals retained a normal blood cell profile compared with wt mice. Moreover, no difference in platelet function was seen in $ProS^{Lox/Lox}$ $Pf4Cre^{+}$ mice compared to control wt mice. In contrast, a tail clipping test showed significantly decreased bleeding times for animals lacking PS in platelets, as compared to wt mice (P = 0.021). When challenged in a tissue factor-induced thromboembolism model, $ProS^{Lox/Lox}$ $Pf4Cre^{+}$ mice (n = 15) exhibited a notable thrombotic phenotype (survival rate 46.7% compared to 85.8% for $ProS^{Lox/Lox}$ mice, n = 14; $P < 0.05$).

Beside its anticoagulant cofactor role for activated protein C, PS acts as cofactor for TFPI α in the inhibition of factor Xa. The complete deletion of *ProS* gene in MK lineage did not affect antigenic TFPI α levels in platelet lysates. Preliminary data on cofactor activity of PS for TFPI α indicate that the absence of PS in platelet lysates abolished the capacity of TFPI α to inhibit factor Xa amidolytic activity.

Summary/Conclusion: These data suggest that platelet PS is delivered at the site of thrombosis to counterbalance procoagulant activities on platelets, thus inhibiting thrombus growth. Upon release, platelet PS may function as an anticoagulant protein by enhancing not only activated Protein C but also critically the TFPI-dependent inhibition of factor Xa thereby blocking prothrombinase activity.

AS 03.2

Toll-like receptor 2 is critical for platelet adhesion to the injured arterial wall

Jäckel S[1], Kiouptsi K[2], Von Brühl M-L[3], Reiβ C[2], Massberg S[4], Walter U[2] and Reinhardt C[2]

[1]University Medical Center of the Johannes Gutenberg University Mainz; [2]Center for Thrombosis and Hemostasis (CTH), University Medical Center, Mainz; [3]German Heart Center, Munich; [4]Ludwig-Maximilians-Universität, Klinikum der Universität München, München, Germany

Innate immune signaling and thrombosis are closely intertwined. Several mechanisms have evolved that connect innate immunity with thrombus formation. In spite of recent reports on functional Toll-like receptor 2 (TLR2) signaling in platelets and endothelial cells it remains unclear whether TLR2 is required for normal hemostasis and it is not resolved if TLR2 signaling plays a role in experimental thrombus formation. Therefore, we set out to explore the role of TLR2 on platelet adhesion to the subendothelial matrix in a murine *arteria carotis communis* ligation model using high-speed intravital epifluorescence microscopy.

In *Tlr2−/−* mice platelet adhesion was vastly impaired at the ligation injury site compared with *WT* controls. No difference in whole blood platelet counts or average tail bleeding times could be detected between both groups. Interestingly, platelet adhesion was similar in *WT* mice and *Myd88−/−*mice suggesting that the involvement of TLR2 in platelet adhesion is independent of its signaling function. Transfusion experiments with fluorescently labeled *WT* platelets into *Tlr2−/−* mice and fluorescently labeled *Tlr2−/−* platelets into *WT* mice were performed to pinpoint whether the observed effects are originating from the vessel wall or from the platelets. Both groups (*Tlr2−/−* platelets in *WT* mice and *WT* platelets in *Tlr2−/−* mice) showed a decreased platelet adhesion compared with *WT* controls (*WT* platelets in *WT* mice). This indicates that both, TLR2 in the vessel wall and in circulating platelets, is required for platelet adhesion. *WT* mice that were infused with a functional inhibitory TLR2-antibody showed significantly decreased platelet adhesion to the injury site compared with the isotype control group. Furthermore, under static conditions the adhesion of washed platelets from *Tlr2−/−* mice to collagen and laminin matrices was strongly impaired compared with *WT* controls. First experiments with whole blood from $Tlr2^{-/-}$ compared with WT mice under flow conditions confirm our previous results of impaired platelet adhesion to collagen and laminin matrices. Deficiency of TLR2 did not result in altered expression levels of the major platelet adhesion molecules integrin α_2, integrin β_1, glycoprotein VI, glycoprotein Ib or plasmatic von Willebrand Factor. This further supports a direct role of TLR2 in platelet adhesion.

Here, we report that TLR2 from circulating platelets and the vessel wall promotes primary platelet adhesion under arterial flow. This effect is independent of the TLR2 adapter molecule MyD88 excluding the involvement of downstream signaling events. We provide first evidence that targeting of TLR2 could be used as a novel therapeutic strategy to inhibit arterial thrombus formation.

AS 03.3

The activated protein C cofactor activity of protein S is enhanced through extracellular phosphorylation by platelet kinases

Stavenuiter F, Gale AJ and Heeb MJ

The Scripps Research Institute, La Jolla, CA, USA

Background and Aims: Protein S is a multifunctional plasma protein of the hemostatic and inflammatory pathways, although mechanisms for its regulation are poorly understood. Anticoagulant reactions of protein S likely occur on activated platelets. Since certain plasma proteins are regulated through extracellular phosphorylation, we investigated whether the anticoagulant activity of protein S is regulated through phosphorylation by platelet-secreted kinases.

Methods and Results: Protein S was phosphorylated upon exposure to activated platelets or their releasates, as judged by immunoblotting for phospho-amino acids and for protein S. The responsible kinases showed casein kinase-1 and casein kinase-2-like properties, since protein S phosphorylation was reduced by specific inhibitors of these casein kinases (10 μM D4476 and 100 μM CK2-inhibitory peptide YNLKSKSSEDIDESS). Involvement of casein kinases in protein S phosphorylation was confirmed using purified kinases. Phosphorylation of protein S by purified casein kinase-1 did not affect its activated protein C cofactor activity in Activated Partial Thromboplastin Time (APTT) assays in protein S-depleted plasma. In contrast, phosphorylation of protein S by purified casein kinase-2 or by casein kinase-1 and casein kinase-2 combined increased protein S cofactor activity ~1.6-fold (158.7 ± 4.8%, $P < 0.01$) or ~2-fold (191.5 ± 6.4%, $P < 0.0001$), respectively. The activated protein C cofactor activity of protein S in protein S-depleted plasma exposed to platelet-secreted kinases was enhanced, while inhibitors against casein kinase-1 and casein kinase-2 reduced this cofactor activity. Proteomic studies of protein S exposed to platelet releasate revealed phosphorylated sites for casein kinase-1 and casein kinase-2 in the EGF2-like domain (Thr137) and Gla-domain (Thr37), respectively. Alignment of the primary sequence of human protein S with those of five other species revealed that Thr37 and Thr137, together with their casein kinase-1 and casein kinase-2 consensus sequences, are completely conserved.

Conclusions: These findings identify platelet-mediated extracellular phosphorylation of protein S as a potential mechanism by which its activity is regulated.

AS 04 – Inflammation and Coagulation in Atherosclerosis

AS 04.1

Increased levels of circulating platelet-monocyte complexes and platelet-neutrophil complexes are associated with myocardial infarction

Rutten B[1], Jukema JW[2], Doevendans PA[1], Pijls HJ[3], Waltenberger J[4], Van Zonnveld A[2], Pasterkamp G[1], Hoefer I[1], De Groot PH[1] and Roest M[1]

[1]UMC Utrecht, Utrecht; [2]Leiden UMC, Leiden; [3]Catharina Hospital, Eindhoven; [4]Maastricht UMC, Maastricht, the Netherlands

Background: Inflammation plays a key role in the development of coronary artery disease (CAD). Platelet-leukocyte complexes contribute to the progression of CAD and have been proposed to be reliable markers of inflammation. For this reason we investigated if circulating platelet-leukocyte complexes can serve as a biomarker for the diagnosis and/or prognosis of CAD.

Methods: We conducted a prospective multicenter cohort study in which 263 CAD patients were admitted for percutaneous coronary intervention (PCI) to four Dutch medical centers: Catharina Hospital in Eindhoven, University Medical Center in Maastricht, University Medical Center in Leiden and the University Medical Center in Utrecht. Citrate and EDTA anti-coagulated whole blood samples were drawn from patients directly before PCI. Monocytes, neutrophils and lymphocytes were identified by scatter gating and CD14 labeling. Platelet-monocyte, platelet-neutrophil and platelet-lymphocyte complexes were quantified by the percentage of cells positively stained for the platelet marker Gp1b within the respective gates. The number of platelets bound per leukocyte was quantified by the mean fluorescence intensity of platelet marker Gp1 per bound leukocyte. Patients were followed for 9 months after intervention for the composite end point major adverse cardiovascular events (MACE), being myocardial

infarction, another PCI, coronary artery bypass graft, or death by cardiovascular disease.

Results: We found significantly elevated levels of platelet-monocyte complexes (33.9 ± 3.6% vs. 26.1 ± 1.3%, mean ± SEM, $P < 0.05$) and platelet – neutrophil complexes (20.5 ± 2.8% vs. 15.0 ± 0.8%, mean ± SEM, $P < 0.05$) in citrate anticoagulated blood of patients that were diagnosed with non-ST elevation myocardial infarction (NSTEMI) ($n = 26$) compared to patients with stable angina ($n = 209$). Comparable results were found in EDTA anticoagulated blood. No differences were found in the number of platelets bound per leukocyte between patient with NSTEMI compared to stabe angina. Levels of platelet-leukocyte complexes and platelets bound per leukocyte were not associated with future MACE ($n = 27$).

Conclusions: Circulating platelet-monocyte complexes and platelet-neutrophil complexes might serve as biomarkers for the diagnosis of CAD, but do not predict future adverse cardiac events.

AS 04.2

Small molecule inhibitors of CD40-TRAF6 interaction reduce atherosclerosis by targeting its inflammatory nature

Zarzycka BA[1], Seijkens T[2], Soehnlein O[2], Schrijver R[3], Vriend G[4], Nabuurs S[4], Weber C[5], Lutgens E[2] and Nicolaes GAF[3]

[1]Maastricht University, Maastricht; [2]Academic Medical Center (AMC), University of Amsterdam, Amsterdam; [3]Cardiovascular Research Institute Maastricht, Maastricht University, Maastricht; [4]CMBI, Radboud University Medical Centre, Nijmegen, the Netherlands; [5]Institute for Cardiovascular Prevention (IPEK), Ludwig Maximilians University, Munich, Germany

Backround: Atherosclerosis is a chronic inflammatory disease of the arterial wall. A pivotal role in the pro-inflammatory activation is played by the co-stimulatory CD40-CD40L dyad. Previously, it was discovered that inhibition of CD40 in hyperlipidemic mice drastically reduces atherosclerosis; however its long-term inhibition results in immunosuppression and/or thromboembolic events. Therefore more downstream inhibition of the CD40L-CD40 dyad should present better targets for pharmacological therapy. CD40 lacks intrinsic signalling activity and thus to elicit intracellular signalling upon activation, CD40 needs to recruit adaptor proteins: the tumour necrosis factor receptor-associated factors (TRAFs). Further, using mice with a mutation in the CD40-TRAF binding site, it was shown that CD40-TRAF6 but not CD40-TRAF2/3/5 interaction is crucial for the atherosclerotic plaque reduction.

Aims: We aimed at identification of small drug-like molecule inhibitors of the CD40-TRAF6 interaction which will interfere specifically with the inflammatory nature of atherosclerosis.

Methods/Results: For the discovery of CD40-TRAF6 inhibitors we used an *in silico* structure-based virtual ligand screening (VLS) approach with a small molecule collection (ChemBridge, ~400,000 compounds). To screen only for drug-like molecules, the compound collection was filtered based on predicted absorption, distribution, metabolism, excretion, and toxicity (ADME/Tox) properties. Next, we applied a hierarchical protocol that combines rigid and flexible docking methods. The 800 most likely binders after *in silico* selection were analyzed *in vitro*, using a cell-based NFκB reporter gene assay. This resulted in the identification of seven hits that reduced NFκB activation in RAW cells in a dose-dependent way (IC50 in a range 0.1–16.1 μM). Moreover, the seven hit compounds suppressed CD40-induced production of IL1β and IL6 in primary bone marrow-derived macrophages in a dose-dependent way. In order to analyze effects of these molecules on atherosclerosis we selected two compounds for *in vivo* analysis in *Apoe*−/− mice with developed initial lesions, which were treated with compounds 1 or 2 at 10 μmol/kg/day for 6 weeks. Total plaque area per aortic arch was reduced by 47.1% and 66.8% in mice treated for compound 1 and 2, respectively. Moreover, aortas of treated mice contained more initial lesions (intimal xanthoma and pathological intimal thickening) and exhibited a decrease in advanced atherosclerosis (fibrous cap atheromata). Compounds 1 and 2 reduced the number of leukocytes per plaque by 43.1% and 52.6%, respectively. Intravital microscopy showed that recruitment of leukocytes, especially monocytes and neutrophils to the endothelium was decreased in compound treated mice. As a result, compound 1 and 2 reduced monocyte adhesion by 40.1% and 51.2% respectively, and neutrophil adhesion by 40.2% and 51.2%, respectively. We verified the direct binding of our hit compounds by SPR and ITC-based direct binding assays in which small compounds bound dose-dependently to the recombinantly expressed target domain.

Conclusion: We have discovered and characterized a group of druglike compounds that inhibit CD40-TRAF6 interaction, which result in reduction of atherosclerosis progression by inhibition of chemokine-mediated leukocyte influx into the arterial wall. These results indicate the possibility of long-term therapeutic inhibition of atherosclerosis and its haemostatic complications as well as of other inflammatory diseases.

AS 04.3

Platelet CD40 exacerbates atherosclerosis by transcellular activation of endothelial cells and leukocytes

Lievens D[1], Seijkens T[2], Kuijpers MJE[3], Winkels H[4], Beckers L[2], Gerdes N[4], Heemskerk JWM[3], Soehnlein O[4], Weber C[4] and Lutgens E[2]

[1]KU Leuven Kulak, Kortrijk, Belgium; [2]AMC, Amsterdam; [3]CARIM, Maastricht, the Netherlands; [4]LMU, Munchen, Germany

Background: Beyond an eminent role in hemostasis and thrombosis, platelets are important mediators of inflammation and protagonists of atherogenesis. Here we investigated the inflammatory propensity of platelet-specific expression of the CD40 receptor, an integral membrane protein of the tumor necrosis factor receptor (TNF-R) family. Besides its presence on immune and other cell types the CD40 receptor is constitutively expressed on platelets where its function remains unknown.

Aim: We therefore investigated the inflammatory propensity of platelet CD40 co-stimulation, as well as its underlying mechanisms in atherosclerosis.

Methods: Platelets were isolated from *Apoe*−/− or *Cd40*−/−*Apoe*−/− mice, activated with thrombin, and injected (3×10^7 platelets, i.v.), into 17-week-old *Apoe*−/− mice every 5 days for 12 weeks. At week 29, atherosclerosis was quantified in the aortic arch. Platelet-leukocyte and platelet-endothelium interactions were quantified with flow cytometry and intravital microscopy.

Results: Compared to infusion of activated *Apoe*−/− (wild type) platelets, injection of activated *Cd40*−/−*Apoe*−/− platelets caused > 2-fold decrease in plaque size (*Apoe*−/− platelets $18.3 \times 10^4 \pm 2.7 \times 10^4$ μm^2 vs. *Cd40*−/−*Apoe*−/− platelets $6.7 \times 10^4 \pm 2.1 \times 10^4$ μm^2, Vehicle $9.8 \times 10^4 \pm 2.8 \times 10^4$ μm^2, $P < 0.05$) in the aortic arch. Absence of CD40 on platelets reduced the absolute number of plaque macrophages (Mac-3) by 39% but did not affect the content of $CD45^+$ cells and $CD3^+$ T lymphocytes. Flow cytometric analysis revealed an elevated number of circulating $Ly6G^+$ neutrophils (+32%) upon injection of activated platelets. However, this increase was absent when CD40-deficient platelets, were injected highlighting the inflammatory potential of platelets and a central role for CD40 in this process. In addition, we detected a significant decrease in the formation of platelet-leukocyte aggregates *in vitro* while intravital microscopy in carotid arteries showed a two-fold decrease of platelet adhesion to the vessel wall of mice, injected with activated *Cd40*−/− platelets.

Conclusions: In sum, this study reveals that platelet CD40 promotes atherosclerosis by interaction with both neutrophils and endothelial cells, thereby amplifying leukocyte recruitment to sites of vascular injury.

AS 05 – Hormones and Thrombosis

AS 05
Exogenous hormones and thrombosis

Cushman M

University of Vermont, Colchester, VT, USA

Exogenous hormones are used in women for contraception and treatment of menopausal symptoms. Both treatments are associated with increased vascular risks, most notably venous thrombosis. Regarding postmenopausal hormones (PHT), conjugated equine estrogens (CEE) plus medroxyprogesterone acetate (MPA) double the risk of deep vein thrombosis (DVT) and pulmonary embolus (PE), and this risk is larger in older women and those who are obese. The absolute risk in obese women is 0.5% per year. In women with factor V Leiden this risk is 0.8% per year in general and 2.9% per year if they have a family history of factor V Leiden and venous thrombosis (VT). Mechanisms for an increased risk of VT with PHT likely include reductions in antithrombin and protein S, and induction of activated protein C resistance. In unpublished data we showed that women with higher D-dimer prior to prescription are at high risk, with a risk similar to that in women with factor V Leiden. Limited evidence suggests that micronized progesterone may not increase the risk of VT with PHT. Further, in observational studies transdermal estrogen was not associated with increased risk and some societies suggest this is reasonable treatment for PHT use in women with prior VT or at risk of VT.

Risk of VT is similarly increased by about two-fold in women using oral contraceptives (OC), with the highest risk in the first year of use. The relative risk is especially high in women with other risk factors such as factor V Leiden, obesity and older age of use. Fortunately due to their younger age, the absolute risk of VT with OC remains low (e.g. about 3.5/1000 in young women with factor V Leiden heterozygosity). Risk depends on the pill type and dose. Available progestin only pills do not seem to increase risk. Pills containing 3rd generation progestins, such as desogestrel and gestodene, and those containing drospirenone, have higher risks than those with 2nd generation progestins, such as levonorgestrel. There are misconceptions among some clinicians that non-oral contraceptives have a lower risk. Vaginal ring ethinyl estradiol plus etonogestrel, depo-MPA, and transdermal ethinyl estradiol plus norgestimate all seem to increase risk of VT. The mechanisms of increased risk for contraceptives are probably similar to PHT; namely activated protein C resistance and reductions in antithrombin and protein S. The clinical approach to use of these medications in general and in women at risk of thrombosis will be discussed.

AS 05.1
The risk of venous thrombosis in oral contraception users with a history of superficial thrombophlebitis

Roach REJ, Lijfering WM, Van Hylckama Vlieg A, Helmerhorst FM, Rosendaal FR and Cannegieter SC

Leiden University Medical Center, Leiden, the Netherlands

Background: Women using oral contraception have a 3–5-fold increased risk of venous thrombosis compared with non-users. Individuals with superficial thrombophlebitis have a 5–6-fold increased risk of a subsequent venous thrombosis. There is consensus that women should discontinue the use of oral contraceptives after an episode of venous thrombosis, but no such consensus exists for oral contraceptive use after superficial thrombophlebitis.

Aim: The aim of our study was to assess the risk of venous thrombosis in oral contraception users with a history of superficial thrombophlebitis.

Methods: From the MEGA study, a large case-control study on risk factors for venous thrombosis, 1428 female patients with a first venous thrombosis and 1755 female control subjects without venous thrombosis were included, all aged < 50 years. Odds ratios (OR) and 95% confidence intervals (95% CIs) for venous thrombosis were calculated in oral contraception users, in women with a history of superficial thrombophlebitis and in women with both oral contraception use and a history of superficial thrombophlebitis, compared with women with neither of these risk factors. The outcomes deep vein thrombosis, pulmonary embolism and deep vein thrombosis with concomitant pulmonary embolism were combined in the overall analyses but also considered separately. Risk estimates were adjusted for age, body mass index, smoking and family history of venous thrombosis. The study was approved by the Medical Ethics Committee of the Leiden University Medical Center and all participants provided written informed consent. Funding: Netherlands Heart Foundation (grant NHS 98.113), the Netherlands Organisation for Scientific Research (grant 912-03-033|2003), Dutch Cancer Foundation (grant RUL 99/1992).

Results: The ORs for venous thrombosis were 6.3 (95% CI, 5.2–7.6) for women using oral contraception and 6.6 (95% CI, 3.4–12.8) for women with a history of superficial thrombophlebitis compared with women with neither of these risk factors. When both factors were present together the OR increased to 51.5 (95% CI, 20.5–129.3). Oral contraception users with a history of superficial thrombophlebitis had a particularly high risk of deep vein thrombosis: OR 86.9 (95% CI, 23.5–321.0) with concurrent pulmonary embolism and OR 71.6 (95% CI, 27.6–185.5) without concurrent pulmonary embolism. The risk of pulmonary embolism alone was also increased, but to a lesser extent: 30.1 (95% CI, 11.1–82.1). When the baseline incidence in this age group is set at 1 per 10,000/year, it follows that 250 women with a history of superficial thrombophlebitis should refrain from oral contraceptive use to prevent one venous thrombotic event per year of non-use.

Summary/Conclusion: In our study we found a markedly increased risk of venous thrombosis, especially deep vein thrombosis, in oral contraception users with a history of superficial thrombophlebitis. Our findings suggest that oral contraceptive use in women with a history of superficial thrombophlebitis may be ill-advised.

AS 05.2
Progestin-only contraception after venous thromboembolism: cohort study

Le Moigne E[1], Roudaut-Le Gall M-L[1], Delluc A[1], Nowak E[2], Mottier D[2] and Le Gal G[2]

[1]Brest University Hospital; [2]Clinical Investigations Center, Brest, France

Background: Contraception is a main problem in women at risk for venous thromboembolism (VTE). Combined oral contraception is contra-indicated in women with a personal history of VTE. Progestin-only contraception may be a good option, but there is little data about risk of recurrent thrombosis, efficacy and side effects associated with progestin-only use in these women.

Aims: We aimed to determine the risk of recurrence of VTE in young women exposed to progestin-only contraception after a first VTE.

Methods: We studied the risk of recurrent VTE during progestin-only contraception in a cohort of young women under 50 years with first proved VTE, admitted from 1992 to 2011 in BrestuniversityHospital. Follow-up information was collected annually about medical events

and thrombosis risk factors, including pregnancy and contraception use. Progestin-contraception users were asked about efficacy and side effects of the treatment. We compared the incidence of recurrent VTE (after stopping anticoagulants) during periods of exposition to progestin-only contraception, combined contraception, pregnancy and no hormones.

Results: Of the 338 women under 50 years with a first VTE, 122 used progestin-only contraception during follow-up. Mean duration of follow-up was 7.5 years, total duration of progestin-use was 476 women-years. We observed six recurrent VTE, two in progestin users, one in combined contraception users, three during post-partum. The incidence for recurrent VTE was 9.8/1000 women-year, and 4.8/1000 women-years during progestin contraception. The incidence of unplanned pregnancies was 0.63/1000 women-year. Bleeding and amenorrhea were frequent. Anyway, 64% of women used progestin-only contraception at least 3 years and 74% of women tolerated it as well as previous combined contraception.

Conclusion: Risk of recurrent VTE after a first event during prolonged use of progestin-only contraception is low. These results are close to the results of another study in women at risk using chlormadinone acetate contraception. Side effects were frequent but did not affect long-term use of progestin-only contraception.

AS 05.03

Heparanase procoagulant activity is elevated in women using oral contraceptives

Nadir Y[1], Moshe M[2], Axelman E[1], Brenner B[1] and Nadir Y[1]

[1]Rambam Health Care Campus; [2]Faculty of Medicine, The Bruce Rappaport Faculty of Medicine, Technion, Haifa, Israel

Background: Estrogen therapy, known to increase the risk of thrombosis, was previously found to up-regulate heparanase expression. Heparanase, known to be involved in angiogenesis and metastasis, was shown to form a complex with tissue factor (TF) and to enhance the generation of factor Xa (Nadir et al., Haematologica, 2010).

Aims: In the present study the effect of estrogen on heparanase procogulant activity was studied.

Methods: Estrogen receptor – positive (MCF-7) and negative (MDA-231) cell lines were incubated with estrogen, tamoxifen and ICI – a pure estrogen receptor antagonist. The cells medium was evaluated for TF/heparanase complex activity, TF activity and heparanase procoagulant activity by chromogenic substrate. Plasma samples of 34 healthy women taking oral contraceptives (OC) and 41 control women not on hormonal therapy were investigated. TF/heparanase activity, TF activity, heparanase procoagulant activity and factor Xa levels were studied using chromogenic substrate. Heparanase and thrombin-antithrombin (TAT) levels were analyzed by ELISA.

Results: Estrogen and tamoxifen increased heparanase procoagulant activity in the medium of estrogen receptor positive (MCF-7) cells. TF/heparanase activity, TF activity, heparanase procoagulant activity and factor Xa were significantly higher in the OC group compared to the control group. The most dramatic difference was observed in heparanase procoagulant activity, reaching a 3.3-fold increase ($P < 0.0001$). Levels of heparanase and TAT measured by ELISA did not statistically differ among the study groups.

Conclusions: Estrogen increases heparanase procoagulant activity. The findings of the present study suggest a new potential mechanism of hypercoagulability in OC users.

AS 06 – Post-Thrombotic Syndrome

AS 06

Post-thrombotic syndrome: evidence-based update on prevention and treatment

Kahn S

Jewish General Hospital, Montreal, QC, Canada

This presentation will review the prevention and treatment of late sequelae of venous thrombosis such as the post-thrombotic syndrome. Post-thrombotic syndrome (PTS) is the most frequent complication of deep-vein thrombosis (DVT). After a proximal DVT, 20–50% of patients will develop PTS and 5–10% of patients will develop severe PTS, which reduces quality of life and has important socio-economic consequences. A number of risk factors for PTS have been identified; of these, proximal location of DVT and a previous ipsilateral DVT are the most consistently predictive. PTS is diagnosed on clinical grounds, based on the presence of signs and symptoms of venous insufficiency in the leg ipsilateral to DVT. Therapeutic options for PTS are limited and mainly rely on (i) prevention of DVT with use of thromboprophylaxis in high risk surgical and medical patients; (ii) prevention of PTS with compression stockings (new data from the SOX Trial will be presented) and, possibly, in select cases, catheter-directed thrombolysis of iliofemoral DVT if bleeding risk is low; (iii) prevention of DVT recurrence with the use of optimal and/or prolonged duration of anticoagulation; (iv) treatment of moderate to severe PTS with various compressive devices. Areas for future research in this important aspect of venous thrombosis will be highlighted.

AS 06.1

The good, the bad, and the ugly: post-thrombotic syndrome in children with upper extremity deep vein thrombosis

Avila M[1], Duan L[2], Williams S[1] and Brandao LR[1]

[1]The Hospital for Sick Children; [2]University of Toronto, Toronto, ON, Canada

Background: Thirty to 50% of pediatric deep vein thrombosis (DVT) involves the upper extremity (UE), reflecting the role of central venous lines (CVL) as its major risk factor. Children with UE-DVT can develop post-thrombotic syndrome (PTS), a chronic and potentially devastating complication. Despite its relatively estimated high frequency, the characterization of pediatric UE-PTS is still lacking.

Aims and Methods: We wished to investigate the occurrence, characteristics, and predictors of UE-PTS in a cohort of children with objectively confirmed UE-DVT followed-up at Sickkids, Toronto, between Apr/1996 and Jun/2011. PTS was determined by the Modified Villalta Scale. Patients were analyzed in three groups according to whether DVT was unprovoked (G1) or provoked (neonates [G2A] vs. non-neonates [G2B]). This study was approved by the ethics review board. Informed consent was waived. Descriptive statistics, univariable and multivariable logistic regression model were applied.

Results: One hundred and sixty-five children (G1 $n = 23$; G2A $n = 32$; G2B $n = 110$) with a median age (interquartile range [IQR]) of G1: 16.1y (14.9–16.9 years); G2A: 17 days (9.5–23 days); G2B: 1.8 years (87 days–10.1 years), $P < 0.001$, were included. Overall, the M/F ratio was 1.5/1.0, with a similar sex distribution among groups ($P = 0.1$). The most common identified risk factors were: G1 (effort-related [82%], idiopathic [18%]); G2A (CVL [100%]); G2B (CVL [95%]; mass effect [5%]). PTS was identified in G1: 92% (mild: 72%, moderate: 28%); G2A 21% (mild: 100%), and G2B 41% (mild: 95%, moderate: 5%) of patients with at least two subsequent measurements > 180 days after DVT, $P < 0.001$.

The last clinic follow-up occurred at a median of 3.25 years (IQR 1.8–5.8 years). The mean PTS-score was assessed at different time-points

(6–18, 19–36, 37–54, and 55–72 months); distribution was: G1: 2.0/2.0/2.5/no f/u; G2A: 0.5/0.0/0.5/0.0; G2B 1.0/1.0/1.0/1.0. The highest scores per group were G1: 4–5 (n = 7/23), G2A: 1–2 (n = 6/32), and G2B: 4–7 (n = 4/110). The most common findings were increased limb circumference and pain (G1) and collaterals and increased limb circumference (G2A/G2B).

Treatment included: G1, heparin/LMWH 65%, lysis 35%; G2A, 97% heparin/LMWH; G2B, 87% heparin/LMWH, 10% not treated, 3% lysis.

We constructed a model to predict the occurrence of ≥ 2.0 points PTS score in 109 patients with at least one clinical follow-up, at least 180 days after DVT diagnosis. Potential predictors considered in univariable analysis were: treatment modality/length, delay in starting therapy, sex, group (G1/G2A/G2B), resolution status, number of segments affected, subclavian involvement, and DVT-recurrence. The final model included resolution status and group: the odds ratio (OR) for the outcome was 7.8 (95% CI 1.9–32.4, P = 0.005) when comparing DVT extension vs. complete resolution; 1.7 (95% CI 0.5–5.5, P = 0.34) for partial vs. complete resolution; and 3.3 (95% CI 0.6–17.3, P = 0.15) for no vs. complete resolution. OR for the outcome was 47.6 (95% CI 4.8–472.8; P = 0.001) in G1 vs. G2A, and 8.4 (95% CI 2.7–26.1; P = 0.002) for G1 vs. G2B.

Conclusion: Pediatric UE-PTS frequency and severity likely depends on UEDVT nature (primary vs. secondary) and on patient's age. Line-related UE-PTS likely has a more benign course, particularly in neonates. Risk stratification seems warranted for tailored treatment of pediatric UE-DVT.

AS 06.2

Post-thrombotic syndrome after central venous catheter removal in childhood cancer survivors is associated with decreased quality of life

Polen Mallard E[1], Weintraub M[1], Stoffer CRN[1], Jaffe DH[2], Burger A[2] and Revel-Vilk S[1]

[1]Hadassah Hebrew-University Hospital; [2]Hebrew University – Hadassah Medical School, Jerusalem, Israel

Background: Although the use of central venous catheters (CVCs) has greatly improved the quality of care of children with cancer, these catheters may cause deep vein thrombosis (DVT). The potential long-term complication of CVC-related DVT (symptomatic and asymptomatic) is the development of the post thrombotic syndrome (PTS). A consensus paper from the Pediatric/Neonatal Hemostasis and Thrombosis Subcommittee of the ISTH recommends that upper venous system PTS assessment should include physical, functional and quality of life (QoL) domains.

Aim: To study PTS post-CVC removal using these three domains in childhood cancer and bone marrow transplantation (BMT) survivors.

Methods: We conducted a prospective study in a consecutive cohort of childhood cancer and BMT survivors with a history of CVC use. All participants were evaluated for PTS during their follow-up visit at the After-cancer Clinic at Hadassah Medical Center. The two available pediatric PTS assessment tools, the Modified Villalta Score (MVS) and the Manco-Johnson Instrument (MJI), were used. Patient and CVC related data, as well as health related quality of life (QoL) (using the PedsQL™ questionnaire) were assessed and associated with occurrence of PTS.

Results: A total of 158 children were enrolled at a median of 41 (4–149) months from CVC removal. Mean ± standard deviation (SD) of age at enrollment was 12.30 ± 5.8 years. Signs and symptoms ipsilateral to the side of CVC (or CVC-related DVT) were considered in determining PTS. PTS was present in 34% (95% confidence interval [CI] 27–43%) of the study population with the MVS criteria and 28% (95% CI 21–35%) with the MJI criteria. Pain was the most common symptom reported in the PTS assessment, which occurred in 13.2% of participants. Higher rates of PTS were found among children with a history of CVC occlusion. In a univariate logistic regression model, the odds ratio (OR) for PTS in children with a history of CVC occlusion was 2.2 (95% CI 1.1–4.4) using the MVS and 2.6 (95% CI 1.2–5.5) using the MJI. PTS was not associated with age at diagnosis, time from CVC removal or history of infection. Higher rates of PTS were found among children with a history of DVT, although the sample size was small (six of the eight participants with a history of DVT). Interestingly, patients who had signs and symptoms of PTS ipsilateral and/or contralateral to the CVC had lower average PedsQL scores compared to those without signs and symptoms of PTS. The mean difference for PedsQL score was 5.64 using the MVS (P = 0.029) and 6.26 using the MJI (P = 0.018). The physical-function domain of the PedsQL score showed similar discrepancies between those with and without PTS.

Conclusion: PTS post-CVC removal, associated with pain in over 10% of cases, is not a rare event. The association between PTS and the history of CVC occlusion confirms earlier findings, and suggests that CVC occlusion may indicate asymptomatic DVT. The lower QoL scores among children with signs and symptoms of PTS indicate the detrimental effects of PTS post-CVC removal and suggest the need to study preventative measures.

AS 06.3

Risk factors for severe post-thrombotic syndrome: VTE Epidemiology Group (VEG) Study

Cohen AT[1], Martinez C[2] and Katholing A[2]

[1]King's College Hospital, London, UK; [2]Pharmaepi.com, Frankfurt, Germany

Background: Severe post-thrombotic syndrome (PTS) with venous ulceration results in significant morbidity and cost. PTS occurs following DVT and PE and the recognition of risk factors may help to evaluate and guide therapy type and duration. To simplify decision making these factors for PTS must be assessed allowing for the presence, quality and absence of anticoagulant therapy.

Aim: To explore potential risk factors for PTS.

Methods: Patient data were retrieved from the subset of general practices in England contributing to the Clinical Practice Research Database (CPRD) that has been linked to data from the Hospital Episodes Statistics (HES) and to the Office for National Statistics (ONS). From January 2001 to October 2011, all VTE cases in the CPRD were verified with an algorithm based on review of medical records and notes, hospital diagnoses, cause of death and anticoagulation therapy. We conducted a nested case-control study in patients with a first VTE. Incident events of venous ulcer associated PTS, defined as severe PTS, during the entire observational period were defined as cases and the date of severe PTS as the index day. For each case we selected five patients free of PTS at random by matching on the index day and with the same duration of observation as the respective case. The independent association between a potential risk factor and severe PTS was derived from conditional multivariate logistic regression models and presented as adjusted odds ratio (OR) with 95% confidence intervals (CIs). Adjustment included age, gender, socioeconomic risk factors, components of the Charlson index, and the type of antithrombotic therapy (VKA, low molecular weight heparin or antiplatelet therapy).

Results: Of 35,373 patients with first VTE 29,550 patients survived more than 7 days and had 81,906 person-years of observation were at risk of PTS. Over the observational period and after at least 90 days following first VTE 486 cases of severe (venous ulcer associated) PTS were identified.

The hazard of VTE recurrence was greater in the following risk factors: the elderly, increasing each decade from the 50s' maximal for those aged 90+, OR 5.27 (2.55–10.88), males OR 1.25 (1.00–1.58), following DVT compared with PE, OR 1.80 (1.38–2.35), following recurrent DVT, OR 1.94 (1.37–2.74), following recurrent PE, OR 2.26 (1.42–3.59); in unprovoked cases OR 1.41 (1.12–1.78); current smokers

OR 1.60 (1.18–2.17); and in those with varicose veins, OR 4.98 (3.10–8.01); no relation was seen with time in therapeutic range (TTR).
Summary/Conclusions: The recognition of risk factors for PTS should facilitate its prevention or early detection and the decision for appropriate therapy including the extension of anticoagulant therapy.

AS 07 – Upcoming Anticoagulants

Rational design of future low molecular weight anticoagulant medications: can we get assistance from novel computational drug discovery methods?

Villoutreix B

Inserm – Université Paris Diderot, Paris, France

Drug discovery is a remarkably complicated process that requires different skills and appropriate technologies. Several steps are needed with most often the need to identify a potential therapeutic target or a novel molecular mechanism involved in the disease state. In the next step, a small chemical compound that modifies the function of this selected target has to be found. This small molecule can be used to further validate the target or as a starting point for hit to lead and lead optimization. Indeed, hit molecules have to be optimized in term of potency, selectivity while paying attention to ADMET properties since ultimately the compounds will be given to human. One would also like to know if the bioactive small molecules acting on the selected therapeutic target could also bind to off-targets and potentially induce toxicity. Several cutting edge in silico approaches and databases have been developed to assist the drug discovery process. We will go through several of these methods and examples of applications will be commented upon with a special emphasis on blood coagulation proteins.

AS 07.1
EP217609, a neutralizable synthetic dual-action FIIa/FXa anticoagulant, has a superior antithrombotic effect compared to its parent compounds in murine models of arterial thrombosis

Alame G[1], Mangin PH[1], Freund M[1], Petitou M[2], Hechler B[1] and Gachet C[1]

[1]UMR_S949, Inserm, Université de Strasbourg, EFS-Alsace, Strasbourg; [2]Endotis Pharma, Romainville, France

Background: EP217609 is a synthetic dual-action anticoagulant combining a direct thrombin inhibitor (α-NAPAP), an indirect factor Xa inhibitor (fondaparinux) and a biotin moiety. It has been reported that this molecule exhibits an unprecedented pharmacologic profile with high bioavailability, long plasma half-life, and potent anticoagulant activity (Olson et al., Blood 2012). Moreover, EP217609 is potentially rapidly neutralized by an avidin injection.
Aims: The aim of the study was to evaluate the antithrombotic potential of EP217609 compared to its parent compounds in two models of localized arterial thrombosis.
Methods: The anticoagulant properties of EP217609 were determined *in vitro* and *ex vivo* in mice by: i) measuring the activated partial thromboplastin time (APTT) and the thrombin clotting time; ii) measuring anti-factor IIa and anti-factor Xa activities. The effect of EP217609 in thrombosis was assessed in two mouse models of arterial thrombosis: a $FeCl_3$-injury of the carotid artery of WT mice or a mechanical injury of carotid arteries bearing atherosclerotic plaques in ApoE-deficient mice. Its impact on haemostasis was determined in a tail-bleeding assay.
Results: *In vitro*, EP217609 exhibited anticoagulant properties similar to its parent compounds. *In vivo*, it reached a 2.0 mM concentration in the plasma, 1.2 h after administration to mice, and presented an elimination half-life of 3.4 h. We determined low and moderate doses of EP217609 exhibiting similar *ex vivo* prolongation of the APTT than a-NAPAP and comparable *ex vivo* anti-FXa activity than fondaparinux, respectively. The effect of EP217609 was then evaluated *in vivo*, in comparison with the effect of the parent compounds used alone or in combination. At doses which hardly affected the APTT (1.09 times increase), EP217609 significantly reduced the thrombus area in both models as compared to a-NAPAP and fondaparinux used alone, but not when they are combined. In contrast, at doses increasing the APTT by 1.5 times, EP217609 did not present superiority as compared to either parent compound used alone or in combination. Interestingly, low doses of EP217609 did not prolong the tail-bleeding time nor the volume of blood lost. Finally, the effect of EP217609 could be neutralized *in vivo* after avidin injection in the $FeCl_3$-injury model.
Conclusion: The antithrombotic profile of EP217609, combined with its possible neutralization, makes it an interesting molecule and a potential drug candidate for indications which remain to be characterized.

AS 07.2
Identification of novel antagonists of protein disulfide isomerase for inhibition of thrombus formation

Flaumenhaft R[1], Khodier C[2], Galinski CN[3], Nag P[2], Passam FH[1], Scalise A[3], Van Hessem L[1], Gunnink S[1], Dandapani S[2], Munoz B[2] and Kennedy DR[3]

[1]BIDMC/Harvard Medical School, Boston; [2]Broad Institute, Cambridge; [3]Western New England College of Pharmacy, Springfield, MA, USA

Background: Protein disulfide isomerase (PDI) is a widely expressed oxidoreductase that is highly concentrated in endoplasmic reticulum and is required for protein folding. However, it can also be released from cells into the extracellular environment, where it catalyzes the rearrangement of intramolecular disulfide bonds in receptors and secreted proteins. Several animal models demonstrate that PDI released from platelets and endothelial cells is required for thrombus formation *in vivo*. Recently, we identified the flavonoid rutin as an inhibitor of PDI. Rutin inhibited both platelet accumulation and fibrin generation during thrombus formation in mouse models at concentrations commonly ingested as nutritional supplements, providing proof-of-principle for PDI inhibitors as a new class of antithrombotics (*J. Clin. Invest.*, 122:2104). Although quercetin flavonoids may be useful as a first generation of PDI inhibitors, they are only modestly potent for PDI (IC_{50} 6 μM), poorly absorbed, and have activities other than PDI inhibition.
Aims: Our goal was to identify potent and selective inhibitors of PDI as novel antithrombotics.
Methods: A high throughput screen of PDI activity was developed based on the ability of the enzyme to reduce the insulin β-chain, resulting in insulin aggregation. This insulin turbidimetric assay was converted to a 1536-well format and an industrial scale screen of approximately 350,000 compounds of the Molecular Libraries Small Molecule Repository was performed.
Results: The primary screen identified 443 putative PDI inhibitors, which were subsequently tested in 8-point dose curves. Forty-one compounds were identified with IC_{50}s < 10 μM. Two compounds, a piperdine (IC_{50} 0.3–0.6 μM) and a bromo indole (IC_{50} 0.6–0.8 μM), were selected for further analysis. To assess the selectively of these compounds, their activity in other bioassays performed within the NIH Molecular Libraries Probe Production Network was evaluated. The piperdine showed no confirmed activity at < 10 μM in any of the other of 380 biological assays in which it has been tested. The bromo indole had confirmed activity at < 10 μM in only two other assays out of 473 in which it had been tested. Within the thiol isomerase family, both compounds demonstrated selectivity for PDI, failing to inhibit either

ERp5, ERp57, or thioredoxin. The piperdine was soluble at 65 μM in aqueous solution and demonstrated 97% stability in GSH at 48 h, indicating that the compound did not inhibit PDI by interacting with the CxxC catalytic domain. The bromo indole was soluble at 81 μM and demonstrated 99% stability to GSH. Consistent with this observation, inhibition of PDI by the piperdine and the bromo indole was entirely reversible. Neither compound demonstrated toxicity in a HeLa cell assay at 20-fold their IC_{50}s. Organic synthesis of 31 analogs of the piperdine lead was performed and structure activity relationships determined. In preliminary *in vivo* studies, the piperdine inhibited platelet accumulation in cremaster arterioles following laser injury.
Conclusions: The compounds identified in this screen will serve as leads for the development of a second generation of PDI inhibitors as a new class of antithrombotics with improved potency and specificity compared with quercetin flavonoids.

AS 07.3

Cardioprotective effects of EWE thrombin, a selective protein C activator, in a mouse model of acute focal myocardial ischemia and reperfusion

Verbout NG[1], Cao Z[2], Liu L[2], McCarty OJT[3], Tucker EI[1], Di Cera E[4], Griffin JH[5], Van Winkle D[2] and Gruber A[1]
[1]Aronora; [2]Oregon Health & Science University and Veterans Affairs Medical Center; [3]Oregon Health & Science University, Portland, OR, USA; [4]Saint Louis University, St. Louis, MO; [5]The Scripps Research Institute, La Jolla, CA, USA

Background: Acute myocardial ischemia resulting from progressive thrombotic coronary artery occlusion is typically not treated with recanalization therapies before the patient arrives to the hospital due to bleeding concerns with current anticoagulant and thrombolytic therapies. A hemostatically safer antithrombotic treatment could improve survival by decreasing the 'time to needle' period.
Aims: EWE thrombin (EWE) is an *E. coli*-derived recombinant protein C-activating thrombin analog (W215A/E217A) that is potently antithrombotic without inducing hemostasis impairment or procoagulant side effects in primates. EWE treatment also reduces neurological deficits without bleeding side effects in an experimental mouse model of ischemic stroke. Here, we tested the hypothesis that EWE reduces infarct size following experimental myocardial ischemia-reperfusion in mice.
Methods: C57BL6 mice were used for all studies. To evaluate the effect of EWE on ischemic injury, the left coronary artery was ligated for 40 min, and EWE (25 μg/kg; iv) or vehicle infused during the last 15 min of occlusion. Mice were sacrificed at 2 h post reperfusion and the infarcted myocardium volumes of EWE- and vehicle-treated mice were determined. Vascular reflow was evaluated in a separate cohort, immediately following ischemia. Fluorescent microspheres were injected into the ventricular apex and 3 min later hearts were removed and sectioned. The fluorescence intensity in each section was quantified to examine EWE effects on reperfusion. To evaluate the direct cardioprotective potential of EWE, we used an ex vivo model of oxygen/glucose deprivation (OGD) and reoxygenation/glucose repletion (RGR). Adult cardiomyocytes were pre-incubated in serum-free media with EWE (0.1–10 μg/mL) or vehicle and subjected to 90 min OGD, followed by 3 h RGR and determination of cell viability with trypan blue exclusion.
Results: EWE increased vascular reflow by 23% compared to vehicle, measured immediately after ischemia. Likewise, treatment with EWE reduced myocardial infarct volume by 33%, measured 2 h post-reperfusion. *In vitro*, EWE improved cardiomyocyte viability from 45% to 73% in a concentration-dependent manner. Cardioprotection was dependent on the enzymatic activity of EWE, since an enzymatically inactive analog (S195A-EWE) produced a result similar to vehicle treatment. Pretreatment with a PAR-1 inhibitor abolished EWE mediated cardioprotection, suggesting cytoprotection was dependent on PAR-1 signaling. EWE-mediated cardioprotection *in vitro* was inhibited by 36% by anti-protein C antibodies (10 μg/mL) and by > 90% by anti-PAR-1 antibodies (20 μg/mL).
Summary/Conclusion: Altogether, treatment with EWE, a selective protein C activator, during ischemia reduced myocardial damage and improved reperfusion *in vivo*, and also preserved cardiomyocyte viability ex vivo. We conclude that treatment with EWE before recanalization therapy may confer outcome benefit in temporal myocardial ischemia.

AS 08 – Antiphospholipid Syndrome

AS 08.1

Conformation of beta2glycoprotein I and its effect on coagulation

Ninivaggi M, Kelchtermans H, Lindhout T and De Laat B
CARIM, Maastricht University, Maastricht, the Netherlands

Background: Contradictory, the antiphospholipid syndrome (APS) is characterized by the presence of vascular thrombosis, but diagnosed by a phospholipid-dependent delay of the coagulation *in vitro*. β2glycoprotein I (β2GPI) is the major antigen in APS. In blood, b2GPI is present in a native conformation (either circular or S-shaped). After interaction with anionic surfaces it opens up (J-shaped conformation), resulting in the exposure of a cryptic epitope in domain I of β2GPI. Importantly, predominantly antibodies reactive to this cryptic epitope in domain I of β_2GPI are associated with thrombosis in APS. In literature anticoagulant properties of β2GPI have been indicated, although no consensus exists about the underlying mechanisms.
Aim: We investigated whether the conformation of β2GPI plays a role in the proposed anticoagulant activity of β2GPI.
Methods: To unravel the role of the conformation of β2GPI in its effect on the thrombin generation (TG), we used the previously described Calibrated Automated Thrombogram (CAT) assay. To study the effect of β2GPI in its open conformation, β2GPI was pre-incubated with 48 μM phospholipids for 15 min before being tested in the TG assay. Two patient-derived monoclonal antibodies P2-6 and P1-117 were tested for their effect in our system. Antibody P1-117 was previously shown to specifically react with the cryptic epitope G40-R43, exposed only in the open conformation of β2GPI, while antibody P2-6 recognizes β_2GPI irrespective of its conformation.
Results: Native β2GPI was found to have no significant effect on the TG regardless of the concentration of tissue factor (TF). On the contrary, β2GPI pre-incubated with phospholipids significantly and dose-dependently inhibited TG when triggered with low TF concentration, suggesting an effect on the intrinsic pathway of the coagulation cascade. As to the effect of the incubation period, increasing incubation times resulted in a further decrease in peak height and increase in lag time. Interestingly, the inhibitory effect of phospholipid-bound β2GPI was completely abolished by adding antibody P1-117, but not P2-6. These data illustrate that thrombosis-related antibodies reactive against epitope G40-R43 in domain I abrogate the observed anti-coagulant effect of phospholipid-bound β2GPI.
Conclusions: We have demonstrated that native β2GPI in circulation obtains its anticoagulant activity in the presence of anionic phospholipids such as activated blood cells, thereby serving as an inhibitory modulator in hemostasis. That only the open conformation of b2GPI exerts this anticoagulant effect, suggests a role for domain I. Indeed, using monoclonal antibodies we have established abrogation of the anticoagulant activity of b2GPI only by antibodies specific for the cryptic epitope on domain I. Our results may therefore provide an explanation for the prothrombotic phenotype in APS patients.

AS 08.2

Human anti-beta2-glycoprotein I autoantibodies bind to platelets but not to endothelium in a mouse model of anti-phospholipid syndrome

Proulle V[1], Furie B[1], Furie R[2] and Furie B[1]

[1]Beth Israel Deaconess Medical Center, Boston MA; [2]North Shore-Long Island Jewish Health System, Great Neck, NY, USA

Background: Antiphospholipid syndrome (APS) is defined by thrombosis, obstetrical complications, and the presence of the lupus anticoagulant, anticardiolipin antibodies, or anti-β2-glycoprotein-I (anti-β2GPI) antibodies. Anti-β2GPI antibodies have been documented as a biomarker for diagnosis of APS, and we have shown their direct role in the pathogenesis of thrombosis *in vivo* using a mouse model of arterial laser-induced injury. *In vitro*, these antibodies in complex with β2GPI have been shown to bind and activate endothelial cells and platelets.

Aims: We asked whether we could determine the cellular target of anti-β2GPI autoantibodies and plasma β2GPI *in vivo* using our thrombosis model in a live mouse and anti-β2GPI autoantibodies affinity-purified from humans with APS.

Methods: Anti-β2GPI antibodies were prepared from the serum of a patient with APS by affinity purification. $F(ab')_2$ fragments of anti-β2GPI autoantibodies, labeled with Alexa 488, and human β2GPI, labeled with Alexa 647, were infused both separately and together into wild type mice. Platelet labeling was performed using anti-CD42 antibody conjugated to Dylight 488 or Dylight 647. Cell binding of labeled β2GPI and anti-β2GPI autoantibodies at the site of injury was imaged after arterial laser-induced injury using intravital microscopy in wild type mice. In some experiments, eptifibatide, an inhibitor of platelet accumulation at the site of injury, was infused into the mouse. Endothelium activation was studied using calcium mobilization after infusion of Fluo-4 AM into the mouse circulation in the presence of eptifibatide.

Results: Alexa 488-conjugated anti-β2GPI $F(ab')_2$ autoantibodies bound specifically to the developing platelet thrombus, which were imaged using anti-CD42 conjugated to Dylight 647. In the presence of $F(ab')_2$ fragments of anti-β2GPI autoantibodies injected simultaneously, we found that Alexa 647-conjugated β2GPI bound specifically to the developing platelet thrombus, which were imaged using anti-CD42 conjugated to Dylight 488. Finally, Alexa 488-conjugated $F(ab')_2$ fragments of anti-β2GPI autoantibodies and Alexa 647-conjugated β2GPI infused simultaneously into the live mouse bound with similar kinetics to the developing thrombus. Experiments examining the binding of Alexa 488-conjugated irrelevant control $F(ab')_2$ IgG or Alexa 647-conjugated albumin showed only non-specific interaction. When platelet accumulation at the site of injury was inhibited by the infusion of eptifibatide prior to infusion of the anti-β2GPI $F(ab')_2$ autoantibodies conjugated to Alexa 488 and β2GPI conjugated to Alexa 647, no significant binding of either anti-β2GPI $F(ab')_2$ autoantibodies or β2GPI was observed. These results indicate that anti-β2GPI $F(ab')_2$ autoantibodies and β2GPI bind to platelets but not significantly to endothelial cells. Moreover, at the site of injury, there was no increase in endothelial cell activation after injection of anti-β2GPI autoantibodies when studied by monitoring calcium mobilization within the endothelium.

Conclusion: We have shown that, *in vivo*, the anti-β2GPI antibody-induced enhancement of thrombus formation is associated with platelet binding of both anti-β2GPI autoantibodies and β2GPI, presumably the anti-β2GPI/β2GPI complex. Using the human anti-β2GPI autoantibodies studied, neither endothelial cell binding nor enhanced endothelial cell activation is observed during thrombus development in this model of APS.

AS 08.3

Fibrin clot properties in patients with antiphospholipid syndrome

Celinska-Löwenhoff M, Iwaniec T, Padjas A, Musial J and Undas A

Jagiellonian University Medical College, Kraków, Poland

Background: Antiphospholipid syndrome (APS) is an autoimmune disease that manifests as venous thromboembolism (VTE), arterial thrombosis and/or pregnancy complications in the presence of antiphospholipid antibodies (APLA). It has been suggested that patients with APS have impaired fibrinolysis. Data on fibrin clot properties in APS are scarce.

Aim: The aim of the study was to test the hypothesis that plasma fibrin clot structure/function is unfavorably altered in patients with APS after VTE and/or arterial thrombosis.

Methods: We investigated 118 patients with APS, including 88 subjects with primary APS, vs. 100 age- and sex-matched controls. Patients were analyzed in subgroups according to clinical presentation (VTE or arterial thrombosis; if both were present – first presentation was recorded). In the VTE subgroup we identified those who had deep vein thrombosis (DVT), pulmonary embolism (PE), or DVT combined with PE. We assessed lupus anticoagulant (LA), anticardiolipin antibodies (ACL) and anti-β2-glycoprotein I antibodies were measured by INOVA kits (USA). The fibrin clot structure was assessed by measurement of permeability (K_s) and turbidity (lag phase and maximum absorbency (Abs_{max}). The efficiency of clot lysis was evaluated by the assessment of clot lysis time (CLT) and maximum rate of increase of D-dimer levels released from fibrin clots along with its maximum concentrations in the effluent. Fibrinogen, tPA and PAI-1 antigens, high-sensitivity (hs)CRP, total homocysteine (tHcy) concentrations were measured.

Results: Of the 118 APS patients, eight subjects had previous myocardial infarction (MI), 26 – had stroke, 61 – symptomatic DVT without PE, 15 patients had PE alone, and 16 – DVT combined with PE. In 67 patients VTE was the first clinical presentation of APS. The patient group did not differ from the controls with regard to lipid profile, glucose, creatinine, hsCRP and tHcy. APS patients had higher fibrinogen, PAI-1 and tPA antigens than controls (all $P < 0.001$). Analysis of plasma fibrin clot variables showed that APS patients had 25.8% lower clot permeability ($P < 0.001$), 23% longer CLT ($P < 0.001$), 9.4% shorter lag phase ($P < 0.001$), 5.4% lower maximum rate of D-dimer release ($P < 0.001$) and 14.1% higher maximum D-dimer level ($P < 0.001$) than controls. Higher clot absorbance was observed in patients with positive ACL IgG ($P = 0.009$), those with negative LA ($P = 0.003$), and whose first clinical presentation was stroke or MI ($P = 0.023$). Patients who experienced PE showed higher K_s ($P = 0.027$), shorter CLT ($P = 0.008$), lower absorbance ($P = 0.006$) and higher D-dimer release rate ($P = 0.048$), regardless of the presence of concomitant DVT or not. The lowest clot permeability was observed in patients who experienced both VTE and arterial thrombosis ($P = 0.01$). Patients whose clinical presentation was only stroke or MI had longer CLT than the remainder ($P = 0.038$). Patients with SLE had less favorable fibrin clot properties with a significant difference only for D-Dimer rate ($P = 0.048$).

Conclusions: Our study demonstrates unfavorably altered plasma clot properties in APS patients, including reduced permeability and impaired fibrinolysis. There are differences in plasma fibrin clot phenotype depending on thrombotic manifestation of APS. Our findings indicate the abnormal clot characteristics represent a novel prothrombotic mechanism of thromboembolism in APS.

AS 09 – Flow and Von Willebrand Factor

AS 09
Activation of A1 domain adhesiveness in VWF by elongational force

Springer T and Kim J
Harvard Medical School, Boston, MA, USA

Multiple mechanisms may contribute to activation of VWF adhesiveness by elongational flow at sites of hemostasis, including enhancement of A1 domain exposure within VWF concatamers and conformational change within the A1 domain or its complex with GPIbα. A receptor and ligand in a single molecule (ReaLiSM) containing the A1 domain, a flexible linker, and GPIbα fused in a single polypeptide and suspended between beads using DNA handles was interrogated with a laser trap. Two pathways for unbinding representing flexed and extended states were previously reported, with the flexed, more stable state predominantly at forces above 10 pN. VWD type 2B mutations in the A1 domain selectively stabilize the extended, high affinity state whereas platelet-type VWD mutations in GPIbα stabilize both states. With ReaLiSM we can also measure the kinetics and force-dependence of receptor-ligand binding. Remarkably, we also see two on-rates for receptor-ligand binding, with the faster on-rate predominating above 10 pN and the slower on-rate predominating below 10 pN. VWD type 2B mutations in the A1 domain selectively increased the fast on-rate, whereas platelet-type mutations in GPIbα increased both on-rates. Our results support force-dependent conformational change as one of the mechanisms that activates VWF in hemostasis.

AS 09.1
Solution structure and dynamics of the major FVIII binding region on von Willebrand factor: implications for type 2N von Willebrand disease

Shiltagh N, Kirkpatrick J, Cabrita LD, Thalassinos K, Tuddenham GD and Hansen DF
University College London, London, UK

Background: The preservation of haemostatic integrity is secured by the activities of von Willebrand factor (VWF). Upon vascular damage, VWF acts as a molecular bridge facilitating the initial adhesion and aggregation of platelets to the site of vessel injury, and consequently thrombus formation ensues. Furthermore, VWF is the protective carrier of pro-coagulant factor VIII (FVIII) in plasma, thereby prolonging its half-life, and efficiently localising FVIII to the incipient platelet plug. Much of the function of VWF has been revealed, however, detailed insight into the molecular structure that enables VWF to orchestrate haemostatic processes, in particular FVIII stabilisation in plasma, is lacking.
Aims: Our principal aim is to determine an atomic-resolution structure of the D' region (TIL'E') of VWF, which is believed to form the primary FVIII binding site. The importance of elucidating the structure of the FVIII-binding region on VWF is two-fold. First, it would provide insights into the mechanism of FVIII docking onto VWF, and the minimal VWF unit required to stabilise FVIII *in vivo*. This would allow for the development of novel approaches to treat both haemophilia A and von Willebrand disease (VWD). Second, analysis of VWD patient mutations, against a background of both structural and functional perturbations, will provide the link between genetic pathology and clinical phenotype.
Methods: TIL'E', containing 16 cysteine residues, was uniformly $^{13}C/^{15}N$-labelled by expression in *Escherichia coli* and purified for structural and dynamic NMR studies. Native mass spectrometry, 1D NMR, and dot blot analyses with both FVIII and a conformational FVIII binding-blocking monoclonal antibody, confirmed that the recombinant TIL'E' fragment was monomeric, homogeneous and binds to FVIII.
Results: We present the high-resolution NMR solution structure of the major FVIII-binding region (D') on VWF, and report on the molecular dynamics and flexibility of its substructure. The complex disulphide-bonded D' region (99 aa) is composed of a two sub-domain architecture – TIL'E'. Domain TIL' lacks extensive secondary structure, wherein five disulphide bonds constitute the main stabilising force constraining the fold. In contrast, E', is a well-structured, all-β-sheet domain. We confirm the disulphide-bond topology of this region. The symbiosis between protein dynamics, structure and biological activity is clarified by nuclear spin relaxation data that reveal interesting motional trends in the D' region; most strikingly, that there is a readily distinguishable mobility differential between TIL' and E'. TIL' is dynamic on at least two time-scales measured by NMR relaxation experiments, and this region is coincident with the clustering of pathological mutations leading to decreased FVIII binding affinity (type 2N VWD). The most severe type 2N VWD mutations circumscribe a pocket of concentrated positive charge density, that is complementary to the negatively charged FVIII a3 domain which mediates high-affinity binding to VWF.
Conclusions: The structural and dynamic data we present strongly suggest that the conformational fluctuations and surface charge distribution of TIL' reveal the major interaction surface mediating the binding of FVIII to VWF.

AS 09.2
Enhanced binding of von Willebrand factor mutants to LRP1 may explain their reduced circulatory half-life

Wohner N[1], Casari C[1], Christophe OD[1], Denis CV[2] and Lenting PJ[1]
[1]Inserm; [2]Inserm U 770, Le Kremlin Bicetre, France

Background: Von Willebrand Disease (VWD) originates from mutations in the gene encoding von Willebrand factor (VWF), which may affect different steps in the life-cycle of the protein, such as biosynthesis/secretion, function and/or clearance. At present, more than 20 different mutations have been identified that are associated with an increased clearance of VWF, which could contribute to the reduced VWF antigen levels in these patients. The mechanisms that mediate the increased clearance of the mutants have remained unsolved. Recently, we have identified the lipoprotein-receptor LRP1 as a clearance receptor for VWF (Rastegarlari et al. Blood 2012 119:2126). Interestingly, VWF only interacts with LRP1 upon exposure to increased shear stress, thereby mimicking interactions between VWF and its platelet receptor glycoprotein Ibα.
Aim: We investigated how VWD-mutations affect the interaction between VWF and LRP1.
Methods and Results: Using a static immunosorbent assay, we first investigated the binding of wild-type (wt)-VWF or fragments thereof to LRP1 in the absence or presence of ristocetin. As expected, no binding of wt-VWF in the absence of ristocetin was observed, whereas in its presence wt-VWF bound dose-dependently to LRP1. This confirms that shear stress-like changes in VWF are needed to allow LRP1 binding. Surprisingly, a number of individual recombinant VWF domains especially the D'D3 fragment displayed binding to LRP1 in the absence of ristocetin. Since several of the VWF mutations that provoke increased clearance of the protein are located in the D'D3 region of VWF, we tested if such mutations modulate binding to LRP1. Simultaneously, given the parallel between the shear stress-regulated interactions of VWF with glycoprotein Ibα and LRP1, we examined how VWD-type 2B mutations affect LRP1 binding. *In vitro* binding experiments revealed that the VWD-type 2B mutants VWF-p.R1306Q and p.V1316M as well as the VWD-type 1 clearance mutant VWF-p.R1205H (the Vicenza variant) show enhanced binding to LRP1. In contrast to wt-VWF, all three mutants interact spontaneously with

LRP1 under static conditions in the absence of shear stress or ristocetin. *In vivo* clearance experiments confirmed that mutants VWF-p.R1205H and VWF-p.V1316M are cleared more rapidly than wt-VWF. However, preliminary analysis revealed that in the presence of the LRP1-inhibitor RAP, clearance of the mutants is delayed and their survival mimics that of wt-VWF in the presence of RAP.
Conclusions: Our data indicate that several VWD-mutations relieve the shear stress-requirement for the interaction with the clearance receptor LRP1. Enhanced binding to LRP1 may provide an explanation why these mutants are cleared more rapidly and are associated with reduced VWF antigen levels in VWD patients.

AS 09.3

Fluid shear dependent regulation of von Willebrand factor (VWF) binding to platelet GpIba: Mechanism revealed by MS analysis of cross-linked VWF

Neelamegham S, Madabhushi S, Dayananda K, Shang C and Jun Q
State University of New York at Buffalo, Buffalo, NY, USA

Background: The domain level organization within the largest glycoprotein in blood, von Willebrand Factor (VWF), regulates many of its functions under fluid shear conditions.
Aim: In order to identify the structural basis of such regulation, VWF was chemically crosslinked and tandem mass spectrometry (MS) was performed in order to identify specific peptides within the protein that lie in close spatial proximity. Findings emerging from such analysis were tested, with focus on the mechanism of fluid shear dependent enhancement of platelet binding to immobilized VWF.
Methods: Full-length dimeric VWF (ΔPro-VWF) reacted with the homobifunctional crosslinker bis(sulfosuccinimidyl)suberate (BS^3) was enzymatically digested and subjected to high-throughput tandem MS. A scoring strategy called XPA was developed to analyze experimental data and to identify crosslinked peptide-pairs that link more than one protein domain. Functional experiments were performed to test hypotheses emerging from such analysis.
Results: Six of the nine inter-domain VWF peptide-pairs identified by such analysis linked VWF-A1 to the VWF-D'D3 domain, including one A1-peptide that forms the VWF binding interface with the platelet receptor GpIbα. MS analysis thus suggests that the proximal location of VWF-D'D3 to -A1 may regulate VWF binding to platelet GpIbα. Functional data support this hypothesis: i. Deletion of the D'D3 domain resulted in a dimeric protein (ΔD'D3-VWF), which unlike ΔPro-VWF, bound GpIbα under static conditions even in the absence of ristocetin ii. In surface plasmon resonance studies, monomeric VWF D'D3-A1 bound immobilized GpIbα with a lower on-rate compared to VWF-A1 iii. ΔD'D3-VWF, but not ΔPro-VWF and multimeric plasma VWF (pVWF), supported platelet binding at low shear stress (1 dyn/cm^2). At higher shears (> 5 dyn/cm^2), platelet translocation velocity was ~50% lower for ΔD'D3-VWF. Abrupt reduction in shear from 10 to 1 dyn/cm^2 released platelets from ΔPro-VWF, but not ΔD'D3-VWF, bearing substrates. iv. A monoclonal antibody against the human VWF-D'D3 domain, DD3.1, reduced VWF-A1 mediated platelet aggregation by > 50%, and it also inhibited platelet thrombus formation in a parallel plate flow chamber assay.
Summary/Conclusion: The D'D3 domain of VWF attenuates the interaction between its A1 domain and the platelet receptor GpIbα. This diminished molecular recognition results in reduced platelet adhesion at low shear rates. At higher shears, platelet deformation enhances the number of A1-GpIbα interactions and this contributes to more robust cell adhesion.

AS 10 – Coagulation and Inflammation

AS 10.1

TLR3 activation is involved in venous thrombosis development

Lemarie CA, Laurance S, Le AN and Blostein MD
Lady Davis Institute, Montreal, QC, Canada

Background: Venous thromboembolism (VTE) afflicts 117 people per 100,000 each year and is an important cause of morbidity and mortality. A number of recent reports indicate that platelets and leukocytes may sense 'pathologic ligands' accumulating in the circulation via a specific set of receptors and translate an activation signal into a prothrombotic state. These receptors may include toll-like receptors (TLR), which recognize self-molecules generated during tissue damage and inflammation in the presence or absence of infection. Endogenous RNA, released from cells under pathological conditions, has been identified as a potent pro-coagulant factor by activating factor XII of the coagulation cascade in arterial thrombosis. TLR3 senses dsRNA and has been increasingly linked to tissue damage. Endogenous RNA might induce TLR3 expression and signaling. Thus, we hypothesize that endogenous RNA might be involved in the inflammatory development of venous thrombosis after vessel injury.
Aims: The objective of the present study is to evaluate the role of endogenous RNA and TLR3 in venous thrombosis.
Methods: First, wild type (WT) mice received an intravenous injection of RNase or vehicle prior to thrombus induction with 5% $FeCl_3$. In separate experiments, WT and TLR3 deficient (−/−) mice received an intravenous injection of polyinosine polycytidylic acid, a synthetic double-stranded RNA (dsRNA) analog, or vehicle and thrombosis was also induced by 5% $FeCl_3$.
The venous wall with thrombi were removed and samples were prepared for hematoxylin and eosin and immunofluorescent staining. Human umbilical vein endothelial cells (HUVECs) or endothelial cells prepared from WT or $TLR3^{-/-}$ mice lungs were incubated with dsRNA and cytokine mRNA expression were analyzed by real time PCR.
Results: RNase treatment significantly reduced thrombus size compared with vehicle injected WT mice ($P < 0.05$). Synthetic dsRNA increases the size of thrombi after $FeCl_3$-induced inferior vena cava injury (IVC) compared to mice treated with vehicle ($P < 0.05$). In $TLR3^{-/-}$ mice, dsRNA did not induce a further increase in thrombus size compared to vehicle control. dsRNA injection was associated with an increase of neutrophil and monocytes infiltration in the thrombus in WT but not in $TLR3^{-/-}$ mice ($P < 0.05$). Leukocyte infiltration was decreased by RNase treatment ($P < 0.05$). We found that dsRNA injection was associated with increased neutrophil extracellular traps (NETs) formation. In the thrombus of WT mice, immunofluorescence staining for myeloperoxidase, neutrophil elastase and citrulinated H3, markers for neutrophils activation, were increased by dsRNA and reduced by RNase treatment in WT mice. Interestingly, in $TLR3^{-/-}$ mice, no increase of these markers was found after dsRNA injection as compared to vehicle control. In HUVECs and murine endothelial cells, dsRNA induced mRNA expression of IL-8 and CCL5. Absence of TLR3 (siRNA in HUVEC or $TLR3^{-/-}$ cells) blocked dsRNA-induced mRNA expression of IL-8, CCL5 and CCL2.
Summary/conclusions: Taken together, we found that endogenous RNA and TLR3 activation participate in thrombus formation and leukocyte recruitment in part by inducing the expression of chemoattractants in the endothelium. These results strongly suggest that TLR3 stimulation after endothelial cell injury participate in thrombus formation by inducing a pro-inflammatory response leading to the recruitment and activation of leukocytes.

AS 10.2

High sensitivity C-reactive protein, body mass index, factor VIII levels and risk of venous thrombosis: results from the MEGA study

Braekkan SK[1], Lijfering WM[2], Rosendaal FR[2] and Cannegieter SC[2]
[1]*University of Tromso, Tromso, Norway;* [2]*Leiden University Medical Center, Leiden, the Netherlands*

Background: The role of C-reactive protein (CRP) as a risk factor for venous thrombosis is debated. Moreover, genetically elevated CRP was not associated with venous thrombosis in a large population based study, suggesting that the observed relationship may be confounded or mediated by other factors. Obesity is associated with a state of chronic low-grade inflammation, and CRP levels correspond to the presence of adiposity in the body. Moreover, increased plasma levels of CRP have been shown to correlate with increasing levels of coagulation factor VIII (FVIII). Both obesity and FVIII are well-established, strong risk factors for venous thrombosis.

Aims: Since controversy exists on the causal role of CRP on venous thrombosis risk, we set out to determine whether an observed association between CRP and venous thrombosis could be explained by a concomitant procoagulant state and/or presence of obesity. To study this hypothesis, we first examined the crude association between CRP and venous thrombosis, and then assessed to what extent FVIII and BMI influenced this relationship.

Methods: High sensitivity CRP (hsCRP), factor VIII antigen (FVIII) and body mass index (BMI) were measured in the Multiple Environmental and Genetic Assessment of risk factors for venous thrombosis-study (MEGA study), a large case-control study including 2205 cases of venous thrombosis and 2777 age- and sex-matched controls. With logistic regression models, odds ratios (OR) for venous thrombosis by percentiles of hsCRP were calculated and further adjusted for BMI and FVIII, introducing one co-variate at the time.

Results: HsCRP values increased linearly with increasing BMI and increasing FVIII levels in both genders. In age and sex-adjusted analysis, the risk of venous thrombosis increased dose-dependently across percentiles of hsCRP. Subjects with an hsCRP level above the 97.5th percentile (> 13.48 mg/L) had a 3.5-fold (OR 3.47; CI95: 2.52–4.78) higher risk of venous thrombosis compared to those with an hsCRP level below the 25th percentile (< 0.68 mg/L). However, adjustment for either BMI (OR for > 97.5th vs. < 25th percentile of hsCRP: 2.71; CI95: 1.95–3.76) or FVIII (OR 1.55; CI95: 1.10–2.21) highly attenuated the risk estimates, and the association between hsCRP and venous thrombosis was no longer present when both BMI and FVIII were included in the adjustment model (OR for > 97.5th vs. < 25th percentile: 1.26, CI95: 0.87–1.81). Similar risk estimates were found in separate analyses of unprovoked and provoked VTE, and in analyses of deep vein thrombosis and pulmonary embolism.

Conclusions: Our findings suggest that CRP is not causally related to venous thrombosis, but rather a marker of concomitant high levels of FVIII and BMI. Persistent rises in FVIII levels have been reported in major illnesses such as chronic inflammation, liver disease, hyperthyroidism and renal disease. Thus, it can be hypothesized that the observed association between CRP and venous thrombosis may be due to presence of chronic diseases that cause a concomitant rise in CRP and FVIII.

AS 10.3

Differential contribution of FXa and thrombin to vascular inflammation in a mouse model of sickle cell disease

Sparkenbaugh EM[1], Chantrathammachart P[2], Hebbel P[3], Van Ryn J[4], Mackman N[1], Key NS[1] and Pawlinski R[1]
[1]*University of North Carolina at Chapel Hill, Chapel Hill, NC, USA;* [2]*Ramathibodi Hospital, Mahidol University, Bangkok, Thailand;* [3]*University of Minnesota, Minneapolis, MN, USA;* [4]*Boehringer Ingelheim Pharma GmbH & Co., Biberach, Germany*

Sickle cell disease (SCD) is a hematologic disorder associated with activation of coagulation and vascular inflammation. We have previously demonstrated that inhibition of tissue factor (TF) with a mouse anti-TF antibody 1H1 prevents activation of coagulation (plasma thrombin anti-thrombin [TAT] levels), attenuates endothelial cell (EC) activation (plasma levels of sVCAM-1) and inflammation (assessed by plasma IL-6) in mouse models of SCD. TF inhibition also attenuated neutrophil recruitment and activation in lungs (measured by organ myeloperoxidase [MPO] levels). Interestingly, deletion of TF from ECs only reduced plasma levels of IL-6 in sickle mice.

In the current study, we investigated the contribution of FXa and thrombin to vascular inflammation in SCD. Four month old Berkley sickle cell (SS) and non-sickle (AA) littermate control mice (n = 9–11) were fed chow containing either no inhibitor (control), the FXa inhibitor rivaroxaban (1.8 mg/g) or the thrombin inhibitor dabigatran (10 mg/g) *ad libitum* for 10 days. Furthermore, we used bone marrow transplantation (BMT) to generate AA and SS mice deficient in either protease activated receptor-1 (PAR-1) or PAR-2 (n = 8–10) on all non-hematopietic cells (n-HCs). These mice were used for the study 4 months after BMT.

SS mice on control chow had increased plasma levels of TAT (2.3-fold, $P < 0.001$), IL-6 (5.6-fold, $P < 0.01$), sVCAM-1 (1.9-fold, $P < 0.001$) and MPO levels in the lungs (2.7-fold, $P < 0.001$) compared to AA controls. Rivaroxaban significantly reduced plasma TAT (3.1 ± 0.6 vs. 6.1 ± 0.6 ng/mL, $P < 0.001$) and IL-6 (7.3 ± 2.4 vs. 19.2 ± 6.7 pg/mL, $P < 0.05$) but had no effect on sVCAM-1 levels. Inhibition of FXa also moderately reduced (24.5%) lung MPO levels. Dabigatran significantly attenuated plasma TAT levels (7.5 ± 2.7 vs. 13.8 ± 9 ng/mL, $P < 0.01$) and lung MPO (70 ± 7.8 vs. 116.7 ± 16.8 ng/mg protein, $P < 0.01$), but had no effect on plasma IL-6 or sVCAM-1 in SS mice. Neither inhibitor induced bleeding or affected red blood cell numbers or hematocrit in AA and SS mice.

In wild-type mice transplanted with SS bone marrow, we observed significant increases in plasma TAT (1.7-fold, $P < 0.05$), sVCAM-1 (1.6-fold, $P < 0.0001$), IL-6 (4.8-fold, $P < 0.001$), and lung MPO (2.8-fold, $P < 0.001$) compared to AA-transplanted controls. PAR-1 deficiency in all n-HCs had no effect on these biomarkers in SS mice. Moreover, PAR-2 deficiency in n-HCs had no effect on coagulation activation (TAT) or EC injury (sVCAM-1) in SS mice. However, SS mice lacking PAR-2 in all n-HCs had significantly attenuated plasma levels of IL-6 (9.4 ± 0.9 vs. 18.9 ± 4.5 pg/mL, $P < 0.05$) and lung MPO (87.4 ± 6.4 vs. 142.4 ± 16 ng/mg, $P < 0.0001$).

This study demonstrated efficient anticoagulation of SS mice with rivaroxaban or dabigatran. However, we found that FXa, but not thrombin, contributes to systemic inflammation (IL-6), likely through TF: FVIIa:FXa-dependent activation of PAR-2 on ECs. nHCs PAR-1 appears to play no role in vascular inflammation in SS mice. Nevertheless, thrombin, and to a lesser extent FXa, contributes to the local neutrophil response in the lung, most likely via a fibrin-dependent mechanism (under investigation). The TF-dependent increase in sVCAM-1 is not mediated by FXa or thrombin. Ligands other than coagulation proteases might contribute to PAR-2-dependent increase in lung MPO.

AS 11 – New Genetic Determinants of Venous Thrombosis

AS 11
New genetic determinants of venous thrombosis: a novel mechanism of hereditary thrombosis by antithrombin resistance

Kojima TY

Nagoya University School of Health Sciences, Nagoya, Aichi, Japan

Background: Venous thromboembolism is a multifactorial disease, resulting from a complex interaction of inherited and environmental factors. To date, numerous genetic defects have been found in the families with hereditary thrombophilia, but there may be still many undiscovered causative mutations.
Aim: We investigated the possible causative gene defect in a large Japanese family with inherited thrombophilia.
Methods: We analyzed the prothrombin gene by the PCR mediated sequencing method. Informed consent was obtained and our Institutional ethics committee approved the study. We prepared recombinant prothrombins, and analyzed their characters and functions. To examine the functions of the recombinant prothrombins in plasma, we prepared reconstituted plasma by mixing prothrombin-deficient plasma with the recombinant prothrombins. The proband's plasma was not suitable for evaluation because of warfarin treatment. We performed three tests of prothrombin activity: a one-stage clotting assay, a two-stage clotting assay, and a chromogenic assay that uses S-2238. We measured thrombin-antithrombin (TAT) complex formation by ELISA. We also performed a thrombin generation assay to determine the potential procoagulant activity of the recombinant prothrombins in plasma.
Results: We found a novel missense mutation in the prothrombin gene (p.Arg596Leu) resulting in a variant prothrombin (prothrombin-Yukuhashi). The mutation cosegregated with deep vein thrombosis in the family, suggesting being a cause of hereditary thrombophilia. The mutation occurred at residue Arg596 within the Na+ binding region of thrombin molecule, which locates at one of the antithrombin binding sites. We observed that the mutant and wild-type prothrombins were fully converted to thrombins in a similar manner within 5 min by prothrombinase. However, conversion of the mutant prothrombin to thrombin appeared to be seconds slower than that of the wild-type thrombin in the clotting assays. In addition, the mutant thrombin likely had a lower catalytic activity for fibrinogen than the wild-type thrombin. Extremely low levels of TAT complex were detected in the mutant thrombin sample, suggesting that disruption of the Na+ binding region structure losing two hydrogen bonds between the thrombin Arg596 and antithrombin Asn265 may be critical for TAT formation. These findings indicate that prothrombin-Yukuhashi can be characterized as a dysprothrombin highly resistant to inhibition by antithrombin. A thrombin generation assay is a comprehensive coagulation function test using a fluorogenic substrate that enables to evaluate not only the initial phase of thrombin generation, but also the late phase of its inactivation. The thrombin generation assay data again suggested that the mutant prothrombin could be a low procoagulant, but was highly antithrombin resistant. Therefore, its active form, the mutant thrombin, would not be inactivated by antithrombin, and would continue to facilitate blood coagulation despite its low activity.
Conclusion: We identified a novel mechanism of hereditary thrombosis by antithrombin resistance, associated with a missense mutation in the prothrombin gene. The antithrombin-resistant thrombin may possess prolonged procoagulant activity *in vivo*, leading to a susceptibility to thrombosis.

AS 11.1
Genome-wide association of quantitative trait loci with levels of hemostatic factors and thrombin generation in the GIFT study

Koenderman JS[1], Castoldi E[2], Tregouet DA[3], Morange PE[4], Lathrop M[5], Vos HL[1], Bertina RM[1], Houwing-Duistermaat J[1], Reitsma PH[1] and De Visser MCH[1]

[1]Leiden University Medical Center, Leiden; [2]Cardiovascular Research Institute Maastricht, Maastricht, the Netherlands; [3]ICAN Institute, Université Pierre et Marie Curie, Paris; [4]Aix-Marseille University, Marseille; [5]Institut de Génomique, Centre National de Génotypage, Evry, France

Background: Deficiencies and elevated levels of several circulating hemostatic factors as well as elevated thrombin generation have been associated with venous thromboembolism. The observed inter-individual variation in de levels of these hemostatic phenotypes can be partly explained by sequence variations in or outside the structural gene encoding these factors or influencing these analytes.
Aim: The aim of this study was to identify new quantitative trait loci (QTL) of several hemostatic traits and to confirm known loci by using genome-wide association study (GWAS) data.
Methods: Plasma levels of coagulation factors (protein C, protein S (free+total), C4BP, antithrombin, heparin cofactor II, fibrinogen, coagulation factors II, V, VIII, IX, X, XI, and protein Z), and thrombin generation parameters under three assay conditions (1 pM tissue factor (TF), 10 pM TF, 10 pM TF+ activated protein C (APC)) were measured in 413 subjects from the Genetics In Familial Thrombosis (GIFT) study. This study consists of 201 small, unrelated thrombophilia families with affected siblings with venous thromboembolism (n = 434). Subjects treated with anticoagulants at time of blood collection (n = 142) were excluded from the analyses of the vitamin K-dependent factors protein C, protein S, protein Z, factors II, IX, X as well as for the thrombin generation parameters.
SNP genotype data were generated with the Illumina 660W-Quad Beadchip. SNPs of high quality (SNP yield > 96%; MAF > 1%; HW P-value > 10^{-6}) were used for imputation with HapMap version 2. After imputation, more than 1.9 million SNPs were in agreement with the quality control settings (imputation $R^2 \geq 90\%$; $5\% \leq$ MAF $\leq 95\%$) for current analyses. Association analysis was performed on the GWAS SNP data and the age and sex adjusted hemostatic traits by using the generalized estimating equations assuming an additive genetic model.
Results: This association analysis revealed genome-wide significant ($P < 5.0*10^{-8}$) results for plasma levels of protein Z and factor VIII, and for the endogenous thrombin potential (ETP) and lag time from the thrombin generation assay performed with 10 pM TF+APC. For protein Z, two loci were identified with a lowest P-value of $1.1*10^{-11}$ at SNP rs12876365 on chromosome 13 near the structural gene, *PROZ*. The second locus, with a lowest P-value of $2.8*10^{-9}$, was located at SNP rs1526520 on chromosome 7 in the *THSD7A* gene that encodes thrombospondin type I domain containing 7A. An association signal for FVIII levels was confirmed in the *ABO* blood group genes on chromosome 9, with a lowest P-value of $5.9*10^{-11}$. Both the ETP and lag time from the thrombin generation assay with 10 pM TF+APC were associated with SNPs on chromosome 1 in the genes *F5* and *NME7*, with P-values in the range of 10^{-9}.
Conclusion: Using GWAS data, we have confirmed association of protein Z levels with SNPs in the structural gene encoding protein Z, and we identified a possibly new quantitative trait locus at *THSD7A* on chromosome 7. A known locus for FVIII levels was confirmed, and the analysis with thrombin generation parameters revealed association with SNPs in the genes *F5* and *NME7*. These novel identified genes can be examined as candidate genes in the investigation of venous thromboembolism.

AS 11.2

Y haplogroup R1b is associated with an increased risk of recurrent venous thrombosis in men

De Haan HG, Van Hylckama Vlieg A, Van Der Gaag KJ, De Knijff P and Rosendaal FR

Leiden University Medical Center, Leiden, the Netherlands

Introduction: The recurrence risk of venous thrombosis is 1.5–2.5 higher in men than in women. Several explanations for the inequity by sex have been proposed, such as differences in age and the inclusion of hormone associated venous thrombosis, but none proved sufficient. We hypothesized a role for the Y chromosome in recurrence risk in men.

Aim: The aim of this study was to examine the effect of variation in the male-specific region of chromosome Y (MSY) in recurrent venous thrombosis in men.

Methods: In order to determine Y haplogroups according to the Y chromosome phylogenetic tree, we genotyped 26 variants of the MSY in the male participants of the MEGA follow-up study (1872 men with a first event of whom 396 had a recurrence during follow-up). Consent and ethical approval were obtained. For each haplogroup, we compared the recurrence risk with all men in the other haplogroups by calculating hazard ratios (HR) with 95% confidence intervals (CI). Currently, we have genotype information of 815 men with a first event of whom 195 had a recurrence during follow-up. Complete results for the total study population will be available at the ISTH congress.

Results: Overall, we observed a cumulative incidence of recurrent venous thrombosis of 33.1 (95% CI 27.9–38.3) per 1000 person years. We identified 19 Y haplogroups among the 815 men, of which haplogroups R1b and I were the most prevalent, 58.5% and 21.1% respectively. The cumulative incidence of recurrent venous thrombosis was 38.4 (95% CI 31.0–45.7) per 1000 person years in R1b carriers compared with 25.8 (95% CI 18.7–32.9) in non-R1b carriers. Carriers of haplogroup R1b had a 1.5-fold higher risk (95% CI 1.1–2.1) of recurrent venous thrombosis than non-R1b carriers. Exclusion of men of non-Dutch origin did not affect this association. We observed no association between recurrent venous thrombosis and carriers of haplogroup I compared with non-I carriers (HR 0.8, 95% CI 0.5–1.1).

Conclusions: Our results show a predisposing effect of haplogroup R1b on recurrence risk of venous thrombosis in men, which may explain the inequity by sex in disease risk. Further study of haplogroup R1b will provide insight in the biology and patho-physiology of recurrent venous thrombosis.

AS 11.3

Whole exome sequencing of > 900 individuals provides insight into genetic architecture of venous thromboembolism

Smith EN[1], Braekkan SK[2], Carson AR[1], Jepsen K[1], Matsui H[1], Wilsgaard T[3], Harismendy O[1], Frazer K[1] and Hansen JB[2]

[1]University of California, San Diego, La Jolla, CA, USA; [2]University Hospital of North Norway; [3]University of Tromsø, Tromsø, Norway

Background: Presently known genetic variants, including common variants identified in GWAS studies, explain 20–30% of venous thromboembolism (VTE) events. Family and twin studies, however, indicate that genetic factors account for about 60% of the VTE risk. Thus, there is an opportunity to identify new gene variants involved in the pathogenesis of VTE. Previously implicated loci include protein coding variants in genes with common alleles of moderate effect (e.g. ABO and F5), and genes with multiple private mutations (e.g. PROC and PROS1), suggesting that a genome-wide search to identify common and rare coding variants may reveal additional loci and alleles.

Aims: We have applied whole exome sequencing to comprehensively identify common and rare coding variants and tested for association with VTE in a case-control study of > 900 individuals.

Methods: Cases who had a first VTE (n = 465) and matched controls (n = 455) were identified from a population-based, nested, case-cohort study (the Tromsø study) comprising 78% (n = 27,158) of the adult residents of Tromsø in Norway. Exome sequencing was performed to an average depth of ~100× to identify common and rare variants. Using the 1000 Genomes Project EUR individuals as reference, we imputed genotypes at SNPs and indels at minor allele frequencies (MAF) > 0.005 in the reference population. We have tested for association with VTE across all sites and are currently performing rare variant collapsing tests of association. The study was approved by the regional committee for research ethics, and all participants gave their informed written consent to participate.

Results: Using whole exome sequencing, we identified 198,868 coding variants including 116,930 missense, 2329 nonsense, and 79,609 synonymous sites. Most sites were rare, with 82% with MAF < 5%. We observed an association between severity of effect and MAF with more deleterious groups of alleles tending to be rarer. We are currently undergoing analyses to test for association between cases and controls and will be performing common variant association similar to GWAS studies and rare-variant association including collapsing variant tests. Preliminary analyses verify previously known genetic risk factors and also identify novel nominally associated variants in relevant pathways such as the coagulation system, lipid metabolism, and microparticle formation in VTE patients compared to age- and sex-matched controls. Imputation to the whole genome resulted in high quality genotype information at 3.3 M SNPs and 300 K indels throughout the genome, effectively covering ~1/3 of the genetic variation present at MAF > 0.005.

Conclusions: This is the first study to comprehensively study protein-coding genetic variation and its association with VTE. In addition to replicating previously implicated sites, we have also identified novel candidates potentially associated with VTE. Further studies will include replication in larger cohorts.

The Anticoagulation of Calf Thrombosis (ACT) project: results from the randomized controlled external pilot trial

Horner D[1], Hogg K[2], Body R[1], Nash MJ[1], Baglin TPT[3] and Mackway-Jones K[1]

[1]Central Manchester University Hospitals NHS Foundation Trust, Manchester, UK; [2]The Ottawa Hospital, Ottawa, ON, Canada; [3]Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK

Background: There is currently little evidence defining the clinical importance of detecting and treating isolated distal deep vein thrombosis (IDDVT). Contemporary international guidelines vary regarding diagnostic and therapeutic advice. The potential benefits of anticoagulation remain poorly defined.

Aims: We sought to evaluate the feasibility of a randomized controlled trial within a modern cohort, to determine whether patients with IDDVT benefit from therapeutic anticoagulation.

Methods: A pragmatic, open label, external pilot randomized controlled trial. Consecutive symptomatic IDDVT patients were approached for inclusion, within an ambulatory thrombosis service. Participants were randomized to receive either phased therapeutic anticoagulation (intervention) or conservative management (control) from diagnosis. Both groups received grade 2 compression stockings and analgesia. All patients underwent assessor blinded color duplex imaging after 7 and 21 days, and follow up at 3 months. Principal fea-

sibility outcomes were recruitment rate and attrition, including loss to follow-up and allocation crossover. The primary clinical outcome was a composite of proximal propagation, pulmonary embolism, death attributable to venous thromboembolic disease or major bleeding. Secondary clinical outcomes included propagation to any site (including local extension confined to the calf), symptomatic progression and minor/nuisance bleeding rates. Analysis was by intention to treat. The trial protocol has been previously published.

Results: During the recruitment phase, 951 patients underwent ambulatory assessment for suspected DVT. Proximal disease was confirmed in 104 cases. Acute IDDVT was detected in 93 cases. Of these patients, 79 were subsequently deemed eligible and 70 (88.6% of those eligible) were recruited. 59/70 (84.3%, 95% CI 74.0–91.0%) patients completed the full protocol. All patients but one were followed up by direct contact after 90 days. A single patient (1.4%) was personally uncontactable: follow up occurred through medical record review and discussion with the primary care practitioner. Allocation crossover occurred in 15 (21.4%) patients.

All predefined feasibility outcomes were successfully achieved. The primary clinical outcome occurred in 4/35 (11.4%) controls and 0/35 in the intervention group (Absolute Risk Reduction [ARR] 11.4%, 95% Confidence Interval [CI] −1.5 to 26.7, $P = 0.11$, number needed to treat [NNT] of 9). There were no cases of major bleeding in either group.

Regarding secondary clinical outcomes, propagation to any site occurred in 11/35 (31.4%) of conservatively treated patients compared with 2/35 (5.7%) of those randomized to anticoagulation (ARR 25.7%, 95% CI 5.9 to 44.3%, $P = 0.001$, NNT 4). Pain scores at day 7 rose from baseline in a significantly higher number of patients treated conservatively, compared to patients treated by therapeutic anticoagulation (6/35 vs. 0/35, $P = 0.03$). Minor bleeding occurred in 3/35 (8.6%) controls and 7/35 (20.0%) anticoagulated patients ($P = 0.31$). Nuisance bleeding rates were equivocal.

Conclusion: We have established feasibility for a definitive trial on the value of therapeutic anticoagulation for IDDVT. Our pilot study currently provides the largest prospective randomized clinical dataset on this topic and demonstrates a non-significant trend towards reduction of serious complications with anticoagulation. This highlights the importance of further evaluation with an appropriately powered design.

Apixaban for the treatment of symptomatic deep-vein thrombosis and pulmonary embolism: a randomized, double-blind trial (AMPLIFY)

Agnelli G, Buller HR, Cohen A, Curto M, Gallus AS, Johnson M, Masiukiewicz U, Pak R, Thompson J, Raskob GE and Weitz JI

AMPLIFY Investigators, Italy

Background: Apixaban, an oral factor Xa inhibitor administered in fixed doses, may simplify the treatment of acute venous thromboembolism. In a previous study, apixaban was shown to be highly effective for the prevention of recurrent venous thromboembolism in patients who had completed 6–12 months of anticoagulant therapy and was associated with rates of major bleeding comparable to placebo [1].

Aims: To compare the efficacy and safety of apixaban alone with those of conventional anticoagulant therapy consisting of low-molecular-weight heparin followed by a vitamin K antagonist in patients with acute symptomatic venous thromboembolism.

Methods: This randomized, double-blind trial compared apixaban, 10 mg twice daily for 7 days followed by 5 mg twice daily for 6 months, with conventional therapy consisting of subcutaneous enoxaparin followed by warfarin in patients with acute symptomatic proximal deep-vein thrombosis and/or pulmonary embolism (NCT00643201). The study was designed to test the hypothesis that apixaban would be non-inferior to conventional therapy for the primary efficacy outcome. The criteria for non-inferiority required that the upper limit of the 95% confidence intervals were below pre-specified margins for both the relative risk (< 1.8) and the risk difference (< 0.035).

The primary efficacy outcome was symptomatic recurrent venous thromboembolism or venous thromboembolism-related death. The principal safety outcomes were major bleeding and major bleeding plus clinically relevant nonmajor bleeding. The diagnosis at study entry, the extent of initial deep-vein thrombosis or pulmonary embolism, and all suspected outcomes were adjudicated by an independent committee whose members were unaware of study group assignments. The trial was sponsored by Bristol-Myers Squibb Company and Pfizer Inc. The protocol was approved by the institutional review board at each participating center, and written informed consent was obtained from all patients.

Results: Five thousand four hundred patients were enrolled at 358 centers in 28 countries. The baseline characteristics of the treatment groups were similar. The diagnosis at study entry was deep-vein thrombosis in 67% of patients and pulmonary embolism with or without deep-vein thrombosis in 33%.

Summary/conclusions: Final results for the efficacy and safety outcomes will be presented.

Dalteparin sodium for the long-term management of venous thromboembolism in cancer patients. The DALTECAN Study

Kakkar A[1], Kessler C[2], Goldhaber SZ[3], Kovacs MJ[4], Spyropoulos AC[5], Ortel TL[6], Pabinger I[7], Huisman MV[8], Bergqvist D[9], Monreal M[10], Turpie AG[11] and Francis CW[12]

[1]University College London, London, UK; [2]Georgetown University Medical Center, Washington, DC; [3]Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; [4]University of Western Ontario, London, ON, Canada; [5]North Shore/LIJ Health System, Lenox Hill Hospital, Hofstra School of Medicine, New York, NY; [6]Duke University Medical Center, Durham, NC, USA; [7]Medical University of Vienna, Vienna, Austria; [8]Leiden University Medical Center, Leiden, The Netherlands; [9]University Hospital Uppsala, Uppsala, Sweden; [10]Hospital Universitari Germans Trias i Pujol, Barcelona, Spain; [11]McMaster University, Hamilton, ON, Canada; [12]University of Rochester Medical Center, Rochester, NY, USA

Background: Venous thromboembolism (VTE) is a common and potentially life-threatening complication in patients with malignant disease. Current treatment guidelines recommend anticoagulation with a low molecular weight heparin for at least 3–6 months, or for the duration of the malignancy. Uncertainty exists whether to extend anticoagulation longer to prevent recurrent thromboembolism.

Aim: The DALTECAN Study was undertaken to determine whether extending anticoagulation with dalteparin in cancer-associated VTE beyond 6 months has an acceptable safety and adherence profile.

Methods: Patients with active cancer and newly diagnosed VTE were enrolled in a single-arm multi-center study and received treatment with dalteparin 200 IU/kg daily subcutaneously for 1 month, followed by 150 IU/kg daily for the subsequent 11 months. Bleeding and recurrent VTE were centrally adjudicated to determine their incidence rates in month 1, months 2–6, and months 7–12 following enrollment.

Results: Three hundred and thirty-four patients with VTE and active cancer were treated with dalteparin, of whom 185 (55.4%) completed 6 months of therapy and 109 (33%) completed 12 months. Overall,

92% of the patients had solid tumors, with lung (16.8%), breast (9.3%), or pancreas (9.3%) as the prevailing primary sites. Baseline ECOG performance status was 0 (29.6%), 1 (48.8%), 2 (20.7%), and 3 (0.3%), with two subjects' status unknown. Therapy adherence was 96% across the entire cohort, with a median treatment duration of 214 days. The overall frequency of major bleeding was 10.2%, observed at a rate of 1.3% per patient-month. The highest major bleeding rate was in the first month of dalteparin therapy at 3.6%, with a frequency declining to 1.1% during months 2–6, and 0.7% over months 7–12, with no statistically significant difference in rates between months 2–6 and 7–12 ($P = 0.39$). The incidence of new or recurrent VTE was 11.1% (37 patients), a rate of 1.4% per patient-month. The rate was highest for month 1 at 5.7%, falling thereafter to 0.8% per month for months 2–6 (incidence 3.4%) and 0.7% per month for months 7–12 (incidence 4.1%). Death occurred in 154 patients, of whom 115 died during the study period and had an adjudicated death. Among these 115 deaths, 105 were due to underlying cancer, four due to VTE, two due to bleeding, and the remaining four deaths were due to other causes.

Summary: Extending dalteparin therapy in patients with VTE and cancer beyond 6 months is not associated with an increase in bleeding compared to the initial period of therapy. The risks for developing major bleeding complications were greatest in the first month of therapy and decreased over the subsequent 11 months. The risk for VTE recurrence was also greatest in the first month after initiating dalteparin, decreased subsequently thereafter, and remained low during the observation period. The adherence rate was high, confirming that an extended LMWH regimen with dalteparin in cancer patients is feasible.

AS 12.4

Safety, efficacy and pharmacokinetics of nonacog beta pegol (N9-GP) for prophylaxis and treatment of bleeding episodes in patients with haemophilia B

Collins PW[1], Colberg T[2], Young G[3], Abdul Karim F[4], Angchaisuksiri P[5], Gursel T[6], Mahlangu J[7], Matsushita T[8], Mauser-Bunschoten E[9], Oldenburg J[10], Walsh C[11], Knobe K[2], Negrier C[12] and ParadigmTM2 investigators

[1]Arthur Bloom Haemophilia Centre, School of Medicine, Cardiff University, Cardiff, UK; [2]Medical and Science, Haemophilia, Novo Nordisk A/S, Søborg, Denmark; [3]Children's Hospital Los Angeles, Los Angeles, CA, USA; [4]Haemophilia Centre, National Blood Centre – Pusat Darah Negara, Kuala Lumpur, Malaysia; [5]Ramathibodi Hospital, Bangkok, Thailand; [6]Gazi University, Ankara, Turkey; [7]Haemophilia Comprehensive Care Centre, Johannesburg, South Africa; [8]Nagoya University Hospital, Nagoya, Japan; [9]Van Creveldkliniek/UMCU, Utrecht, The Netherlands; [10]University Clinic Bonn, Bonn, Germany; [11]Mount Sinai School of Medicine, New York City, NY, USA; [12]Hopital Edouard Herriot, Lyon, France

Background: Nonacog beta pegol (N9-GP) is a glycoPEGylated recombinant factor IX (rFIX) with a significantly longer plasma half-life (93 h) as compared to currently available plasma-derived and recombinant FIX products (18–19 h).[1] N9-GP is therefore expected to reduce the burden of treatment by decreasing dosing frequency in prophylaxis as well as controlling bleeding episodes with fewer injections. In this phase 3 trial, paradigmTM 2, two different prophylaxis dose levels of N9-GP were tested, along with an on-demand treatment arm.

Aims: The primary objective of this trial was to evaluate immunogenicity of N9-GP. Key secondary objectives were to assess therapeutic and prophylactic efficacy, pharmacokinetic (PK) properties and general safety of N9-GP.

Methods: Haemophilia B patients with ≤ 2% FIX activity, aged 13–70 years, with no history of inhibitors and at least 150 exposures days (ED) to other FIX products were included. The trial was approved by local IRB/REC and all participants signed an informed consent before any trial related activity. The aim was to have at least 25 patients completing each prophylaxis arm and at least 10 patients completing the on-demand treatment arm. Patients for the two prophylaxis regimens were randomised to once weekly N9-GP dosing of 10 or 40 U/kg, respectively, for 52 weeks. Treatment in the on-demand arm lasted for 28 weeks. Here patients were dosed with 40 or 80 U/kg for mild/moderate or severe bleeding episodes respectively. Same treatment regimen was used for prophylaxis patients experiencing breakthrough bleeding episodes. Immunogenicity was evaluated as the primary endpoint; incidence of inhibitory antibodies against FIX defined as titre ≥ 0.6 Bethesda Units (BU). Efficacy endpoints included frequency of bleeds among prophylaxis patients, haemostatic response to N9-GP infusion based on a 4-point categorical scale, as well as FIX activity as a surrogate marker. Following completion of the dosing period, all patients were offered continued treatment with N9-GP in the extension trial, paradigmTM 4.

Results: The trial is on-going, though recruitment has been completed. Results will be presented at the meeting.

Conclusions: Conclusions will be presented at the meeting.

AS 12.5

An antibody to thrombin's exosite 1 prevents thrombosis without causing bleeding

Baglin T[1], Langdown J[1], Ivanciu L[2], Camire R[2], Ali M[3], Philippou H[3] and Huntington J[1]

[1]Department of Haematology, University of Cambridge, Cambridge University Hospitals, Cambridge, UK; [2]Department of Haematology, Children's Hospital of Philadelphia, Philadelphia, PA, USA; [3]Academic Unit of Molecular Vascular Medicine, University of Leeds, Leeds, UK

A 53 year old female presented with a subdural haematoma following a head injury. The coagulation screen indicated a severe coagulopathy (prothrombin time 50 s, APTT 190 s, thrombin time > 100 s). An inhibitor was demonstrated by mixing studies, and was identified as an anti-thrombin IgA paraprotein at 3 g/L. The antibody was purified by Jacalin agarose, thrombin agarose and size-exclusion chromatography. The K_d was determined to be in the low nanomolar range, with a fast on- and slow off-rate (1×10^6/M/s and 1×10^{-3}/s, respectively). The antibody was completely unable to bind prothrombin. The antibody did not block the active site of thrombin as shown by cleavage of small substrates and inhibition by antithrombin. Exosite 1 binding was suggested by the ability of the antibody to inhibit fibrinogen cleavage in a purified system, and a 30% increase in rate of S-2238 cleavage. Competitive binding with fluorescently labeled hirugen confirmed exosite 1 as the binding site on thrombin. A Fab fragment was prepared from the antibody by papain cleavage and co-crystallised with human PPACK-Thrombin, and a 1.9 Å structure was solved showing an interaction between CDRH3 and exosite 1.

Whilst at first it appeared the patient had a severe bleeding disorder this was not the case. She had undergone knee surgery 6 months before presentation. A pre-operative coagulation screen had not been performed. There was no abnormal bleeding during or after surgery although it is highly likely that the paraprotein was present at the time. She also made a rapid complete recovery following the subdural haematoma with full resolution of the haematoma without rebleeding without treatment. Five years later she remains well with no spontaneous haemorrhage or bleeding after further trauma. These observations suggested that the IgA does not inhibit normal haemostasis, but that it might prevent thrombosis.

In a mouse femoral vein 10% ferric chloride injury model using fluorescein labelled fibrinogen, the antibody at concentrations > 40 nM completely abolished fibrin deposition. Up to, and including the high-

est concentration used (4 mM), tail bleeding times were not prolonged. In a murine carotid artery occlusion model, with a 5% ferric chloride injury, the antibody was able to prevent arterial occlusion and maintain blood flow. At the maximum concentration studied (400 nM), blood loss from a tail clip was not increased compared to saline controls.

We have identified an antibody that appears to prevent thrombosis without causing bleeding. A therapeutic derivative of this IgA might thus permit unlimited dose escalation of antithrombotic therapy without increasing bleeding – the Holy Grail of thrombosis research.

AS 13 – Role of FXII Activation in Mechanism of Thrombosis

AS 13.1

Histidine-rich glycoprotein binds to DNA, RNA and fXIIa with high affinity and attenuates contact-mediated coagulation in a mouse model of arterial thrombosis

Vu T, Zhou J, Leslie BA, Stafford AR, Fredenburgh JC and Weitz JI
McMaster University, Hamilton, ON, Canada

Background: Histidine-rich glycoprotein (HRG) is an abundant plasma protein that binds fibrin(ogen) and other plasma proteins, but whose function is unclear. The activated partial thromboplastin time (aPTT) is shortened in HRG deficient humans and mice; and we have previously shown that HRG modulates the contact pathway by binding factor (f) XIIa (K_d 21 nM) and attenuating its capacity to activate fXI. Because DNA and RNA serve as physiological activators of the contact pathway, the capacity of HRG to bind polyanions may endow it with a regulatory role in thrombosis.

Objective: To quantify HRG modulation of DNA- and RNA-mediated activation of the contact pathway *in vitro* and in a mouse model of arterial thrombosis.

Methods: Binding of HRG to DNA and RNA was assessed by surface plasmon resonance (SPR). The inhibitory effects of HRG on fXII activation and fXIIa and thrombin activation of fXI were assessed with chromogenic assays. The effects of HRG on DNA- and RNA-mediated activation of coagulation were assessed in clotting assays using human and mouse plasma. To explore effects *in vivo*, we compared the time to occlusion (TTO) after $FeCl_3$-induced carotid artery injury in HRG (−/−) and wild-type mice.

Results: SPR analyses reveal that HRG binds DNA and RNA (K_d values of 0.9 ± 1.3 and 1.4 ± 1.6 nM, respectively). Consistent with binding, HRG inhibits DNA-mediated (a) fXII activation by kallikrein (IC_{50} = 22 nM), (b) activation of fXI by fXIIa (IC_{50} = 460 nM), and (c) feedback activation of fXI by thrombin (IC_{50} = 3600 nM). HRG inhibits RNA-mediated activation and propagation of the contact pathway with similar potency. The concentrations of DNA and RNA required to shorten the aPTT by 50% in HRG-depleted human plasma are 8- and 24-fold lower, respectively, than in control plasma; a difference that is abolished when the deficient plasma is supplemented with 2 μM HRG. Similar results are obtained when DNA or RNA is used to activate plasma from HRG (−/−) and wild-type mice; and addition of human HRG to plasma from HRG (−/−) mice abrogates the difference. In an arterial injury model, the TTO in HRG (−/−) mice is 11.8 ± 2.8 min, whereas that in wild-type mice is over 30 min ($P < 0.0005$); this difference is abolished when HRG (−/−) mice are administered 2 μM human HRG.

Conclusions: HRG binds DNA, RNA and fXIIa with high affinity and is a potent inhibitor of contact-mediated activation of coagulation. HRG (−/−) mice exhibit accelerated thrombosis compared to controls; a difference that is abrogated with HRG administration. These data suggest that HRG attenuates contact-mediated thrombosis by modulating the prothrombotic properties of fXIIa and extracellular nucleic acids.

AS 13.2

Selective depletion of contact factors with antisense oligonucleotides attenuates catheter thrombosis in rabbits

Yau JW[1], Liao P[1], Stafford AR[1], Fredenburgh JC[1], Revenko AS[2], Monia B[2] and Weitz JI[1]
[1]*Thrombosis and Atherosclerosis Research Institute, Hamilton, ON, Canada;* [2]*Isis Pharmaceuticals, Inc., Carlsbad, CA, USA*

Background: Indwelling central venous catheters can trigger upper extremity deep vein thrombosis and pulmonary embolism. Neither low-dose warfarin nor low-molecular-weight heparin prophylaxis prevents this problem. Recently, we reported that upstream inhibition at the level of factor (f) XIIa was better than downstream inhibition at the level of fXa and thrombin to prevent catheter-related thrombosis *in vitro* and *in vivo* (Blood 2011; 118(25):6667–6674 and Acta Biomater 2012; 8(11):4092–4100). This demonstrates that the contact pathway plays an important role during catheter-induced clotting.

Aim: To further explore the role of the contact pathway in catheter thrombosis, we used antisense oligonucleotides (ASO) to knock down the levels of fXII, fXI or high-molecular-weight kininogen (HK) in rabbits and examined their effect on the time to catheter occlusion (TTO) in both an acute and a chronic model.

Methods: Rabbits (n = 6–8/group) were randomized to receive 30 mg/kg/week of control, fXII-, fXI- or HK-directed ASO for 4 weeks. Hepatic mRNA levels and plasma protein levels were quantified. Activated partial thromboplastin times (APTT) and prothrombin times (PT) were also measured. To initiate the occlusion study, a 6 F catheter was inserted into the right atrium via the jugular vein. In the acute study, blood was withdrawn from the catheter every 5 min and re-injected, and the catheter was then flushed with saline. TTO was determined as the time when blood could no longer be withdrawn from the catheter. TTO was scored as 4 h if catheter occlusion did not occur. In the chronic study, blood was withdrawn once-daily and TTO was determined as the time when saline could no longer be injected, or scored as 30 days if catheter occlusion did not occur.

Results: Specific ASO treatment reduced hepatic mRNA levels of fXII, fXI and HK by 97%, 84% and 57%, respectively, and plasma protein levels by 97%, 96% and 87%, respectively; whereas the control ASO had no effect on any parameters. FXII-, fXI-, or HK-directed ASOs prolonged the APTT in rabbits by 4.7-, 3.6-, and 3.1-fold compared with rabbits given control ASO, whereas PT in rabbits showed no difference between the ASO groups. In the acute occlusion study, the mean TTO (± standard deviation) in the control group was 40.5 ± 6.2 min. fXII-, fXI- and HK- directed ASO treatments significantly prolonged the mean TTO by 2.8-, 4.4-, and 2.6-fold, respectively ($P < 0.05$). In the chronic study, the mean TTO in the control group was 10.3 ± 6.5 days. FXII- and fXI- directed ASO treatments significantly prolonged ($P < 0.01$) the mean TTO by 2.0- and 2.5-fold, respectively, whereas the HK-directed ASO had little effect.

Summary/Conclusions: fXII- or fXI- directed ASO attenuates catheter thrombosis in both acute and chronic rabbit models. These findings support the role of the contact pathway in catheter thrombosis, thereby identifying new targets and novel methodology to prevent thrombosis in patients with indwelling central venous catheters.

AS 13.3

Factor XII promotes blood coagulation independent of factor XI in the presence of long chain inorganic polyphosphates

Puy C[1], Tucker EL[1], Wong ZC[1], Gruber A[1], Gailani D[2], Smith SA[3], Choi SH[3], Morrissey JH[3] and McCarty OJT[1]

[1]Oregon Health & Science University, Portland, OR; [2]Vanderbilt University School of Medicine, Nashville, TN; [3]University of Illinois, Urbana, IL, USA

Background: Inorganic polyphosphates (polyP), which are secreted by activated platelets (short chain polyP) and accumulate in bacteria (long chain polyP), support the contact activation of factor XII (FXII) and accelerate the activation of factor XI (FXI) by thrombin. FXII-deficient mice have been shown to be more resistant to $FeCl_3$-induced arterial occlusion than either factor IX (FIX) or FXI deficient mice, suggesting that FXII also contributes to thrombosis in a FXI-independent manner *in vivo*. It has been shown that the injection of polyP induces coagulopathy in mice in a FXII-dependent manner, but the role of FXI in this process remains unclear.

Aims: The aim of the present study was to determine whether FXII activation by polyP promotes blood coagulation and experimental thrombus formation in a FXI-independent manner.

Methods and Results: Both long and short polyP promoted thrombin-initiated coagulation of plasma in a concentration-dependent manner. Neither the activated factor X (FXa) inhibitor, rivaroxaban, nor antibodies that inhibit FXI activation by activated FXII (FXIIa) or FIX activation by activated FXI (FXIa) were able to inhibit the procoagulant effect of long polyP. In contrast, the FXIIa inhibitor, corn trypsin inhibitor (CTI), blocked the procoagulant effect of long polyP, suggesting that the activation of FXII by polyP promotes coagulation in a FXI-independent manner. In purified system, long polyP significantly enhanced the rate of FXII activation in presence of prekallikrein (PK) and high molecular weight kininogen (HK) and the rate of PK activation by FXIIa. We observed that long polyP enhanced the rate of FXI activation by α-thrombin. In contrast, polyP did not increase FXI activation by FXIIa. In the presence of FXII, PK and HK, long and short polyP blocked the generation of FXIa, suggesting that the activation of FXII by polyP promote kallikrein generation but not FXI activation. We found that addition of 50 μM long polyP decreased the recalcification time of FXI-deficient plasma by up to 60%. The procoagulant activity of long polyP in FXI-deficient plasma was inhibited by a blocking FIX antibody, and eliminated by the presence of CTI or rivaroxaban, suggesting that the activation of FXII by long polyP shortens the clotting time of FXI- deficient plasma in a manner that is dependent of FIX and FX. In a purified system, FXIIa was unable to activate FIX or FX but the activation of PK by long polyP promoted FIXa generation. We also observed that FXIIa could activate prothrombin in a dose dependent manner. In an *ex vivo* model of occlusive thrombus in which recalcified human blood was driven through collagen and tissue factor (TF)-coated capillary tubes, inhibition of FXIIa with CTI but not of FXI with a neutralizing antibody abolished the prothrombotic effect of long polyP.

Summary/Conclusions: We propose that in addition to its established effects on FXI activity and FXII activation, long polyP promotes FXII-mediated blood coagulation, bypassing FXI. Accordingly, some polyP containing pathogens may have evolved strategies to exploit polyP-initiated FXII activation for virulence, and selective inhibition of FXII may improve the host response to pathogens.

AS 14 – Methods and Relevance of Microparticle Detection

AS 14

Microparticle detection: why and how?

Harrisson P

University of Birmingham Medical School, Birmingham, UK

Microvesicles (MV), exosomes and apoptotic bodies (collectively known as extracellular vesicles or EV) are becoming recognised as potentially important biomarkers in many diverse areas of clinical research. It is clear that they play previously unrecognised important roles in normal cellular physiology and provide novel intercellular communication mechanisms. Their levels in body fluids are probably an accurate reflection of health or disease of specific organs and tissues and the underlying inflammatory and activation status of the vascular endothelium and circulating blood cells. The circulating pool of EV are heterogeneous (derived from platelets, leucocytes, erythrocytes, the vascular endothelium or other tissues), small (traditionally it was thought that exosomes range from 50 to 100 nm, MV from 100 to 1000 nm and apoptotic vesicles 1–3 μ in size, but in reality there is considerable overlap between the three main types), can express antigens from their cell of origin, are often procoagulant (with expression of anionic phospholipids) and sometimes carry nucleic acids (e.g. mRNA and microRNA). Pre-analytical variables are important (e.g. blood sampling, processing, centrifugation (number of steps, time, g values etc), isolation techniques and storage of samples) as they can significantly impact upon EV measurement. The ISTH vascular biology SSC has made a number of recommendations about pre-analytical and analytical variables that will help to improve standardization of their measurement. Despite this it is clear that the centrifugation steps used to measure or isolate plasma EV will result in the loss of larger vesicles. Most traditional MV assays are based upon (i) Measurement of procoagulant potential (e.g. thrombin generation or clotting based assays), (ii) Capture using specific ligands (e.g. Annexin-V) or specific antibodies (e.g. Tissue factor) (iii) Measurement of their size (by electron microscopy) and (iv) concentration and phenotype (by flow cytometry). More recently proteomic and genomic screening of purified EV have revealed unique signatures. Although there are many methods available to measure circulating EV, most methods also exhibit significant limitations and standardization issues. For example the procoagulant and/or Annexin-V capture assays by definition only measure procoagulant EV and do not provide information on phenotype (i.e. origin) and size. Although EV size, number and phenotype can be potentially measured by flow cytometry, many instruments cannot reliably measure EV below ~500 nm, although new generation cytometers are beginning to significantly extend this threshold down to below 200 nm and beyond. Measurement of EV by flow cytometry is again an area where standardization is very important and use of calibration beads has been recommended by the ISTH vascular biology SSC to control for instrument noise and set defined size gates. A number of alternative technologies have now been investigated for measuring EV (e.g. Atomic Force Microscopy and Nanoparticle Tracking Analysis) and suggest that the number of EV in plasma may be considerably underestimated by flow cytometry. Comparison of methods using different types of calibration beads and biological standards should therefore help to confirm and fully understand these observations. Standardised and accurate measurement of EV (including their size, phenotype (origin), content and concentration) could therefore provide novel diagnostic and prognostic markers of various disease states.

AS 14.1

The activation pathway determines the properties of platelet-derived microvesicles

Aatonen MT, Grönholm M, Lopez-Contreras D and Siljander PRM
University of Helsinki, Helsinki, Finland

Platelets release microvesicles (MVs) both from plasma membrane (microparticles, PMPs) and from endosomal route (exosomes). Changes in *in vivo* platelet-MV levels correlate to various physiological (e.g. gender, age, pregnancy, exercise) and pathological states. Therefore, we have used different activating pathways to induce MV formation and systemically compared their number, size and molecular make-up.

Platelets were isolated from healthy volunteers with modified gradient-procedure to improve sample purity and activated with physiologically relevant agonists on comparison to Ca^{2+}-ionophore (A23187). Enriched microparticle and exosome populations were isolated with differential centrifugation method. MVs number and size distribution were analyzed by nanoparticle tracking analysis (NTA) and correlated with total protein, lipids and EM, respectively. Proteomic comparison was made from pooled samples of six healthy donors with LTQ-Orbitrap-XL mass spectrometry.

Size distribution data from NTA and EM showed that 64–85% of MVs were < 250 nm depending on activation and 95–99% were < 500 nm. Only 0.5–5% of PMVs were in the 0.5–1 μm range. PMVs induced by thrombogenic/immunological or A23187 -pathways showed significant differences in the total protein and the lipid amounts and the proteomic cargo compared to their time-matched constitutively formed controls. Proteomic analysis of PMVs identified proteins of cytoplasmic (47%), surface (16%), organelle (15%) and unknown (14%) origins and 8% as secreted proteins. From 537 total proteins, 12 proteins were shared by all the exosome and PMP conditions, including CD9 and α-IIb integrin. 60% of proteins were unique to each condition, whereas Multimerin-1 was found in all exosomes but not in PMPs.

Our data show that the activation pathway significantly modulates the quantity and the molecular composition (protein/lipid) of the subsequently formed PMVs, but not so much their size distribution. The scarcity of PMVs in the 0.5–1 μm range strongly urges to re-evaluate the data obtained with the 1st generation flow cytometers. Agonist-specific proteomic profiles suggest that different PMVs should be individually tested in cell biological assays to reveal the physiological and pathological significance of PMVs.

AS 14.2

Physical interpretation of the size and concentration of extracellular vesicles measured by advanced techniques

Van Der Pol E[1], Gardiner C[2], Harrison P[3], Sturk A[1], Van Leeuwen TG[1] and Nieuwland R[1]
[1]*Academic Medical Center, University of Amsterdam, Amsterdam, the Netherlands;* [2]*John Radcliffe Hospital;* [3]*Churchill Hospital, Oxford, UK*

Background: Novel advanced techniques are utilized to determine the size and concentration of extracellular vesicles. All techniques provide data, but often the measured physical quantity or units are different, precluding comparison and validation of measurements with established techniques. We have developed a model to enable data comparison between five different techniques that are increasingly used to detect vesicles.

Aims: Facilitate data comparison between different techniques based on the underlying physical parameters of each technique and provide thorough insight in the application and limitations.

Methods: A heterogeneous mixture of beads (Thermo Fisher Scientific, Waltham, MA, USA) of known size and concentration and a standard population of vesicles from human cell-free urine (n = 5) were prepared and analyzed by single particle tracking (SPT; Nanosight NS500), resistive pulse sensing (RPS; Izon qNano), a novel flow cytometer (Apogee A50-Micro), a conventional flow cytometer (BD FACSCalibur), and transmission electron microscopy (TEM). Data interpretation and comparison is enabled by presenting size distributions on the same absolute scale using a physical model, including data from TEM and flow cytometry, which was previously impossible. The size distributions from the well-characterized mixture of beads were used to investigate the capabilities of each technique, thereby facilitating the interpretation of data obtained from the standard population of vesicles.

Results: Using the beads we obtained that, among the techniques capable of measuring in suspension, surprisingly, flow cytometry can resolve the smallest differences in size, whereas SPT detects the smallest vesicles, and RPS is most accurate in determining the concentration. All methods produce different size distributions and concentrations for the standard population of vesicles.

Conclusions: Various detection techniques produce different size distributions and concentrations for a standard population of vesicles. However, most differences can be explained based on the underlying physical parameters of the technique, which we have investigated using a well-characterized mixture of beads. Since the techniques have divergent capabilities, the most suitable technique for detecting vesicles depends on the requested information.

AS 14.3

Microparticles from blood plasma revealed by cryo-electron microscopy, receptor-specific gold labeling and flow cytometry

Brisson AR, Arraud N, Tan S, Linares R and Gounou C
University of Bordeaux, Bordeaux, France

Microparticles (MPs) derived from activated or apoptotic cells are found in plasma and other body fluids in physiological conditions and are present at elevated levels in various diseases, including cardiovascular diseases and cancer. MPs present surface receptors originating from their parental cells, which has promoted the concept of using MPs as biomarkers of diseases. However, research on MPs is rendered difficult by their small size and by the limitations of analytical methods currently in use.

Our overall aim is two-fold, first to improve our basic understanding on MPs by describing the size, morphology and phenotypes of MPs in physiological and pathological conditions, and second to develop reliable methods of EV detection and quantification.

In this initial study, we focused on MPs from platelet-free plasma (PFP) samples of healthy donors. Cryo-Electron Microscopy (EM) was used to reveal the morphology and size of the various types of particulate material present in pure plasma. Gold nanoparticles functionalized with various types of ligands were developed and used for labeling selected sub-populations of MPs, principally MPs exposing phosphatidylserine (PS), MPs derived from platelets and MPs derived from red blood cells, using Annexin-5 (Anx5), anti-CD41 and anti-glycophorin antibodies (Abs), respectively. In parallel, flow cytometry analysis of PFP was performed, focusing essentially on Anx5-binding MPs.

We found that PFP samples contain three main morphological types of MPs, consisting of spherical MPs, tubular-shaped MPs and large cell fragments. Spherical MPs constitute about 75% of all MPs present in PFP, most of them ranging in diameter from 50 to 500 nm. Tubular MPs form about 15% of all MPs, with a length extending over 5 μm, while large cell fragments extend up to 10 μm. Strikingly, we found that, in PFP, the sub-population of MPs that expose PS and bind Anx5 comprises only 25% of all MPs. We found also that about 20% of PFP MPs expose CD41, while most of the large cell fragments derive from red blood cells. Size histograms of the whole MP population and of the sub-populations of PS-positive, CD41-positive and glycophorin-positive MPs were determined, for the first time. In addition,

the influence of treatments like aging, centrifugation and freeze-thawing on MPs' structure and PS-exposure was investigated, showing a direct influence of some of these parameters on PS-exposure.
This study provides novel basic knowledge on plasmatic MPs and will serve as a reference for characterizing MPs in various pathological situations.

AS 15 – New Approaches to Antiplatelet Therapy

AS 15.1

Clinical implications of very low on-treatment platelet reactivity in patients treated with thienopyridines: the poba study (predictor of bleedings with antiplatelet drugs)

Cuisset T[1], Grosdidier C[2], Quilici J[1], Morange PE[2], Bonnet J-L[1] and Alessi M-C[2]

[1]*Service de Cardiologie;* [2]*UMR Inserm 1062, Marseille, France*

Background: New P2Y12 blockers and platelet monitoring has been proposed to optimize platelet inhibition after acute coronary syndrome (ACS) and improve ischemic outcomes. However, bleeding complications remain the 'Achilles' heel' of antiplatelet therapy and platelet monitoring could be useful to evaluate this risk.
Aims: The present study was designed to define the 'hyper response' to thienopyridine (very low on-treatment platelet reactivity (VLTPR)) as the most predictive threshold value of Platelet reactivity index VASP (PRI VASP) for prediction of non access-site related bleeding events. We also aimed to identify predictors of bleeding and VLTPR in patients treated with thienopyridines.
Methods and Results: One thousand five hundred and forty-two consecutive patients undergoing coronary stenting for ACS were included in the present study (287 on clopidogrel 75 mg, 868 on clopidogrel 150 mg and 387 on prasugrel 10 mg). During 6-month follow-up, 9% of patients ($n = 139$) suffered from non-access site related BARC bleeding complications. These patients were more often women, non-diabetic and had lower PRI VASP values than others ($P < 0.001$). ROC curves analysis (AUC = 0.71, $P < 0.01$) identified a threshold value for VLTPR of PRI VASP $\leq 10\%$ to predict bleeding events with a sensitivity of 17% and a specificity of 97%. While prasugrel was the main predictor of VLTPR in the whole population (OR [95% CI]: 10.2 [3–34.2]; $P < 0.001$), VLTPR was the strongest and independent predictor of bleeding (OR [95% CI]: 4.7 [2.7–8.3]; $P < 0.001$).
Conclusion: The present study identified VLTPR (PRI VASP $\leq 10\%$) as the strongest predictor of bleeding complications in patients treated with thienopyridines. This marker could be useful for tailored therapy and bleeding prevention.

AS 15.2

First ex vivo and *in vivo* assessment of anfibatide, a novel glycoprotein Ib-IV-V complex antagonist, in healthy human volunteers in phase I clinical trial

Li BX[1], Dai X[2], Yang Z[2], Qian F[2], Zhang G[2], Xu Z[2], Liu J[3], Liang C[1], Reheman A[4] and Ni H[4]

[1]*Lee's Pharmaceutical Holdings Limited., Shatin, Hong Kong;* [2]*Zhaoke Pharmaceutical co. ltd., Anhui;* [3]*School of Life Sciences, University of Science and Technology of China, Hefie, China;* [4]*Canadian Blood Services and St. Michael's Hospital, University of Toronto, Toronto, ON, Canada*

Background: Platelet adhesion and aggregation at the site of vascular injury are critical for hemostasis and thrombosis. It has been well accepted that interaction between the GPIb complex and von Willebrand factor (VWF) plays a key role in initiation of platelet adhesion, particularly at high shear. Platelet surface integrin aIIbβ3, through interaction with fibrinogen or other ligands, then mediates platelet aggregation and formation of a hemostatic plug or thrombus. Recently, the indispensable role of the GPIb-VWF interaction in platelet aggregation at extremely high shear (e.g. > 10,000/s; areas of stenosis following arteriosclerosis and/or thrombus growth) has been highlighted. Therefore, both the GPIb complex and aIIbb3 are considered major targets for antithrombotic therapies. Although several inhibitors of aIIbβ3 have been developed for antithrombotic therapies, no drug has been successfully developed to target the GPIb complex even though there are limitations for anti-aIIbβ3 therapies, including severe bleeding in some patients. The GPIb complex is, therefore, an attractive target for anti-thrombotic therapy.
Aims: To assess the effect of anfibatide on platelet function and safety in healthy human volunteers in phase I clinical trial.
Methods: Anfibatide, a 30 kDa polypeptide, was purified from *Agkistrodon acutus* snake venom and analyzed by mass spectrometry. The effects of Anfibatide on human platelet function were studied by *in vitro* platelet aggregometry, *ex vivo* perfusion chamber, and thrombealastography (TEG). The safety and efficacy of Anfibatide on platelet function and coagulation were evaluated in a total of 94 healthy human volunteers in a phase I clinical trial. The review board of Yijishan Hospital approved the study. All subjects provided informed consent.
Results: Anfibatide strongly inhibited ristocetin-induced human platelet aggregation and platelet adhesion, aggregation, and platelet thrombus formation on a collagen coated surface under high shear flow (1500/s). It also inhibited thrombus formation at low shear (300/s) but the efficacy was less than that at high shear conditions. Importantly, Anfibatide effectively dissolved the preformed thrombi when we continuously perfused Anfibatide-treated whole blood through perfusion chambers, demonstrating its potential as an anti-thrombotic therapy. TEG revealed no significant change in coagulation parameters after Anfibatide treatment. In this phase I clinical trial, no serious adverse events, premature discontinuations due to adverse events, or deaths occurred during the study. Results showed that Anfibatide can bind to approximately 95% of GPIb and inhibit up to 90% of ristocetin specific platelet aggregation without significantly prolonging human bleeding time, activated partial thromboplastin time, prothrombin time, or thrombin time. The inhibitory effect was undetectable 4 h after Anfibatide was withdrawn. There was also no spontaneous bleeding and no bleeding from blood collection sites. Anfibatide did not significantly affect platelet count and no anti-Anfibatide antibodies were detected in the subjects, suggesting that Anfibatide is well-tolerated in healthy individuals.
Conclusions: This research represents a comprehensive study of Anfibatide in healthy human subjects. This is the first clinical evidence that Anfibatide exhibits strong anti-platelet effects, excellent reversibility, and no significant bleeding diathesis in healthy human volunteers. Given these promising findings, Anfibatide may represent a novel and safe anti-platelet treatment.

AS 15.3

A network-biology based approach to elucidate determinants of platelet reactivity in aspirin-treated cardiovascular patients

Zufferey A[1], Ibberson M[2], Reny J-L[3], Nolli S[3], Docquier M[1], Xenarios I[2], Sanchez J-C[1] and Fontana P[3]

[1]*University of Geneva, Geneva;* [2]*University of Lausanne, Lausanne;* [3]*University of Geneva and University Hospitals of Geneva, Geneva, Switzerland*

Background: High platelet reactivity in aspirin-treated cardiovascular patients is a risk factor for recurrence of ischemic event, at least in acute settings. The determinants of platelet reactivity are largely unknown, but the investigation of healthy subjects suggests that they

are genetically determined. Network-biology is a novel and promising approach to identify cellular modulators of complex processes, such as platelet reactivity.
Aims: To identify the molecular mechanisms modulating platelet reactivity in aspirin-treated cardiovascular patients.
Methods: Platelet reactivity was assessed in 110 cardiovascular patients treated with aspirin 100 mg/day by light-transmission aggregometry using several agonists. Patients with extreme phenotypes were further studied by complementary platelet-derived 'omics approaches including quantitative proteomics, transcriptomics and genomics. These datasets were integrated using a network biology approach.
Results: More than 1000 proteins and 5000 mRNAS were quantified and 1.5 million SNPs were identified. The integration of the omics data allowed the construction of a network of 99 nodes (RNA/proteins) and 309 edges, representing platelet activation pathways differentially expressed in both phenotype groups. Genetic variants were then integrated into the network as a way to potentially stratify the patient population. Two network clusters presented a higher density of protein-protein relationships that were also confirmed in the literature. These included genes involved in cytoskeleton dynamics, integrin alpha-IIbIIIa-related aggregation processes and glucose metabolism.
Summary/Conclusion: As it is unlikely that a single causal gene or protein predicts the response to aspirin, a more holistic approach is required. Here we used a network-based strategy that allowed the seamless integration of several 'omics datasets. Using this strategy, we unveiled several candidate pathways modulating platelet reactivity in aspirin-treated cardiovascular patients. Aggregation relying on alpha-IIbIIIa, together with glucose metabolism and cytoskeleton dynamics appear to play a role in the modulation of platelet reactivity in cardiovascular patients under aspirin-treatment. These candidate pathways may delineate new targets for the prevention of ischemic events in cardiovascular patients.

AS 16 – Functional Characterisation of Hereditary Platelet Disorders

AS 16
Genetics, platelet dysfunction and bleeding

Freson K
Katholieke Universiteit Leuven, Leuven, Belgium

Inherited platelet disorders (IPDs) typically comprise defects in platelet number (thrombocytopenia), volume and/or function. Bleeding due to IPDs typically occurs immediately after injury, primarily in skin, mucous membranes, nose and gastrointestinal tracts. Platelets are easy accessible cells and different assays are available to study platelet function under basal and activated conditions. Defects in platelet morphology, adhesion, aggregation and secretion can result from mutations in platelet-specific genes leading to 'isolated' IPDs or from mutations in widely expressed genes leading to an IPD combined with a broader clinical phenotype. Recently, novel methods in epigenetics, proteomics and functional genetics in zebrafish led to the discovery of novel insights in the complexity of IPDs. I will discuss how we used these techniques to describe the role of DNA methylation in GNAS for regulating platelet function via cAMP, to define changes in lysosomal-like granules with differential cathepsin expression in platelets of Alternating Hemiplegia of Childhood patients and to show a role for Niemann Pick type C1 in megakaryopoiesis and platelet production starting from the observation in the zebrafish to verify thrombocytopenia in NPC1 patients. Though significant progress was made during the last years, the genetic factors that cause IPDs still remain largely unknown. IPDs are characterized by a high degree of genetic heterogeneity and are considered as rare diseases of man. Over the last decade, 274 patients were identified in our laboratory with an IPD of unknown etiology. After exclusion of known genetic causes, 176 patients have an isolated IPD that mainly includes thrombocytopenia (59 cases) or storage pool disease (29). In addition, 98 patients have an IPD combined with bone (26), neurological (60), endocrinological (4) or immune (4) defects. We also studied 6 IPD patients with bleeding problems due to a defect in the extra cellular matrix. By combining a genome-wide exome sequencing approach with knowledge of the platelet defect and extensive studies of the pathophysiology of IPDs, genes and pathways will be discovered that place pointers at new regulators of platelet function and/or formation. This last action will be performed as a collaborative effort of the BRIDGE-BPD consortium (www.bridgestudy.org) for rare bleeding and platelet disorders. Patients are collected by 34 specialized referral centers in Belgium, France, Germany, the Netherlands, the UK and the USA. I will here discuss the six IPD patients with a defect in the extracellular matrix. These patients have a variant of the Ehlers Danlos syndrome (EDS) with spontaneous bleeding problems and platelets with abnormal morphology. Genetics factors have been identified by candidate gene screening (COL1A1) and a pilot exome sequencing project from BRIDGE (novel gene on 15q15). We studied whether their abnormal platelets arose from defects in megakaryopoiesis due to an altered extra cellular matrix. This translational project based on knowledge exchange across different clinical disciplines, is expected to gain insights in molecular regulation of megakaryopoiesis and/or platelet function for also improved diagnosis and treatment of IPDs and to link these findings to other disease aspects.

AS 16.1
Abnormal megakaryocyte development and platelet function in a mouse model of gray platelet syndrome

Kahr WHA[1], Lo WC[2], Ni R[3], Li L[1], Pluthero FG[1], Vaezzadeh N[3], Weyrich AS[4], Di Paola JA[5], Landolt-Marticorena C[6] and Gross PL[3]
[1]Hospital for Sick Children; [2]University of Toronto, Toronto; [3]McMaster University, Hamilton, ON, Canada; [4]University of Utah, Salt Lake City, UT; [5]University of Colorado, Denver, CO, USA; [6]Toronto Western Hospital, Toronto, ON, Canada

Background: Gray platelet syndrome (GPS) is characterized by macrothrombocytopenia, bleeding, splenomegaly and the absence of platelet al. pha granules. The GPS molecular defect has recently been identified by our group (Nat Genet. 2011; 43(8):738–40) and others (Nat Genet. 2011; 43(8):732–4; Nat Genet. 2011; 43(8):735–7) as loss of function mutation of *NBEAL2* (neurobeachin-like 2).
Aims: To study platelet development and function in a mouse model of GPS.
Methods: Deletion of exons 4–11 *of Nbeal2* resulted in viable *Nbeal2*−/− mice. Platelet granule content and morphology were assessed by light, electron and immunofluorescence microscopy (IFM). Platelet protein content was assessed by immunoblotting and IFM, which was also used to observe megakaryocyte (MK) development in bone marrow cultures stained for DNA and structural and granular proteins. Platelet function was assessed by Multiplate analyzer, light transmission aggregometry (LTA) of washed platelets and flow cytometry. Spleen size was determined by weight. Thrombus formation in laser-injured cremaster arterioles was assessed using IFM; bleeding was evaluated by tail tip transection.
Results: Electron microscopy confirmed the absence of alpha granules in *Nbeal2*−/−platelets, and immunoblotting detected an absence of the abundant MK-synthesized alpha granule cargo proteins von Willebrand factor (VWF), thrombospondin-1 and platelet factor 4 (actin and P-selectin were normal). *Nbeal2*−/− MKs cultured from bone marrow showed decreased proplatelet formation, and while P-selectin distribution appeared normal, VWF (normally packaged into alpha granules) was observed to accumulate near the outer membrane, and in some MKs may have been extruded. *Nbeal2*−/− mice exhibited splenomegaly (spleen weight 0.13 +/- 0.03 g compared to WT 0.09 +/- 0.02 g; $n = 8$, $P < 0.005$). Relative to WT, collagen-induced aggregation of *Nbeal2*−/− platelets was reduced by half ($P < 0.001$) in the

Multiplate analyzer. LTA showed similar responses at high agonist concentrations and weaker response of *Nbeal2*−/− platelets to low concentrations, with < 5% aggregation seen with thrombin (0.05 U/mL, WT = 48%), CRP (0.05 μg/mL, WT = 21%) and U46619 (0.2 μM, WT = 76%). Flow cytometry showed CD41 activation (JONA expression) by thrombin and ADP (not collagen) was greatly reduced in *Nbeal2*−/− mice, as were thrombin and collagen (not ADP) induced P-selectin expression; maximal thrombin-induced P-selectin expression in *Nbeal2*−/− mice was 25% of WT. The peak size of laser-induced thrombi were smaller in *Nbeal2*−/− mice ($P < 0.05$). The ratio of P-selectin expression to thrombus size (identified via membrane GPIbβ) increased by less (40 vs. 70 AU, $P < 0.0001$) in thrombi generated in *Nbeal2*−/− mice compared to WT. Time to half maximal ratio (THMR) did not increase and the THMR of αIIb up-regulation was also similar for *Nbeal2*−/− and WT. *Nbeal2*−/− mice showed increased blood loss following tail tip transection (508 ± 162 vs. 43 ± 27 μL for WT).

Summary/Conclusions: *Nbeal2*−/− mice represent the first mammalian model of GPS. Like GPS patients, *Nbeal2*−/− mice exhibit splenomegaly, prolonged bleeding and platelet aggregation abnormalities, and their platelets lack both alpha granules and cargo. Exploiting the experimental advantages of our animal model, we have observed that megakaryopoiesis is abnormal and impaired in *Nbeal2*−/− mice, as is laser-induced thrombus formation. Our results confirm the importance of alpha granule secretion for platelet function *in vivo*.

AS 16.2

Nbeal2-deficient mice reveal a key role of platelet a-granules in arterial thrombosis, thrombo-inflammatory brain infarction and wound healing

Deppermann CN[1], Cherpokova D[1], Nurden P[2], Thielmann I[1], Kraft P[3], Nurden AT[2], Eckes B[4], Stoll G[3], Stegner D[1] and Nieswandt B[1]

[1]University Hospital and Rudolf Virchow Center, Würzburg, Germany; [2]Hôpital Xavier Arnozan, Pessac, France; [3]University of Würzburg, Würzburg; [4]University of Cologne, Cologne, Germany

Background: The most abundant platelet organelles, α-granules, contain more than 300 different proteins, which upon release participate in thrombus formation, haemostasis, inflammation and wound healing. However, the exact contribution of the plethora of α-granule proteins to thrombotic and thrombo-inflammatory processes has not been established. The gray platelet syndrome (GPS) is a rare congenital platelet disorder characterised by the lack of α-granules and their contents. Platelets of GPS patients appear gray and enlarged in the light microscope and aggregate poorly upon stimulation with thrombin and collagen. Characteristics of GPS include a macrothrombocytopenia, splenomegaly, myelofibrosis and a mild to moderate bleeding tendency that is occasionally severe. Only recently, mutations in *NBEAL2* (neurobeachin-like 2) have been linked to GPS. NBEAL2 is a large 302 kDa member of the BEACH-WD40 domain protein family. Other members of this family, such as Neurobeachin, Nbeal1, Lrba and Lyst, have been associated with protein trafficking.

Aim: Despite an extensive knowledge of α-granule contents and of the multiple roles for biologically active proteins secreted from platelets, relatively little is known about how they help to maintain haemostasis or of their participation in arterial thrombosis and thrombo-inflammatory processes. We now report the use of *Nbeal2*−/− mice to overcome the limitations of studying haemostasis and platelet pathology in patients with GPS and to investigate for the first time the role of α-granules and their contents *in vivo*.

Methods: Mice lacking the Nbeal2 protein were generated and megakaryocyte (MK) and platelet function and ultrastructure were assessed *in vitro* using biochemical methods combined with confocal and electron microscopy. *In vivo* function of Nbeal2-deficient platelets was studied in models of haemostasis, arterial thrombosis, ischaemic stroke and wound healing.

Results: *Nbeal2*−/− mice are viable and fertile but display the characteristics of human GPS with defective α-granule biogenesis in MKs, which leads to platelets lacking α-granules. Nbeal2-deficiency had no obvious effect on MK-differentiation and proplatelet formation *in vitro* or platelet life span *in vivo*. Nbeal2-deficient platelets showed impaired adhesion, aggregation and coagulant activity under flow ex vivo which translated into severely defective arterial thrombus formation *in vivo* and profound protection from thrombo-inflammatory brain infarction following focal cerebral ischaemia. Furthermore, wound healing experiments showed a reduced myofibroblast differentiation at the site of injury, which was attributed to decreased TGFβ release from Nbeal2-deficient platelets.

Conclusion: This study provides complementary evidence that NBEAL2 is essential for platelet α-granule biogenesis and reveals for the first time that α-granule constituents are critically required not only for haemostasis but also thrombotic and acute thrombo-inflammatory disease states while promoting tissue repair after injury.

AS 16.3

Defective thrombus formation in hermansky pudlak syndrome mice is due to impaired platelet granule exocytosis and reduced protein disulfide isomerase release

Sharda AV, Kim SH, Flaumenhaft R, Bowley S, Furie BC and Furie B

Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, USA

Background: Protein disulfide isomerase (PDI) is secreted from platelets upon cell activation, is captured on platelets and endothelial cells via β3 integrins and is required for thrombus formation.

Aims: To determine the potential role of platelet granules in PDI-mediated thrombus formation we studied a Hermansky Pudlak syndrome 6 (HPS6) mouse model in which platelet dense granules are absent.

Methods: Intravital microscopy using a laser injury model in mouse cremaster muscle arterioles was employed to determine the effect of the HPS6 mutation on platelet deposition, fibrin generation and extracellular PDI release during thrombus formation. Thrombin-induced granule exocytosis *in vitro* was studied using immunoflow cytometry and translocation of P-selectin and Toll Like Receptor 9 (TLR9) and Lysosome Associated Membrane Protein 1 (LAMP1) secretion as markers. Platelet Factor 4 (PF4) secretion was measured by ELISA.

Results: Platelet accumulation and fibrin generation were nearly absent in HPS6$^{-/-}$ mice after laser-induced injury. Extracellular PDI associated with the injured vessel wall was diminished, in the presence or absence of eptifibatide. *In vitro* studies demonstrated that HPS6$^{-/-}$ platelets contain similar levels of PDI compared to wild type platelets, but exocytosis of alpha granules, lysosomes and T-granules, the storage organelles for PDI, from HPS6$^{-/-}$ platelets showed decreased sensitivity to thrombin. At intermediate thrombin concentrations, P-selectin translocation from the alpha granule membrane into the plasma membrane and PF4 secretion from alpha granules were significantly lower in HPS$^{-/-}$ platelets compared to wild type platelets ($P < 0.001$ at 0.05 and 0.1 U/mL thrombin). Similarly, expression of TLR9, a T-granule marker, and LAMP1, a lysosome marker, required higher concentrations of thrombin to obtain comparable release from HPS6$^{-/-}$ platelets and wild type platelets ($P = 0.01$ at 0.05 U/mL thrombin). Release or expression of P-selectin, PF4, TLR9 and LAMP1 was comparable from wild type and HPS$^{-/-}$ platelets at a thrombin concentration of 1 U/mL. These results suggest a relative defect in granule exocytosis in HPS6$^{-/-}$ platelets. Infusion of wild type platelets to approximately 10% of the *in vivo* platelet concentration or infusion of recombinant PDI in HPS6$^{-/-}$ mice rescued both platelet thrombus formation and fibrin generation after laser injury. In contrast, neither infusion of an inactive PDI mutant nor thioredoxin had any effect on thrombus formation in HPS6$^{-/-}$ mice.

Conclusions: These results demonstrate that in HPS6$^{-/-}$ mice in which platelets lack dense granules, the exocytosis of alpha granules, T-granules and lysosomes is defective. At the concentrations of thrombin generated *in vivo* following laser injury, extracellular PDI accumulation is impaired due to either decreased PDI secretion or decreased PDI capture, or both. Defective granule exocytosis, in particular a deficiency in the release of the extracellular PDI necessary for PDI-mediated thrombus formation, is likely responsible for the bleeding disorder observed in Hermansky Pudlak syndrome. In this model, platelet accumulation and fibrin generation can be rescued with exogenous PDI despite the absence of platelet dense granules and their ADP and polyphosphate contents. This is the first example of a model of a human disease characterized by impaired PDI expression leading to a bleeding disorder.

AS 17 – Challenges in Therapeutic Management of VTE

AS 17.1

Risk of bleeding in patients with acute venous thromboembolism treated with rivaroxaban or enoxaparin/VKA and concomitant ASA therapy or NSAIDs: subanalysis from EINSTEIN DVT and PE studies

Davidson BL[1], Verheijen S[2], Lensing AWA[3] and Gebel M[3]
[1]*Harborview Medical Center, Seattle, WA, USA;* [2]*Biomedical Sciences, University of Amsterdam, the Netherlands;* [3]*Bayer HealthCare, Wuppertal, Germany*

Background: Combined anticoagulant and acetylsalicylic acid (ASA) therapy, or to a lesser extent non-steroidal anti-inflammatory drug (NSAID) therapy, is associated with an increased risk of bleeding in patients with atrial fibrillation and arterial vascular disease. The effect of concomitant use of these medications on bleeding in patients with venous thromboembolism is of considerable clinical importance.
Aim: This post hoc analysis assessed the impact of combined anticoagulant and ASA or NSAID therapy on bleeding risk compared with anticoagulant therapy alone in patients with deep vein thrombosis (DVT) and/or pulmonary embolism (PE) who participated in the EINSTEIN DVT and PE studies (The EINSTEIN Investigators. *NEJM* 2010; 363:2499; The EINSTEIN-PE Investigators. *NEJM* 2012; 366:1287).
Methods: ASA therapy was defined as all drugs containing ASA (including acetylsalicylates), while NSAIDs were defined by means of ATC code M01A. Bleeding events that were adjudicated as clinically relevant (major and non-major) were used for this analysis. Antiplatelet therapy other than ASA was used very infrequently and not analysed further.
Event rates per 100 patient-years with or without exposure to ASA or NSAID therapy were computed for the entire at-risk period, and hazard ratios (HR) for use vs. non-use (adjusted for age and creatinine clearance) were calculated using co-medication as a time-dependent covariate.
Results: The safety population comprised 4130 patients who received rivaroxaban and 4116 patients who received enoxaparin/vitamin K antagonist (VKA), of whom 1202 (14.6%) and 1884 (22.8%) patients received concomitant ASA or NSAID therapy, respectively. During ASA-rivaroxaban treatment, clinically relevant bleeding occurred with an event rate of 34.9 per 100 patient-years compared with 16.1 during non-ASA use (HR = 1.79 [95% CI 1.35–2.38]), whereas during ASA-enoxaparin/VKA treatment, an event rate of 39.1 was found, compared with 17.8 when ASA was not used (HR = 1.58 [1.16–2.15]). In patients treated with ASA-rivaroxaban, major bleeding occurred with an event rate of 3.3 per 100 patient-years compared with 1.6 during non-ASA use (HR = 1.49 [0.62–3.57]), whereas during ASA-enoxaparin/VKA treatment an event rate of 6.9 was found, compared with 2.9 during non-use (HR = 1.49 [0.73–3.02]). During NSAID-rivaroxaban treatment, clinically relevant bleeding occurred with an event rate of 37.6 per 100 patient-years compared with 15.8 during non-use (HR = 1.93 [1.47–2.53]), whereas during NSAID-enoxaparin/VKA use, an event rate of 37.3 was found, compared with 17.4 during non-use (HR = 1.68 [1.29–2.21]). During NSAID-rivaroxaban treatment, major bleeding occurred with an event rate of 4.74 per 100 patient-years compared with 1.43 during non-use (HR = 2.60 [1.23–5.48]), whereas during NSAID-enoxaparin/VKA treatment, an event rate of 8.4 was found compared with 2.7 during non-use (HR = 2.32 [1.31–4.12]).
Conclusions: The combination of anticoagulant and NSAID therapy increased the risk of both clinically relevant bleeding and major bleeding by approximately two-fold, whereas for concomitant ASA use, the risk of clinically relevant bleeding was increased by about 1.5-fold without a statistically significant effect on major bleeding alone. The increase in risk of clinically relevant and major bleeding was similar for patients treated with rivaroxaban and those treated with enoxaparin/VKA. DVT and PE patients should avoid taking NSAIDs for prolonged periods without an important clinical indication for NSAID use.

AS 17.2

Vitamin K antagonist treatment patterns and persistence after venous thromboembolism in non-cancer patients: VTE Epidemiology Group (VEG) Study

Cohen A[1], Martinez C[2], Wallenhorst C[2] and Bamber L[3]
[1]*King's College Hospital, London, UK;* [2]*Im Dinkelfeld 32, Frankfurt;* [3]*Bayer HealthCare, Wuppertal, Germany*

Background: Anticoagulation with vitamin K antagonists (VKAs) and low molecular weight heparins (LMWHs) is effective in preventing recurrence of venous thromboembolism (VTE). Guidelines typically recommend 3 months' treatment for events provoked by temporary risk factors, with longer treatment considered for unprovoked VTE. VKA management of VTE, deep vein thrombosis and pulmonary embolism in primary and secondary care is not well documented.
Aims: To assess treatment patterns and persistence with VKA treatment in a large contemporary cohort of unselected patients with non-cancer-related VTE.
Methods: A population-based cohort study, involving two million patients, retrieved data from the subset of general practices in England contributing to the Clinical Practice Research Datalink (CPRD) linked to data from the Hospital Episodes Statistics (HES) and to the Office for National Statistics (ONS). From January 2008 to October 2011 all incident cases of VTE were stratified into provoked and unprovoked non-cancer-related VTE. All VTE cases were verified with an algorithm based on review of medical records, hospital diagnoses, cause of death and anticoagulation therapy.
We identified all patients who initiated VKA use in the first 3 months after an initial VTE and followed them for the entire duration of VKA treatment. The observation of patients with a recurrent VTE and major bleeding was censored at the time of the event. VKA use was defined by prescriptions, repeated international normalized ratio tests, medical codes and electronic search of medical notes. Duration of VKA use was estimated by connecting VKA prescriptions based on a prescription length of 28 days and a 28 days grace period. Persistence with VKA treatment was derived from Kaplan–Meier estimates and expressed as the percentage of those on VKA therapy at 3, 6 and 12 months.
Results: A total of 8504 patients had a first VTE and a follow-up of at least 7 days: 5019 patients with DVT and 3485 patients with PE with or without DVT. The mean age of patients was 63.5 years; 46.4% were male. Of the total, 3130 (36.8%) patients had a provoked non-cancer event and 5374 (63.2%) patients had an unprovoked event.

Of the 5374 patients with unprovoked VTE, 15.4% had no record for anticoagulation use in the 90 days after the venous thromboembolic event and 84.6% of patients received anticoagulation (67.0% VKA alone, 12.2% both LWMH and VKA, and 5.4% LWMH alone). Higher rates of anticoagulation were recorded for PE patients (86.1%) compared with DVT patients (79.3%).

Persistence with VKA therapy in the complete VTE cohort was 77.4% at 3 months, 50.3% at 6 months and 11.4% at 12 months. Treatment persistence for patients with provoked VTE was 76.8%, 49.0% and 10.3% at 3, 6 and 12 months, respectively, and for unprovoked VTE these values were 77.8%, 51.1% and 11.9%, respectively.

Summary/Conclusions: Currently, VKA therapy after provoked VTE is given for longer than recommended. Conversely, after unprovoked VTE, patients receive VKA therapy for shorter durations than recommended. Reasons for the non-adherence to guidelines merit further investigation.

AS 17.3

Elderly patients with venous thromboembolism: cancer or no cancer, a different therapeutic approach?

Mahe I[1], Bertoletti L[2], Sterpu R[1], Pépin M[1], Hennou S[1], Schellong S[3], Garcia-Bragado F[4], Monreal M[5] and G. RIETE[6]

[1]Louis Mourier Hospital, Colombes; [2]Hôpital Nord – CHU St-Etienne, Saint Etienne, France; [3]Municipal Hospital of Dresden Friedrichstadt., Dresden, Germany; [4]Hospital de Girona Dr Josep Trueta, Girona; [5]Hospital Universitari Germans Trias i Pujol, Barcelona; [6]RIETE, Barcelona, Spain

Background: Elderly patients are usually excluded from clinical trials assessing anticoagulant therapies in venous thromboembolism (VTE) treatment. However, current guidelines recommend similar anticoagulant therapy for patients with VTE, regardless of their age, even though its efficacy and safety have not yet been assessed in the elderly.

Aims: To assess the rate of recurrent VTE, major bleeding and death in patients older than 75 years who experienced pulmonary embolism (PE) or deep venous thrombosis (DVT) during anticoagulation; to further investigate occurrence of these events in subgroups according to the presence or not of cancer, and type of anticoagulation used.

Methods: We used data from the Registro Informatizado de Enfermedad TromboEmbólica (RIETE) registry, an ongoing international, multicentred, real-life prospective registry of consecutive patients presenting with symptomatic, acute VTE. All patients provided written or oral consent for participation in the registry, in accordance with local ethical committee requirements. Outcome measures includedVTE, PE, DVT, major bleeding, death, presence or not of cancer, and antithrombotic medication.

Results: Up to December 2010, 11,403 patients older than 75 years had been enrolled in RIETE. Of these, 2229 (19.5%) had active cancer. During the course of anticoagulation (mean, 216 ± 440 days), 2.3% of patients developed recurrent PE, 2.2% recurrent DVT, 3.9% had major bleeding, and 12.8% died. Compared with patients with no cancer, patients with cancer were frailer, with more comorbidities; they had a higher risk of VTE recurrence (5.2% vs. 4.4%, $P = 0.04$ [for PE, 3.1% vs. 2.2%, $P = 0.004$; for DVT, 2.2% in both groups]), major bleeding (5.1% vs. 3.6%, $P = 0.001$), and death (28% vs. 9.1%, $P = 0.0001$).

In the group without cancer, patients receiving long-term LMWH experienced significantly more VTE recurrence (5.8% vs. 3.8%, $P = 0.006$), PE recurrence (2.9% vs. 1.9%, $P = 0.005$) and major bleeding (6.0% vs. 2.5%, $P = 0.001$) than those who were receiving VKA.

In the group with cancer, although they were at higher risk for bleeding and recurrent VTE, patients receiving LMWH experienced nonsignificantly less PE recurrence than those receiving VKA (1.8% vs. 2.02%, $P = 0.3$); a similar rate was observed in patients without cancer and receiving VKA (1.9%). In patients receiving long-term LMWH, the rate of major bleeding was similar in patients with and without cancer (6.1% and 6.0%, respectively).

Conclusions: We identified two different populations in elderly patients with VTE. Overall, in patients without cancer, long-term LMWH therapy was harmful in terms of recurrent VTE and major bleeding. However, in patients with cancer, long-term LMWH therapy had a different effect, and kept the risk of PE recurrence within the range of that of patients without cancer, without increasing the risk of bleeding. Further studies are needed to prospectively assess the efficacy and safety of long-term LMWH therapy in the elderly patient.

AS 18 – Prevention of Recurrent VTE

AS 18.1

Assessment of the risk of recurrent venous thrombosis using a genetic risk score comprising five genetic markers

Van Hylckama Vlieg A[1], Flinterman LE[1], Bare LAL[2], Cannegieter SC[1], Arellano AR[2], Tong CH[2], Devlin J[2] and Rosendaal FR[1]

[1]Leiden University Medical Center, Leiden, the Netherlands; [2]Celera, Alameda, CA, USA

Background: Previously, we reported on a genetic risk score (GRS) comprising five single nucleotide polymorphisms (SNP) improving the prediction of a first venous thrombosis. The prediction of recurrent venous thrombosis using individual genetic risk predictors has proven to be challenging.

Aim: The aim of this study was to assess whether the 5-SNP GRS is associated with recurrent venous thrombosis.

Methods: Patients with a first venous thrombosis included in the MEGA case-control study between 1999 and 2004, were followed for a recurrent venous thrombosis up to 2009 ($n = 4731$). Included in the current analyses were patients with a first venous thrombosis without a history of malignant disease or oral anticoagulant use during follow-up and with a valid measurement for all five SNPs included in the GRS ($n = 3121$). Consent and ethical approval were obtained. The GRS for each individual was calculated by summing the number of risk-increasing alleles for each of the following five SNPs: rs6025 (F5, factor VLeiden), rs1799963 (F2, 20210 G>A), rs8176719 (ABO), rs2066865 (FGG 10034 C>T) and rs2036914 (F11). The risk of recurrent venous thrombosis associated with the GRS was calculated continuously, i.e. per addition of one risk allele, and after stratification in a low and high risk score (i.e. ≤ 2 risk alleles and ≥ 5 risk alleles) by calculating hazard ratios (HR), adjusted for age and sex. The cumulative incidence of recurrence was calculated after 2 and 4 years of follow-up for individuals with a low GRS and individuals with a high GRS. Analyses were performed in the overall patient group and after stratification into patients with a first idiopathic or provoked event. Idiopathic thrombosis was defined as absence of surgery, trauma, plaster cast, hormone use (oral contraceptives and hormone therapy), or pregnancy within 3 months before the first event, and not within 4 weeks postpartum.

Results: The 5-SNP GRS was positively associated with the risk of recurrent venous thrombosis, i.e. the addition of one risk allele to the GRS increased the risk of a recurrence (HR = 1.2; 95% CI: 1.1–1.3). This risk was similar in patients with an idiopathic or provoked first event. After stratification in a high and low GRS, the risk of recurrence was higher in patients with a high GRS than in patients with a low GRS (Overall HR = 2.0, 95% CI: 1.5–2.6; idiopathic first event: HR = 1.7, 95% CI: 1.1–2.5; provoked first event: HR = 2.2, 95% CI: 1.5–3.2).

The overall 2-year cumulative incidence of recurrence was 6.1% (95% CI: 5.2–6.9). The incidence was clearly higher in patients with a high GRS than in patients with a low GRS (high: 10.3%, 95% CI: 7.2–13.4; low: 4.4%, 95% CI: 3.2–5.6). This difference remained also after 4 years of follow-up (high GRS: 14.9%, 95% CI: 11.3–18.5, low GRS:

8.8%, 95% CI 7.1–10.5). The GRS was predictive of the risk of recurrent thrombosis both in patients with an idiopathic and patients with a provoked first event.
Summary/Conclusion: This 5-SNP GRS was associated with an increased risk of recurrent thrombosis. The GRS can identify patients with a high absolute risk of recurrence.

AS 18.2

Prevention of pulmonary embolism recurrences by retrievable vena cava filter: results of the randomized multicenter trial PREPIC 2

Mismetti P[1], Ennezat P-V[2], Quéré I[3], Jeannot S[2], Barral F-G[2], Couturaud F[4], Elias A[5], Teinturier C[6], Laporte S[6] and Meyer G[7]
[1]Teaching Hospital, Saint-Etienne; [2]Centre hospitalo-Universitaire, Lille; [3]Saint Eloi Hospital, Montpellier; [4]Hôpital de la Cavale Blanche, Brest; [5]Hopital Toulon Font Pre, Toulon; [6]Centre Hospitalo-Universitaire, Grenoble; [7]Hopital Européen Georges Pompidou, Paris, France

Background: Vena cava filter insertion in patients with an acute proximal deep vein thrombosis (DVT) with or without pulmonary embolism (PE) is associated with a lower risk of PE at short-term (< 1 month) but an increase risk of DVT at long term (> 6 months) (Decousus H et al. *N Engl J Med* 1998; PREPIC Study Group. *Circulation* 2005). In this way, retrievable filter could be used during the high-risk period of PE recurrences and then removed to avoid the late increase in the risk of DVT recurrences.
Aim: To assess the efficacy and safety of retrievable filter implanted for 3 months in patients with symptomatic PE.
Methods: We conducted a multicenter prospective open randomized study with a blind evaluation that compared retrievable vena cava filter (ALN) maintained for 3 months with no filter insertion in patients receiving anticoagulant therapy for an unprovoked acute symptomatic confirmed PE associated with a thrombosis of the lower limb. Patients were eligible if they were considered at high risk of PE recurrences, i.e. when presenting at least one of the following risk factors: age over 75, right ventricular dysfunction, active cancer, bilateral and/or ilio-caval DVT, cardiorespiratory insufficiency. A systematic retrieval of filter was planned at 3 months in the filter group and both groups were followed-up for three additional months. The primary efficacy outcome was recurrent PE at 3 months. Secondary outcomes were DVT at 3 months, VTE at 6 months, major bleeding, overall mortality at 3 and 6 months and filter complications.
Results: The study recruited 399 patients in 18 centers from August 2006 to July 2012: 200 given filter (filter was really inserted in 193) and 199 given no-filter. All patients received an initial parenteral anticoagulant therapy (heparins 85%, fondaparinux 15%) followed by vitamin K antagonists (89%) or prolonged low molecular weight heparins (11%). Median age was 76 years, 35% had a history of DVT or PE, 97% had a concomitant DVT, 25% had a cancer. Last patient last visit was January 16th, 2013. Recurrence of PE at 3 months occurred in six patients (3.0%) in the filter group compared to three patients (1.5%) in the no-filter group, RR = 2.0 (0.51–7.89). These events included six and two fatal PE respectively. At 3 months, no difference was found on DVT (0.5% in both groups); eight patients in the filter group had major bleeding (4.0%), vs. 10 in the no-filter group (5.0%). At 3 months, 15 deaths (7.5%) occurred in the filter group and 12 (6.0%) in the no-filter group. Filter removal was attempted in 165 patients and successful for 152 (92.1%). Thirteen patients died before retrieval, and retrieval was not attempted for the following reasons: permanent indication of filter or poor clinical status (11 patients), vena cava filter thrombosis (3) or patient's refusal (1). Results at 6 months will be presented at the congress.
Conclusions: In the lack of contra-indication to anticoagulation, these results do not plead for retrieval vena cava filter insertion in patients with an acute PE.

AS 18.3

D-dimer to select patients with a first unprovoked venous thromboembolism (VTE) who have anticoagulants stopped at 3–7 months or have treatment continued indefinitely: a multicentre management study

Kearon C and For the D-dimer Optimal Duration Group
McMaster University, Hamilton, ON, Canada

Background: Patients with unprovoked venous thromboembolism (VTE) who have a normal D-dimer level 1 month after withdrawing anticoagulant therapy have been reported to have a reduced recurrence risk; however, it remains uncertain if this risk is low enough to justify using D-dimer to decide if anticoagulation is stopped.
Aims and Methods: We did a prospective multicentre study to determine if patients < 75 years with a first unprovoked proximal DVT or PE have a low risk of recurrence (about 5% per year, with an upper 95% CI of no more than 7.0% per year) if they have a negative point-of-care D-dimer test (Clearview-Simplify, Alere; qualitative result [positive or negative]) while on anticoagulants, and again 1 month after stopping therapy (Negative D-dimer group). Patients with a positive D-dimer test remained on, or restarted, anticoagulants and continued them indefinitely (Positive D-dimer group). Patients provided written informed consent, and the study was approved by the research ethics boards of all clinical centres.
Results: Four hundred and ten patients (51 years, SD 14; 44% females) were enrolled after 5.0 months (SD 1.3) of initial anticoagulant therapy and have been followed for 2.0 years (SD 0.9) to date. D-dimer was positive on therapy in 14/410 (3.4%) patients who, therefore, remained on anticoagulants. Of 391 patients with a negative D-dimer on therapy and then had anticoagulants withdrawn, D-dimer converted to positive at 1 month in 57 (15%) patients, and 55 of these restarted anticoagulant therapy. 320/410 (78%) patients were in the Negative D-dimer group and 318 of these remained off anticoagulant therapy. In the Negative D-dimer group, recurrent VTE was: 5.6% per year (95% CI 4.0–7.8; 35 recurrences) in all patients (n = 318); 8.2% per year (95% CI 5.6–11.6; 29 recurrences) in men (n = 179); 3.9% per year (95% CI 1.6–8.1; six recurrences) in women with an initial VTE not associated with estrogens (n = 81); and 0% per year (95% CI 0.0–2.6; 0 recurrences) in women with an initial VTE associated with estrogens (n = 58). The rates of recurrent VTE differed among the three subgroups (P = 0.0014). In the Positive D-dimer group, recurrent VTE and major bleeding were each 2.6% per year (95% CI 0.8–6.2; four recurrent VTE and four major bleeds) in the 69 patients who remained on anticoagulant therapy. Findings will be updated when scheduled follow-up is completed on 30 June 2013.
Conclusion: There was a high risk of recurrent VTE in men with a first unprovoked VTE who had a D-dimer test that remained negative 1 month after stopping therapy; therefore, negative D-dimer testing alone does not justify stopping anticoagulants after 3–7 months in men. However, the risk of recurrent VTE in women with unprovoked VTE who had negative D-dimer testing, including those who had VTE that was not associated with estrogen therapy, appears to be low enough to justify stopping anticoagulants after 3–7 months.

AS 19 – Vascular Disorders

AS 19.1

Risk factors for chronic pulmonary hypertension: VTE Epidemiology Group (VEG) Study

Cohen AT[1], Martinez C[2] and Rietbrock S[2]
[1]King's College Hospital, London, UK; [2]Pharmaepi.com, Frankfurt, Germany

Background: Chronic pulmonary hypertension (CPH) occurs in around 5% of patients following pulmonary embolism (PE) and

results in significant morbidity, mortality and cost. CPH occurs following index PE and less commonly following an index deep vein thrombosis (DVT), presumably in conjunction with sub-clinical PE. The recognition of risk factors may help to evaluate high risk groups and guide therapy type and duration. To simplify decision making these factors for CPH must be assessed allowing for the presence, quality and absence of anticoagulant therapy.

Aim: To explore potential risk factors for CPH.

Methods: Patient data were retrieved from the subset of general practices in England contributing to the Clinical Practice Research Database (CPRD) that has been linked to data from the Hospital Episodes Statistics (HES) and to the Office for National Statistics (ONS). From January 2001 to October 2011, all VTE cases in the CPRD were verified with an algorithm based on review of medical records and notes, hospital diagnoses, cause of death and anticoagulation therapy. We conducted a nested case-control study in patients with a first VTE. CPH in any time during the entire observational period were defined as cases and the date of CPH as the index day. For each case we selected five non-CPH controls at random matched on the index day and with the same duration of observation as the respective case. The independent association between the potential risk and CPH was derived from conditional multivariate logistic regression models and presented as adjusted odds ratios (ORs) with 95% confidence intervals (CIs). Adjustment included age, gender, socioeconomic risk factors, components of the Charlson index, and the type of antithrombotic therapy (VKA, low molecular weight heparin or antiplatelet therapy).

Results: Of 35,373 patients with first VTE, 29,550 patients survived more than 7 days, had 81,906 person-years of observation, and were at risk of CPH. Over the observational period and after at least 90 days following first VTE 256 cases of CPH were identified.

The OR of CPH was greater in the following risk factors: following PE compared with DVT, OR 3.92 (2.56–6.01), PE with DVT compared with DVT, OR 4.43 (2.19–8.98); and with recurrent PE, OR 2.43 (1.28–4.62) but not with recurrent DVT.

Patients were less likely to develop CPH were males, OR 0.63 (0.42–0.95); as were those with INR with Time in Therapeutic Range (TTR) > 60%, OR 0.22 (0.07–0.66); TTR 40–60%, OR0.33 (0.11–0.99) compared to those with poor control TTR < 40%.

Summary/conclusions: The recognition of risk factors for CPH should facilitate the need for further investigations and the decision for appropriate therapy and extension of anticoagulant therapy in VTE patients.

AS 19.2

Residual vein thrombosis as a strong predictor of recurrent thromboembolism and post-thrombotic syndrome: a prospective cohort study

Prandoni P[1], Lensing AWA[2], Prins MH[3], Noventa F[1], Pesavento R[1], Tormene D[1] and Villalta S[4]

[1]University of Padua, Padua, Italy; [2]Centre for Vascular Medicine, Amsterdam; [3]Department of Clinical Epidemiology, Maastricht, the Netherlands; [4]Division of Internal Medicine, Treviso, Italy

Background: Whether residual vein thrombosis (RVT) increases the risk of recurrent venous thromboembolism (VTE) after an episode of deep vein thrombosis (DVT) is controversial. Moreover, it is virtually unknown whether and to what extent RVT increases the risk of the post-thrombotic syndrome (PTS).

Aims: We sought to determine the risk of recurrent VTE, mild and severe PTS over a 3-year follow-up in a wide cohort of patients with proximal DVT who had the ultrasound assessment of the common femoral and the popliteal veins 3 months after the thrombotic episode.

Methods: We followed-up prospectively for up to 3 years 906 consecutive outpatients who referred with an episode of proximal DVT, as shown by compression ultrasonography (CUS), and received conventional anticoagulation. Patients with a recent (< 2 years) episode of DVT involving the same leg were excluded, as were those unavailable for repeating CUS. After 3 months the common femoral and the popliteal veins were scanned in the transverse section with CUS. RVT was accepted in case of a vein diameter > 4 mm under maximum compressibility in at least one spot. Over the 3-year follow-up the development of recurrent VTE, mild and severe PTS (as assessed with the Villalta scale) was independently recorded by three investigators.

Results: RVT was detected in 483 of the 906 patients (53.5%). Patients with RVT were more likely to be males (52.3 vs. 42.3%; $P = 0.038$), to have a previous VTE (15.7 vs. 10.2%; $P = 0.017$) and to have an extensive (both femoral and popliteal) involvement of the vein system (54.9 vs. 28.6%; $P < 0.00001$). After the 3-year follow-up period recurrent VTE developed in 82 patients (17.0%; 32 in the ipsilateral leg) in the group with RVT and in 41 (9.7%; nine in the ipsilateral leg) in that without RVT; overall PTS in 275 (56.9%; severe in 35) and 127 (30.0%; severe in 10), respectively. After adjusting for age, sex, previous VTE, obesity, risk factors for DVT (unprovoked or provoked), location of DVT, presence of clinically symptomatic PE and duration of anticoagulation the HR and its 95% CI for the development of recurrent VTE in patients with RVT as compared with those with earlier vein recanalization was 1.94 (1.32–2.83), and that of PTS 2.27 (1.83–2.81).

Conclusions: RVT, as assessed by CUS 3 months after an episode of proximal DVT, is a powerful and independent predictor of recurrent VTE and PTS in patients with proximal DVT. Males, patients with previous VTE and those with extensive involvement of the deep vein system are more likely to develop RVT.

AS 19.3

Health-related quality of life after catheter-directed thrombolysis for deep vein thrombosis; from the CaVenT study

Enden TR, Wik HS, Kvam AK, Haig Y, Klow NE and Sandset PM

Oslo University Hospital, Oslo, Norway

Background: Additional catheter-directed thrombolysis (CDT) with alteplase for extensive deep vein thrombosis (DVT) reduces the frequency of the long-term chronic complication post-thrombotic syndrome (PTS) compared to standard treatment. PTS has been shown to be a predictor of reduced quality of life (QOL) following DVT of the lower limb.

Aims: To investigate whether additional CDT improves long-term QOL compared to standard treatment with anticoagulation and compression stockings alone.

Methods: The CaVenT Study was an open, multicenter, randomized, controlled trial. Prior to treatment allocation, written informed consent was obtained. Patients (18–75 years) with high proximal DVT above mid-thigh level and symptoms < 21 days were randomized to receive additional CDT or standard treatment alone. At 6 and 24 months follow-up visits patient reported QOL was obtained using the generic QOL questionnaire EQ-5D and the venous disease-specific QOL questionnaire VEINES-QOL/Sym. PTS was assessed with the Villalta scale. The study protocol was approved by the Regional Committee for Medical and Health Research Ethics and the Norwegian Medicines Agency, and was registered at www.clinicaltrials.gov with the unique trial identifier NCT00251771.

Results: One hundred and eight-nine of 209 patients completed 24 months follow-up. Mean age was 51.5 years (SD 15.8) and 70 (37%) participants were female. Mean duration of symptoms before diagnosis and start of treatment was 6.6 days (SD 4.6). Most baseline demographic and clinical characteristics, including VEINES-QOL/Sym and EQ-5D scores, were fairly equally distributed between the two treatment groups. After 24 months PTS was observed in 41% allocated CDT compared to 56% of control patients ($P < 0.05$). There were no differences between the two treatment arms regarding the

patient reported outcomes EQ-5D index and VEINES-QOL and -Sym scores. Patients who developed PTS reported poorer long-term outcomes in terms of all three scores ($P < 0.001$), and regarding the VEINES scores these differences were also present at 6 months follow-up ($P < 0.001$); all differences were likely to represent clinically meaningful differences.

Summary/Conclusion: Long-term QOL did not differ between patients treated with additional CDT for a high proximal DVT compared to anticoagulation and compression therapy alone. Patients who developed PTS reported poorer generic and disease-specific QOL and more symptoms than patients without PTS. QOL should be included as an outcome measure in clinical studies with patients who are at risk of PTS.

AS 20 – New Developments in Treatment of VTE

AS 20.1

A phase 2 randomized, double-blind, placebo-controlled trial of PRT064445, a novel, universal antidote for direct and indirect factor Xa inhibitors

Crowther M[1], Kitt M[2], Lorenz T[2], Mathur V[3], Lu G[2], Hutchaleelaha A[2], Hollenbach S[2], Curnutte J[2] and Becker RC[4]
[1]McMaster University, Ontario, ON, Canada; [2]Portola Pharmaceuticals, South San Francisco; [3]MathurConsulting, Woodside, CA, USA; [4]Duke University, Durham, NC, USA

Background: Direct factor Xa inhibitors have superior anticoagulant efficacy and/or safety relative to warfarin and low molecular weight heparin but are limited by lack of a specific antidote to reverse anticoagulation during episodes of serious bleeding or before surgery. PRT064445 (PRT) is a modified, human recombinant fXa that is catalytically inactive but retains high-affinity binding to direct fXa inhibitors (fXai) and heparin-antithrombin III complexes. It competes with native fXa for fXai drugs, thus reversing direct and indirect fXai-mediated anticoagulation. In a previous Phase 1 study ($n = 32$), in the presence of PRT in subject plasma samples, ex-vivo thrombin generation and anti-fXa activity of rivaroxaban were reversed in a dose-dependent manner.

Aims: To evaluate dose-response of PRT in reversing the anticoagulant effects of several fXai, pharmacokinetics (PK), and overall safety in up to 144 healthy volunteers.

Methods: This ongoing Phase 2, double-blind, placebo-controlled study is examining the effects of PRT with apixaban, rivaroxaban, enoxaparin, and betrixaban. Each fXai will be studied with up to four different dose cohorts of PRT or placebo in a 6:3 ratio (i.e. up to 36 subjects per fXai). Subjects are treated on Days 1–6 with fXai (to steady state) and then dosed with IV PRT or placebo on Day 6, 3 h after the fXai dose. Pharmacodynamic and safety data are collected through Day 48 and PK through Day 10. A chromogenic assay was used to determine anti-fXa activity.

Results: We are reporting available data from the first PRT dose cohort of nine subjects, who received apixaban 5 mg bid (11 doses), followed by a bolus of PRT (90 mg) or placebo IV. Anti-fXa activity peaked at 3 h after the last dose of apixaban at which time PRT/placebo was administered. Within 2 min, the mean anti-fXa activity decreased by −65% following PRT ($n = 4$) vs. +6% in the placebo group ($n = 2$). At 10, 30, and 60 min post-PRT or placebo, the comparable values were −47% vs. +7%; −29% vs. +11%; and −17% vs. +3%. Similarly, plasma concentrations of *unbound* apixaban decreased immediately after PRT but were unchanged following placebo. Based on a mean apixaban plasma concentration of 474 nM and an estimated PRT plasma concentration of 314 nM, the PRT/apixaban molar ratio was 0.66, indicating that this initial low dose of 90 mg PRT bound approximately two thirds of the apixaban in the plasma. This value is in good agreement with the observed 65% decrease in anti-fXa activity. PRT was temporally associated with a transient reduction in tissue factor pathway inhibitor (TFPI) activity and increase in F1+F2, but no change in D-dimer. There were no thrombotic or allergic-type adverse events, serious adverse events, or deaths. PRT was well tolerated; 5/9 subjects experienced one or more adverse events; all were mild.

Summary/Conclusions: Emerging in vivo data from this trial confirm prior ex-vivo observations and animal models that PRT reverses anticoagulant effects of fXai. PRT is a well-tolerated, and potentially promising, universal antidote for fXai. Additional data with higher doses will be presented.

AS 20.2

No need for a rivaroxaban dose reduction in renally impaired patients with symptomatic venous thromboembolism

Bauersachs R[1], Lensing AWA[2], Pap A[2] and Decousus H[3]
[1]Klinikum Darmstadt GmbH, Darmstadt; [2]Bayer HealthCare, Wuppertal, Germany; [3]Université Jean Monnet, Saint-Etienne, France

Background: Rivaroxaban is an oral, direct Factor Xa inhibitor. One-third of the rivaroxaban dose is excreted renally as unchanged drug. Consequently, rivaroxaban exposure increases with declining creatinine clearance (CrCl), with area under the curve ratios of 1.44 (95% confidence interval [CI] 1.08–1.91), 1.52 (95% CI 1.15–2.01) and 1.64 (95% CI 1.24–2.17) observed in patients with CrCl 50–79, 30–49 and < 30 mL/min, respectively (Kubitza et al. 2010). Dose-finding studies for deep vein thrombosis (DVT) treatment showed a flat dose-response for recurrent venous thromboembolism (VTE), with no increase in major bleeding for total daily doses of rivaroxaban of 20–60 mg and no increase in major bleeding in patients with CrCl 50–79 mL/min or < 50 mL/min. Therefore, in the EINSTEIN DVT and PE studies, the rivaroxaban dose was not reduced in patients with renal impairment.

Aims: To assess rates of bleeding and recurrent VTE in patients with renal impairment treated with fixed-dose rivaroxaban compared with standard VTE treatment in EINSTEIN DVT and PE.

Methods: Patients with acute symptomatic DVT and/or pulmonary embolism were randomized to receive fixed-dose rivaroxaban (15 mg twice daily for 3 weeks followed by 20 mg once daily) or subcutaneous weight-adjusted enoxaparin followed by a vitamin K antagonist (VKA) (international normalized ratio 2.0–3.0) for 3, 6 or 12 months. Patients with CrCl < 30 mL/min were excluded. Rates of major bleeding and recurrent VTE were assessed. Subgroup analyses were performed for patients with normal renal function (CrCl ≥ 80 mL/min) and mild (CrCl 50–79 mL/min) or moderate (CrCl < 50 mL/min) renal impairment.

Results: A total of 4130 patients received rivaroxaban and 4116 patients received enoxaparin/VKA. Major bleeding occurred in 40 (1.0%, three fatal) and 72 (1.7%, eight fatal) patients in the rivaroxaban and enoxaparin/VKA groups, respectively (hazard ratio [HR] = 0.54; 95% CI 0.37–0.79; $P = 0.002$). In patients with normal renal function, major bleeding occurred in 23/2739 (0.8%) patients receiving rivaroxaban and in 29/2776 (1.0%) patients receiving enoxaparin/VKA (HR = 0.79, 95% CI 0.46–1.37). In patients with mild renal impairment, major bleeding occurred in 14/1024 (1.4%) patients and 30/993 (3.0%) patients, respectively (HR = 0.44, 95% CI 0.24–0.84). In patients with moderate renal impairment, major bleeding was observed in 3/329 (0.9%) patients and 13/320 (4.1%) patients, respectively (HR = 0.21, 95% CI 0.06–0.73). In the rivaroxaban group, the incidence of recurrent VTE increased from 49/2748 (1.8%) patients with normal renal function to 24/1030 (2.3%) and 11/332 (3.3%) patients with mild or moderate renal impairment, respectively. In the enoxaparin/VKA group, the incidence increased similarly from 52/2787 (1.9%) to 30/992 (3.0%) and 11/322 (3.4%) patients, respectively.

Summary/Conclusions: Rivaroxaban 15 mg twice daily for 3 weeks, followed by 20 mg once daily, was not associated with increased major

bleeding in patients with reduced renal function. Compared with enoxaparin/VKA, rivaroxaban was associated with a relative risk reduction of major bleeding of ~55% and ~78% in patients with mild and moderate renal impairment, respectively. The incidence of recurrent VTE increased with declining renal function in both treatment groups (P-value for trend = 0.002). We conclude that a rivaroxaban dose reduction is not indicated in patients with DVT or pulmonary embolism with mild/moderate renal impairment.

AS 20.3

Inhibition of coagulation factor XII provides thromboprotection in extracorporeal circulation without increasing bleeding risk

Larsson M[1], Theinert K[1], Labberton L[1], Rayzman V[2], Nolte MW[3], Panousis K[2], Pragst I[3], Dickneite G[3] and Renné T[1]

[1]Karolinska Institutet, Stockholm, Sweden; [2]CSL Limited, Parkville, Vic., Australia; [3]CSL Behring GmbH, Marburg, Germany

Background: Anticoagulation treatment for prevention of thromboembolic diseases is associated with an increase in potentially life-threatening bleeding. Thus, it constitutes a priority to develop novel targets for efficient and safe anticoagulation. Deficiency in coagulation factor XII (FXII) protects mice in models of thromboembolic disease. Despite its critical role in thrombosis, FXII deficiency does not increase bleeding risk in patients.

Aims: Here, we analyzed inhibition of FXII activity in rabbits as a potential novel anticoagulation strategy, devoid of bleeding risk.

Methods and Results: We used phage display to develop a monoclonal antibody directed against activated FXII (anti-FXIIa antibody CSL-3F7). CSL-3F7 selectively interferes with FXII-mediated thrombin formation and clotting in rabbit plasma. CSL-3F7 dose-dependently blocked collagen-induced thrombus formation under venous and arterial flow in rabbit blood. To analyze the efficacy and safety of CSL-3F7 in a clinical setting that requires potent anticoagulation, we set up a model of Extra Corporeal Membrane Oxygenation (ECMO) for rabbits. A single bolus of CSL-3F7 was as efficient as high-dose, heparin in terms of thromboprotection during ECMO and prevented clot formation for up to 6 h. In contrast, bypass systems occluded in < 3 min in buffer-infused animals. Despite its striking thromboprotective efficiency, CSL-3F7 did not increase skin and cuticle bleeding times and had no effect on blood loss as assessed by liver and skin wound injury.

Conclusions: The data establish CSL-3F7, a FXIIa-neutralizing antibody, as a potent thromboprotective agent in extracorporeal circulation and indicate that targeting FXII activity offers a safe strategy for prevention of thrombosis that is not associated with the frequent complications of bleeding seen with currently used anticoagulants.

AS 21 – The Interplay Between Coagulation and Inflammation

AS 21

Tissue factor signaling and inflammation

Ruf W

The Scripps Research Institute, La Jolla, CA, USA

The Tissue Factor (TF) pathway is directly linked to physiological repair mechanisms and the host defense against infection. TF is induced by inflammatory mediators in myelo-monocytic cells where danger signals from dying cells or associated with complement activation regulate TF procoagulant activity dependent on protein disulfide isomerase, coupling the initiation of inflammation with local activation of the coagulation cascade. The role of TF is not restricted to the initiation of coagulation and, in addition, signaling of TF protease complexes plays a pivotal role in the regulation of innate immune responses and inflammation. Recent data show that the TF pathway is a critical inducer of the chronic inflammation in obesity. TF adipocyte signaling contributes to the development of obesity, whereas TF expressed by adipose tissue macrophages regulates their inflammatory phenotype. Loss of TF-PAR2 signaling in the hematopoietic compartment of obese mice attenuates adipose tissue inflammation and promotes a switch of adipose tissue macrophages to an anti-inflammatory phenotype typically seen in lean mice. TF forms two distinct signaling complexes. The binary, coagulation inactive TF-VIIa complex interacts with 1 integrins and only cleaves PAR2. The ternary TF-VIIa-Xa complex mediates Xa-dependent activation of PAR1 or PAR2. Xa signaling in this complex is strictly dependent on the endothelial protein C receptor (EPCR). Macrophages found in adipose and tumor tissues express components of these signaling complexes. Further insight into the control of macrophage phenotypes by the TF pathway is expected to emerge from the characterization of regulated expression and interactions of TF signaling components in macrophages during acute and chronic inflammation.

AS 21.1

Formation of neutrophil extracellular traps in skin wounds of mice retards healing

Wong SL[1], Martinod K[1], Demers M[1], Gallant M[2], Wang Y[3] and Wagner D[1]

[1]Boston Children's Hospital, Harvard Medical School; [2]Boston Children's Hospital, Boston, MA; [3]Pennsylvania State University, Pennsylvania, PA, USA

Background: Wound healing is an important restorative process in response to tissue injury. Failure of effective wound repair in chronic inflammatory conditions can result in ulcers and amputation. Approximately 3–6 million people in the US suffer from non-healing wounds. Inflammation is one of the early phases of wound repair in which neutrophils play a central role. Upon stimulation, neutrophils can release their chromatin and granule proteins, forming neutrophil extracellular traps (NETs) that act as another mechanism of innate immunity. Peptidylarginine deiminase 4 (PAD4) is abundantly expressed in neutrophils and can decondense chromatin by converting arginine on histones to citrulline. PAD4-mediated histone hypercitrullination is a critical step for neutrophils to extrude their chromatin to make NETs. NETs limit the spread of bacteria and may kill them via the locally concentrated antibacterial components. Their non-specific cytotoxicity, however, may also be injurious to host tissue. High concentration of neutrophil elastase, which is also a NET component, can cause excessive degradation of the wound matrix that is unfavorable to healing. Whether NETs are present in wounds and their impact on the healing process has not been explored.

Aims: Our aims were to determine whether NETs are formed during wound healing and to examine whether they facilitate wound repair or delay the process.

Methods: Full thickness wounds were made with sterile 4-mm biopsy punches in the dorsal skin of wild-type (C57BL/6) mice. Wounds were observed for the presence of extracellular DNA. Mice deficient in CD18 ($CD18^{-/-}$) with defective leukocyte recruitment to sites of tissue damage, and wild-type mice depleted of neutrophils using an anti-Ly6G antibody (1A8 clone) were used to examine whether neutrophils were the main producers of such extracellular DNA. $PAD4^{-/-}$ mice whose neutrophils cannot make NETs were used to evaluate the impact of NETs formation in wound healing. The wounds were digitally photographed for 14 days and total wound area was calculated using ImageJ software. Recruitment of neutrophils and re-epithelialization reflected by keratinocyte migration were examined by histology. Citrullination of histone H3 (H3Cit), a marker for NETs formation, and neutrophil marker (Ly6G) were localized in wound sections by fluorescence microscopy and quantified by Western blotting.

Results: Western blot analysis of wounds from wild-type mice showed that H3Cit appeared the first day after wounding and peaked from days 3 to 7. Immunofluorescence imaging revealed the co-localization of H3Cit with $Ly6G^+$ cells in the scab. H3Cit was absent in wounds from $CD18^{-/-}$ or $PAD4^{-/-}$ mice and reduced by ~80% in mice depleted of neutrophils. $PAD4^{-/-}$ mice exhibited accelerated wound repair, re-epithelialization and wound closure. NET-like extracellular DNA structures, seen as blue spikes with hematoxylin, were observed in wounds from wild-type but not $PAD4^{-/-}$ mice.
Summary: Neutrophils are the main producers of extracellular DNA during wound healing and NETs represent a major component of skin wounds. PAD4-dependent NET production has a negative impact on healing, thus inhibition of NET formation may accelerate wound repair.

AS 21.2
Protease-activated receptor 1 contributes to early immune responses in the lung after influenza A infection

Antoniak S[1], Milner J[2], Beck M[2] and Mackman N[1]
[1]UNC McAllister Heart Institute; [2]UNC Gillings School of Global Public Health, Chapel Hill, NC, USA

Background: Influenza A (IVA) is a RNA virus that infects the lungs and causes considerable morbidity and mortality. Toll-like receptor-3 (TLR3) signaling plays a central role in controlling IVA replication. TLR3 activation leads to the expression of an antiviral program that includes interferon (IFN). Recruited natural killer (NK) cells kill infected cells. Furthermore, IVA infection was shown to induce local production of different proteases that activate protease-activated receptor-1 (PAR1). Recently, we found that PAR1 deficiency resulted in increased coxsackievirus B3-induced myocarditis. This observation was mediated by a PAR1-dependent increase in TLR3-IFNβ-CXCL10 expression. In contrast to our findings, the Riteau group found that PAR1 stimulation resulted in increased mortality after IVA infection. Two companies have developed anti-PAR1 drugs as novel antiplatelet drugs. However, PAR1 is expressed by many cell types and these drugs may have off-target effects and possibly interfere with early immune responses.
Aim: At present, the role of PAR1 during virus infection of the lung is controversial. Here, we investigated whether PAR-1 plays a role in the innate immune responses to IVA.
Methods: Male $PAR1^{+/+}$ (wild-type, WT) and $PAR1^{-/-}$ mice (age of 10–12 weeks) were infected intranasally with 50 μl of 0.02 hemagglutinating units of IVA H1N1/PR8. IVA genome levels, expression of IFNs and inflammatory mediators were analyzed by qRT-PCR 1, 3 and 7 days post infection (dpi) in lungs of infected WT and $PAR1^{-/-}$ mice. Further, we analyzed the effect of PAR1 stimulation on the TLR3-signaling pathway on bone-marrow derived macrophages (BMDM). Lastly, we analyzed the role of PAR1 for NK cell activity.
Results: $PAR1^{-/-}$ mice exhibited significantly reduced levels of IFNβ in the lung compared to WT mice 1 dpi. ($P < 0.05$). In addition there were reduced levels of the NK cell marker, NK1.1, and five-fold more IVA genomes in the lungs of $PAR1^{-/-}$ mice compared to WT mice 3 dpi ($P < 0.05$). Increased IL1β and TNFα expression was also observed in PAR-1 deficient mice lungs compared to WT mice 3 dpi. However, WT mice exhibited higher levels of IFNγ, CXCL10, IL1β and TNFα in the lungs compared to $PAR1^{-/-}$ mice 7 dpi. TLR3 stimulation experiments with BMDM showed that PAR1 activation enhances TLR3-IFNβ-CXCL10 pathway in a p38 dependent fashion. Furthermore, we found that maximal NK cell activity of a splenocyte population was dependent on the PAR1 expression.
Conclusion: We found that PAR1 contributes to early antiviral immune responses in the lung after IVA infection. An absence of PAR1 was associated with reduced IFNβ and NK cell infiltration in the lung that appears to lead to increased virus replication and inflammation 3 dpi. Our data indicate that PAR1 has a role in early immune responses by inducing early innate immune responses to IVA. We speculate that inhibition of PAR1 might lead to accelerated IVA replication in the early phase of infection.

AS 21.3
Activated protein C glycosylation status dictates protease-activated receptor 1 proteolysis and anti-inflammatory signaling efficacy

Gleeson E, Ní Áinle F, Kenny BA, O'Donnell J and Preston RJS
Trinity College Dublin, Dublin 12, Ireland

Background: Protein C circulates in plasma as two major glycoforms (α and β), characterized by the presence (α-protein C) or absence (β-protein C) of an N-linked glycan chain at position Asn-329. Upon activation, a recombinant mimic of β-activated protein C (APC^{N329Q}) exhibits significantly improved ability to maintain endothelial cell barrier integrity and limit endothelial cell apoptosis compared to wild type APC. Despite its potential importance in defining endogenous APC anti-inflammatory activity, the molecular basis of enhanced β-APC cytoprotective signaling is currently unknown.
Aims: We sought to determine how enhanced protease-activated receptor 1 (PAR1)-dependent cytoprotective signaling by β-APC is mediated, and investigate whether site-specific glycosylation status is also an important determinant in PAR1-independent APC cell signaling. Furthermore, we examined whether partial glycosylation and associated enhanced PAR1 signaling function was similarly conserved in murine APC.
Methods: A PAR1 cleavage alkaline phosphatase reporter assay was used to assess the rate of PAR1 proteolysis by APC on HEK293T cells co-transfected with endothelial cell protein C receptor (EPCR). APC inhibition of lipopolysaccharide (LPS)-induced pro-inflammatory cytokine secretion from human or murine myeloid cells was assessed by ELISA or by using cytokine-specific reporter cell lines. The role of APC glycosylation in PAR1 proteolytic activity and anti-inflammatory function was determined by enzymatic removal of APC N-linked glycans with PNGase F, and also by utilization of recombinant APC variants rendered incapable of glycan moiety attachment at specific sequons, namely Asn-248 (APC^{N248Q}), Asn-313 (APC^{N313Q}) and Asn-329 (APC^{N329Q}) in human APC, and Asn-330 in murine APC ($mAPC^{N330Q}$).
Results: The rate of EPCR-dependent PAR1 proteolysis by PNGase F-treated APC was more than double that of untreated APC. APC^{N329Q} exhibited comparably enhanced PAR1 proteolysis to that of PNGase F-treated APC, whereas variants APC^{N313Q} and APC^{N248Q} were similar in efficacy to wild type APC. PAR1-dependent inhibition of TNFα and IL-6 secretion from macrophages was significantly more effective in the presence of either PNGase F-treated APC or APC^{N329Q} than with untreated wild type APC. No difference, however, was observed in the ability of untreated, PNGase F-treated, or recombinant site-specific glycan variant APC to mediate PAR1-*independent* inhibition of TNFα secretion from LPS-treated monocytes. Finally, SDS-PAGE analysis revealed that murine APC migrates as a glycosylation-dependent doublet, which, like human APC, mediates significantly increased PAR1-dependent inhibition of TNFα and IL-6 secretion from LPS-stimulated murine macrophages upon pre-incubation with PNGase F. In addition, a recombinant version of murine β-APC ($mAPC^{N330Q}$) exhibited equally improved anti-inflammatory activity to that of PNGase F-treated murine APC in the same assay.
Summary/Conclusions: In this study, we show that the PAR1-dependent anti-inflammatory signaling activity of both human and murine APC is regulated by N-linked glycans at Asn-329 and Asn-330 respectively, which act to impede efficient PAR1 proteolysis and thereby limit cytoprotective signaling. Furthermore, our data imply a key role for the endogenous β-APC glycoform in dictating PAR1-dependent

APC anti-inflammatory activity *in vivo*, and highlights the therapeutic potential of recombinant N-linked glycan sequon-specific APC variants for the treatment of acute inflammatory disease.

AS 22 – Inhibitors in Haemophilia A

AS 22.1

Factor VIII gene (F8) mutation and inhibitor development in non-severe hemophilia A

De Groot-Eckhardt CL[1], Van Velzen AS[1], Peters M[2], Peerlinck K[3], Oldenburg J[4], Santagostino E[5], Astermark J[6], Van Heerde WL[7], Hermans C[8], Morfini M[9], Castaman G[10], Haya S[11], McRae S[11], Reitter-Pfoertner SE[12], Kamphuisen PW[13], Van Der Bom JG[14], Fijnvandraat KJ[1] and For the INSIGHT consortium[15]

[1]Emma Children's Hospital, Academic Medical Center, Amsterdam, the Netherlands; [2]Emma Children's Hospital, amsterdam, the Netherlands; [3]University of Leuven, Leuven, Belgium; [4]University Hospital Bonn, Bonn, Germany; [5]Angelo Bianchi Bonomi Hemophilia and Thrombosis Centre, Milan, Italy; [6]Malmö University Hospital, Lund University, Malmö, Sweden; [7]St. Radboud University Medical Center, Nijmegen, the Netherlands; [8]St-Luc University Hospital, Brussels, Belgium; [9]Azienda Ospedaliera Careggi, Florence, Italy; [10]La Fe Polytechnic and University Hospital, valencia, Spain; [11]Royal Adelaide Hospital, Adelaide, Australia; [12]Medical University of Vienna, Vienna, Austria; [13]University Medical Center Groningen, Amsterdam, the Netherlands; [14]Sanquin Research/Leiden University Medical Center, Leiden, the Netherlands

Background: The development of neutralizing antibodies (inhibitors) towards factor VIII is a major complication in non-severe hemophilia A, profoundly aggravating the bleeding pattern. Identification of high risk patients is hampered by lack of data on the association between factor VIII gene (*F8*) mutations and the development of inhibitors that take exposure days to therapeutic factor VIII concentrates into account.

Aims: To determine the risk of inhibitor development in patients with non-severe hemophilia A and to analyze the association with *F8* mutation, taking exposure days to therapeutic factor VIII concentrates into account.

Methods: The study population was derived from a source population of 2711 non-severe hemophilia A patients (factor VIII 2–40%), treated in 34 hemophilia treatment centers in Europe and Australia (the INSIGHT consortium). The association between *F8* mutation and inhibitor development was assessed in 1112 patients, only recruited from centers that had genotyped at least 70% of their patients. Inhibitor risk was calculated as Kaplan–Meier incidence with cumulative number of exposure days as time variable. Thus, risk was calculated as the proportion of patients that developed an inhibitor after a certain number of exposure days (e.g. 20 or 50) to therapeutic factor VIII concentrates.

Results: During 44,800 exposure days (median 24 exposure days per patient; Inter Quartile Range (IQR), 7–90), 59 of the 1112 patients developed an inhibitor; cumulative incidence of 5.3% (95% confidence interval (CI), 4.0–6.6) after a median of 28 exposure days (IQR, 12–71). The inhibitor risk at 50 exposure days was 6.7% (95% CI, 4.5–8.9) and at 100 exposure days this risk was further increased to 13.3% (95% CI, 9.6–17.0). Among a total of 221 different *F8* point mutations 19 were associated with inhibitor development. The inhibitor risk was highest for R593C, D2074G, R2159C and W2229C, reaching 19%, 21%, 39% and 42%, respectively, at 50 exposure days.

Conclusion: Among a total of 221 different point mutations, 19 mutations were associated with inhibitor development. Longitudinal analysis revealed that the inhibitor incidence in non-severe hemophilia A patients with certain *F8* mutations approaches the incidence observed in patients with severe hemophilia. These results emphasize the importance of *F8* genotyping in non-severe hemophilia A. New preventive and therapeutic approaches in this patient group are urgently needed.

AS 22.2

Effect of type and intensity of FVIII exposure on inhibitors development in hemophilia A: first results of an individual patient data meta-analytic project

Marcucci M[1], Mancuso ME[2], Santagostino E[2], Kenet G[3], Elalfy M[4], Holzhauer S[5], Bidlingmaier C[6], Escuriola Ettingshausen C[7], Iorio A[1] and Nowak-Göttl U[8]

[1]McMaster University, Hamilton, ON, Canada; [2]IRCCS Cà Granda Foundation, Maggiore Hospital Policlinico, Milan, Italy; [3]Sheba Medical Centre, Tel-Hashomer, Israel; [4]Ain Shams University, Cairo, Egypt; [5]Charite, Berlin; [6]University Hospital Munich, Munich; [7]HZRM – Haemophilia Centre Rhein Main, Frankfurt-Moerfelden; [8]Univ. Hospital Münster, Münster, Germany

Background: The role of treatment-related factors in the development of inhibitors in hemophilia A patients is highly debated; in view of the scanty evidence from randomized and large prospective trials, a collaboration between researchers to pool a large amount of individual patient data (IPD) and a rigorous methodological approach to their analysis can maximize the reliability of the obtainable evidence.

Aims: To explore the impact of the source of FVIII concentrate and of the intensity of treatment on inhibitor development in previously untreated patients (PUPs) with hemophilia A using different statistical approaches to investigate the role of possible confounders.

Methods: Data source: prospectively collected IPD on PUPs with moderate-severe hemophilia A treated in hemophilia centers in Germany, Italy, Israel, Egypt. Outcome: Inhibitor formation (Bethesda titer > 0.5 BU). Treatment-related risk factors on study: FVIII source (recombinant [rFVIII] vs. plasma-derived [pdFVIII]) and treatment intensity (high-intensity [initial dose ≥ 150 IU/Kg/week] vs. low-intensity). Other risk factors included as covariates/confounders: family history of inhibitors, severity of hemophilia, gene mutation (null/non-null), age at the first exposure to FVIII, regimen (on-demand/prophylaxis), surgery at first exposure and birth year. Statistical methods: meta-analysis of the pooled cohorts by (i) univariate and multivariate Cox regression, with exposure days (EDs) as time-to-event; (ii) CART analysis; (iii) Cox regression with covariate-adjustment using propensity scores for FVIII source and intensity; (iv) calculating the Average effect of Treatment on Treated (ATT) using different methods of matching/stratification on propensity score. Analyses were stratified by country and/or included country as covariate. Multiple-imputation techniques were used to manage missing data. Sub-group analyses: severe patients and high responding (HR) inhibitors.

Results: 761 PUPs (86% severe) were followed up for over 150 EDs (3–490), 241 (31.7%) of whom treated with rFVIII; among 700 patients with available data on initial weekly dose, 116 (16.6%) received a high-intensity treatment. Twenty-seven percent (208/761) developed inhibitors (172 HR) considering the entire population, 38% among patients treated with rFVIII and 22% among those treated with pdFVIII (unadjusted HR 2.2, 95% CI 1.6–3.0); 53% among those receiving an high-intensity treatment and 23% among those treated less intensively (unadjusted HR 3.6, 95% CI 2.6–4.9). Only treatment intensity, and not FVIII source, held an overall statistically significant effect in multivariate Cox analyses, either directly adjusted for covariates or adjusted for propensity scores, and showed a stable significant ATT across different matching methods. According to a significant interaction effect between the two treatment-related factors, rFVIII was associated to a higher risk of inhibitors vs. pdFVIII only in case of low-intensity treatment. CART analysis assigned hierarchically and

automatically a primary effect to treatment intensity and family history of inhibitors, and a secondary effect to FVIII source. Similar results were found for only severe patients and only HR.
Conclusion: Different statistical approaches to pooled IPD confirmed that a high intensity treatment increased the risk of inhibitor while the effect of recombinant or plasma-derived FVIII sources was partially confounded by patient-related risk factors and dependent on the intensity of the exposure.

AS 22.3
Defective indoleamine 2,3-dioxygenase induction is associated with inhibitor development in severe hemophilia A patients carrying F8 gene null mutations

Matino D[1], Iorio A[2], Gargaro M[1], Santagostino E[3], Santoro C[4], Di Minno G[5], Morfini M[6], Puccetti P[1] and Fallarino F[1]
[1]University of Perugia, Perugia, Italy; [2]McMaster University, Hamilton, ON, Canada; [3]Angelo Bianchi Bonomi Hemophilia and Thrombosis Centre, Milan; [4]University La Sapienza, Rome; [5]Federico II University, Naples; [6]Azienda Ospedaliera Careggi, Florence, Italy

Background: The occurrence of neutralizing antibodies (inhibitors) to FVIII is a major obstacle to successfully treating hemophilia A patients. Mutations resulting in the absence (or severe truncation) of FVIII protein are associated with the highest risk of inhibitor formation in that they prevent a patient's immune system from initiating central tolerance to FVIII. However, the occurrence of inhibitors only in a minority of those patients on replacement therapy suggests that effective regulatory mechanisms of peripheral tolerance operate extrathymically in most patients harboring FVIII-reactive lymphocytes. A recently elucidated mechanism whereby antigen-presenting cells (APCs) promote and maintain peripheral tolerance involves immunosuppressive tryptophan catabolism by indoleamine 2,3-dioxygenase (IDO). When activated in APCs, the immunoregulatory enzyme IDO changes the antigen-presenting profile of those cells from immunogenic to tolerogenic, contributing to immune homeostasis under a variety of pathophysiological conditions.
Aims: To study the possible role of peripheral tolerance to FVIII, we investigated IDO induction, expression, and activity in severe hemophilia A patients for any possible relationship with inhibitor development.
Methods: We enrolled 45 severe hemophilia A patients who had developed high-titer inhibitors (> 5 BU/mL) and 45 age-matched inhibitor-negative patients (consistently inhibitor-free after at least 150 ED). All subjects in this study, whether inhibitor-positive or inhibitor-negative, carried F8 gene mutations expected to cause complete absence of functional FVIII protein, namely large deletions, nonsense mutations, or intron 1 and 22 inversions, which are all thought to prevent central tolerance development to FVIII. PBMCs were isolated by standard technique. IDO competence was assessed by evaluation of IDO protein and mRNA induction, while IDO activity was analyzed by HPLC measurement of l-kynurenine production (the first breakdown product of tryptophan catabolism by IDO). Informed consent was obtained before enrollment, according to a protocol approved by the ethical committees of the individual participating Centers, in accordance with the Declaration of Helsinki.
Results: Significant differences in IDO induction were found between inhibitor-positive and inhibitor-negative patients by: (i) immunoblot analysis of protein expression (densitometry units; inhibitor-positive patients, 8.9 ± 7.3; inhibitor-free patients 20.5 ± 9.2; $P < 0.0001$); (ii) RT-PCR for IDO mRNA (mRNA fold change; inhibitor-positive patients 1.65 ± 0.54; inhibitor-free patients 3.35 ± 1.6; $P < 0.0001$); and by (iii) kynurenine production (μm/L; inhibitor-positive patients 0.90 ± 0.53; inhibitor-free patients 1.84 ± 0.94; $P < 0.0001$). Overall, 32 out of the 45 inhibitor-free patients showed upregulated IDO expression and function in response to stimulation, whereas 16 of the 45 inhibitor-positive patients were capable of up-regulating IDO (OR 4.45; 95% CI 1.83–10.8, $P = 0.001$).
Conclusions: Our results support the relevance of peripheral tolerance mechanisms in the development of FVIII inhibitors. In particular, our data show that defective IDO induction is associated with inhibitor development in severe haemophilia A patients. Further details on peripheral tolerance in haemophilia A patients could help develop an effective strategy to predict or even prevent (or eradicate) inhibitors through mechanisms of tolerance acquired in the periphery, whether in prophylaxis – to reduce the incidence rate of inhibitors – or in ITI to increase its likelihood to succeed.

AS 23 – What's New in Fibrinolysis?

AS 23.1
PAI-1 is a critical determinant of senescence and survival in klotho mice, a murine model of accelerated aging

Eren M[1], Boe AE[1], Sheila BM[1], Place AT[1], Nagpal V[1], Budinger GR[1], M Mutlu G[1], Miyata T[2] and Vaughan E[1]
[1]Northwestern University, Chicago, IL, USA; [2]Tohoku University, Sendai, Japan

Background: Advanced age contributes to the development of frailty and disease in humans, but the fundamental mechanisms that drive aging are incompletely understood. Cellular senescence correlates with the synthesis of several secreted factors, collectively termed the Senescence-Messaging Secretome (SMS), including insulin-like growth factor binding proteins (IGFBPs), interleukins (ILs), TGF-b, and plasminogen activator inhibitor-1 (PAI-1). The *klotho* gene functions as an aging-suppressor gene; thus klotho-deficient (*kl*/*kl*) mice develop an accelerated aging-like phenotype characterized by a truncated lifespan (64 ± 26 days), infertility, ectopic calcification, and emphysema. Since PAI-1 is markedly elevated in *kl*/*kl* mice and is a critical determinant of replicative senescence *in vitro*, we hypothesized that PAI-1 is essential for development of the phenotype in *kl*/*kl* mice.
Aims: We aimed to investigate the effects of PAI-1 deficiency (partial or complete) on the phenotypic abnormalities exhibited by *klotho* mice.
Methods: Heterozygous *klotho* and PAI-1 knockout mice were bred to generate partial (*kl*/*klpai-1*+/−) or complete (*kl*/*klpai-1*−/−) PAI-1 deficiency in *klotho* mice. Lifespan, body weight and physical activity level of these mice were monitored. Plasma levels of SMS factors, FGF23 and Vitamin D_3 were measured by ELISA methods. Senescence in kidneys was assessed by measuring expression levels of $p16^{Ink4a}$ by qRTPCR and immunostaining. Telomere length in various tissues was quantitatively determined using a qRTPCR method. Emphysema phenotype was characterized by histological evaluation of lung tissues and measuring the partial oxygen pressure in arterial blood. The von Kossa stain was performed on kidney and heart tissues to study ectopic calcification.
Results: Partial (*kl*/*klpai-1*+/−) or complete (*kl*/*klpai-1*−/−) PAI-1 deficiency increased the average lifespan of *kl*/*kl* mice by 4.0-fold to 257 ± 171 and 275 ± 127 days, respectively ($P = 0.0001$). The median survival was 58 days for *kl*/*kl*, 163 days for *kl*/*klpai-1*+/− and 246 days for *kl*/*klpai-1*−/− mice. Furthermore, both *kl*/*klpai-1*−/− and *kl*/*klpai-1*+/− mice exhibited increased body weight, normal fertility, and were protected against emphysematous changes and ectopic calcification developed by *kl*/*kl* mice. While plasma levels of SMS factors IGFBP-3 and IL-6 were significantly elevated in *kl*/*kl* mice, PAI-1 deficiency normalized these factors in *kl*/*klpai-1*+/− and *kl*/*klpai-1*−/− mice. Similarly, *kl*/*kl* mice had shortened telomere length in a number of tissues including liver, aorta, and skin, whereas in *kl*/*klpai-1*+/− and *kl*/*klpai-1*−/− mice, telomere length in these tissues was preserved. Moreover, the renal expression of the senescence biomarker $p16^{Ink4a}$ was 3.1-fold higher in *kl*/*kl* and reduced by 80% in *kl*/*klpai-1*−/− mice. Finally, *kl*/*klpai-1*+/− and *kl*/*klpai-1*−/− mice had significantly

decreased plasma levels of FGF23 (99%) and vitamin D3 (76%), which are biochemical hallmarks of klotho deficiency.
Conclusion: This is the first demonstration that modulating the activity of PAI-1, a key component of the SMS, can prolong survival and prevent the development of senescence in a mouse model of accelerated aging. These findings indicate that PAI-1 is a critical determinant of senescence *in vivo* and that novel therapies targeting PAI-1 or other components of the SMS may prevent senescence and aging-related pathologic changes in humans.

AS 23.2

Hyperfibrinolytic states induce blood-brain barrier disruption by a plasmin-bradykininn dependent mechanism.

Marcos-Contreras OA, Martinez de Lizarrondo S, Yvan Frigout C, Orset C, Bardou P, Isabelle, Focault I, Montagne A, Maubert E, Parcq J, Vivien D and Gauberti M*

Inserm UMR-S U919, GIP Cyceron, Caen, France, Caen, France

Background: Hyperfibrinolysis is a pathological condition occurring in various clinical disorders and treatments, such as trauma, liver cirrhosis or administration of fibrinolytics. It is characterized by an exacerbated activity of endogenous clot-bursting proteases, including tissue-type plasminogen activator (tPA). Apart from increased bleeding tendency, the pathophysiological implications of hyperfibrinolysis remain largely unknown.
Aims: To develop an experimental model of hyperfibrinolysis and to study its effects on the intact blood-brain barrier (BBB).
Methods: In order to induce sustained high plasmatic levels of tPA, in C57BL6J mice, we performed hydrodynamic transfection of a cDNA encoding for tPA with specific expression in the liver. Subsequently, we assessed the effects of tPA overexpression on BBB permeability and cerebrovascular inflammation by Near Infrared Fluorescence, immunohistology, quantitative PCR and molecular magnetic resonance imaging (MRI).
Results: 48 h after hepatic transfection, plasmatic overexpression of tPA induced BBB leakage. We did not find difference between control and tPA transfected animals in inflammation markers: Iba-1 positive cells, positive vessels overexpressing vascular endothelial adhesion molecule 1 (VCAM-1), mRNA levels of: interleukine-1 beta (IL-1B), tumor necrosis factor (TNF). Deletion of the finger domain (to prevent its interaction with the low density lipoprotein related receptor, LRP) or mutation of the K2 domain of tPA (to prevent its interaction with the N-Methyl-D-Aspartate receptor, NMDA-R) did not influence post-transfection BBB permeability. In contrast, concomitant administration of tranexamic acid, epsilon-aminocaproic acid or aprotinin completely prevented BBB leakage, suggesting a plasmin-dependent mechanism. This effect was NMDA-R, protease activated receptor-1 and matrix-metalloproteinases independent. In fact, we demonstrated that tPA-induced BBB leakage was dependent on bradykinin and the subsequent activation of endothelial B2 receptors, because Icatibant (a clinically available B2 receptor antagonist) completely prevented the BBB disruption. This suggests that plasmin triggers bradykinin generation, effect that provokes BBB leakage.
Conclusion: Circulating plasminogen activators induce BBB leakage in a plasmin, bradykinin and B2 receptor activation-dependent manner. Icatibant appears as a promising therapy to prevent the deleterious effects of fibrinolytics on the BBB.

The interplay of DNA, histones and neutrophil leukocytes with plasmin dependent lysis of plasma clots

Varjú I[1], Kolev K[1], Longstaff C[2], Szabó L[3], Varga-Szabó V[1], Farkas AZ[1] and Machovich RA[1]

[1]*Institute of Medical Biochemistry, Semmelweis University, Budapest, Hungary;* [2]*National Institute for Biological Standards and Control, South Mimms, UK;* [3]*IMEC, Research Centre for Natural Sciences, Hungarian Academy of Sciences, Budapest, Hungary*

Background: Neutrophil extracellular traps (NETs) are networks of DNA and associated proteins produced by nucleosome release from activated neutrophils in response to inflammatory stimuli. Our recent studies have shown that DNA and/or histones modify the structure of fibrin clots and their resistance to mechanical and enzymatic destruction.
Aim: The present study addresses the effect of certain NET components (DNA and histones) on clot lysis expanding our previous observations from purified fibrin to more physiologically relevant conditions in a more complex system including plasma clots and human neutrophil leukocytes.
Methods: Neutrophil leukocytes were isolated from the buffy coat of human blood and following activation with phorbol myristic acid (PMA) or N-formyl-methionine-leucine-phenylalanine (fMLP) the cells were incorporated in fibrin clots. Scanning electron microscopy (SEM) was used to evaluate the structure of cell-fibrin clots. Penetration of a yellow fluorescent protein-fusion variant of tissue plasminogen activator (tPA-YFP) in plasma clots supplemented with Alexa-labeled fibrinogen was monitored by laser scanning confocal microscopy (LSM) as an indicator of tPA-induced lysis. Plasmin-catalyzed lysis of fibrin and plasma clots was followed with time lapse photoscanning of the transparent fluid/opaque clot boundary in 0.4 mm high channels of microslides (IBIDI[TRADEMARK]). Turbidimetric assay was applied as an additional tool for studying the effects of NET components on plasma clot lysis. Residual plasmin activity measured on a synthetic chromogenic plasmin substrate (Spectrozyme-PL) was used to monitor the time course of plasmin inactivation by defibrinogenated plasma and pure α_2-plasmin inhibitor.
Results: SEM evidenced that PMA and fMLP-activated neutrophils produced a meshwork of fine fibers (diameter in the range of 10 nm) tangled in the fibrin scaffold composed of fibers about 10-fold thicker than the NET filaments. In the functional fibrinolytic assays this meshwork was modelled with the addition of DNA and histones to clotting blood plasma. According to LSM studies, addition of DNA and histones at 0.05–0.2 mg/mL inhibited penetration of tPA in plasma clots: the average distance for penetration over 30 min decreased by 28% in line with changes in the generated plasmin activity detected with Spectrozyme-PL. If lysis of clots prepared in microslides was initiated with plasmin applied to their surface, DNA and/or histones had negligible effect on the resolution of pure fibrin, whereas in plasma clots DNA slowed down the movement of the lysis front by 50% and histones partially reversed this effect. DNA enhanced the inhibition of plasmin by defibrinogenated plasma (plasmin activity was 29% and 37% lower after 10 and 40 s of inactivation, respectively, compared to the DNA-free assay), but the interaction of plasmin with isolated α_2-plasmin inhibitor was not significantly affected by DNA.
Conclusion: NET constituents hamper both tPA- and plasmin-induced fibrinolysis on the surface of plasma clots through effects on plasminogen activation and plasmin inactivation. Expanding previous work with purified components, the present data provide further support for NET-dependent modulation of fibrinolysis relevant to deep vein thrombosis in inflammatory diseases or clots formed on atherosclerotic plaques with necrotic debris.

AS 24

Fibrinogen and β-amyloid association alters thrombosis and fibrinolysis: a possible contributing factor to Alzheimer's disease

Strickland S, Cortes-Canteli M, Jin Ahn H, Zamolodchikov D, Hultman K, Kruyer A and Norris EH

The Rockefeller University, New York, NY, USA

The Tissue Factor (TF) pathway is directly linked to physiological repair mechanisms and the host defense against infection. TF is induced by inflammatory mediators in myelo-monocytic cells where danger signals from dying cells or associated with complement activation regulate TF procoagulant activity dependent on protein disulfide isomerase, coupling the initiation of inflammation with local activation of the coagulation cascade. The role of TF is not restricted to the initiation of coagulation and, in addition, signaling of TF protease complexes plays a pivotal role in the regulation of innate immune responses and inflammation. Recent data show that the TF pathway is a critical inducer of the chronic inflammation in obesity. TF adipocyte signaling contributes to the development of obesity, whereas TF expressed by adipose tissue macrophages regulates their inflammatory phenotype. Loss of TF-PAR2 signaling in the hematopoietic compartment of obese mice attenuates adipose tissue inflammation and promotes a switch of adipose tissue macrophages to an anti-inflammatory phenotype typically seen in lean mice. TF forms two distinct signaling complexes. The binary, coagulation inactive TF-VIIa complex interacts with 1 integrins and only cleaves PAR2. The ternary TF-VIIa-Xa complex mediates Xa-dependent activation of PAR1 or PAR2. Xa signaling in this complex is strictly dependent on the endothelial protein C receptor (EPCR). Macrophages found in adipose and tumor tissues express components of these signaling complexes. Further insight into the control of macrophage phenotypes by the TF pathway is expected to emerge from the characterization of regulated expression and interactions of TF signaling components in macrophages during acute and chronic inflammation.

Alzheimer's disease (AD) is a neurodegenerative disorder in which vascular pathology plays an important role. Since the -amyloid peptide (A) is a critical factor in this disease, we examined its relationship to fibrin clot formation in AD. In vitro and in vivo experiments showed that fibrin clots formed in the presence of A are structurally abnormal and resistant to degradation. Fibrin(ogen) was observed in blood vessels positive for amyloid in mouse and human AD samples, and intravital brain imaging of clot formation and dissolution revealed abnormal thrombosis and fibrinolysis in AD mice. Moreover, depletion of fibrinogen lessened cerebral amyloid angiopathy pathology and reduced cognitive impairment in AD mice. These experiments suggest that one important contribution of A to AD is via its effects on fibrin clots, implicating fibrin(ogen) as a potential critical factor in this disease.

AS 24.1

Fibrinogen promotes obesity and high fat diet-associated diseases through a mechanism linked to its aMβ2 binding motif

Flick MJ[1], Cruz C[1], Raghu H[1], Divanovic S[1], Stankiewicz TE[1], Kopec AK[2] and Luyendyk JP[2]

[1]Cincinnati Children's Hospital, Cincinnati, OH; [2]Michigan State University, East Lansing, MI, USA

Obesity is a worldwide epidemic that predisposes individuals to numerous comorbidities including atherosclerosis, hypertension, type II diabetes, and non-alcoholic fatty liver disease (NAFLD). Systemic inflammation has been proposed as a contributing factor in virtually all of the obesity-associated diseases. Notably, obesity is further characterized by enhanced coagulation activity including extravascular fibrin deposition in multiple organ systems. Fibrin(ogen) has been shown to promote pro-inflammatory activity through engagement of the leukocyte integrin receptor $\alpha_M\beta_2$ (Mac-1). To determine if fibrin (ogen)/$\alpha_M\beta_2$ interactions promote the development of obesity-associated pathologies, we fed wild-type mice and mice expressing a mutant form of fibrinogen that retains normal clotting function, but lacks the leukocyte integrin receptor $\alpha_M\beta_2$ binding motif (i.e. Fib$\gamma^{390-396A}$ mice) a high fat diet (HFD) for up to 20 weeks. Intriguingly, Fib$\gamma^{390-396A}$ mice gained significantly less weight following HFD challenge relative to wild-type animals. Differences in adipose tissue mass, but not lean tissue mass, as determined by EchoMRI analysis, directly correlated with differential weight gain in HFD fed wild-type mice compared to Fib$\gamma^{390-396A}$ mice. In agreement with analysis of body composition, the weights of multiple white adipose tissue depots, as well as brown adipose tissue, were reduced in Fib$\gamma^{390-396A}$ mice at the end of the 20-week challenge period. The genotype-dependent difference in body and adipose tissue weight could not be accounted for by differential consumption of HFD. In concert with significant changes in body weight, Fib$\gamma^{390-396A}$ mice displayed significantly lower blood fasting glucose levels when analysed at 12, 14 and 18 weeks on HFD. Fib$\gamma^{390-396A}$ mice were also found to be profoundly resistant to HFD-induced NAFLD development. Specifically, Fib$\gamma^{390-396A}$ mice exhibited significantly reduced histological evidence of hepatic steatosis and inflammation, lower hepatic triglyceride levels, and reduced hepatic mRNA levels of pro-inflammatory mediators known to exacerbate NAFLD (i.e. TNFα, MCP-1). These data suggest fibrin(ogen) influences the pathogenesis of obesity-driven disease sequelae by controlling both local inflammatory processes and by an unanticipated, and as yet uncharacterized, mechanism linking fibrin(ogen) to HFD-induced increase in adiposity.

AS 24.2

Plasma fibronectin supports hemostasis, controls the diameter of fibrin fibers, and regulates thrombosis

Wang Y[1], Reheman A[2], Kalantari J[3], Jin JW[2], Gross PL[4], Weitz JI[4], Rand ML[5], Freedman J[3] and Ni H[6]

[1]University of Toronto; [2]Li Ka Shing Knowledge Institute of St. Michael's Hospital; [3]Li Ka Shing Knowledge Institute of St. Michael's Hospital, University of Toronto, Toronto; [4]Thrombosis and Atherosclerosis Research Institute, Hamilton; [5]The Hospital for Sick Children, University of Toronto, Toronto; [6]Canadian Blood Service, St. Michael's Hospital, University of Toronto, Toronto, ON, Canada

Background: Plasma fibronectin (pFn) has long been suspected to play a role in thrombosis/hemostasis, but this has remained controversial. We previously demonstrated that pFn supports thrombosis in pFn-conditional deficient mice (PNAS, 2003). Interestingly, depletion of pFn in fibrinogen (Fg)/VWF−/− mice resulted in enhanced platelet aggregation and thrombus formation in these mice, revealing a functional switch of pFn in the absence of Fg or VWF (Blood, 2009). However, the mechanism controlling this switch is unknown. Furthermore, the hemostatic function of pFn is unclear.

Methods: In addition to triple deficient mice (Fg/VWF/pFn−/−, TKO), we established Fg/pFn−/− and VWF/pFn−/− mice by crossing pFn conditional knockout mice with VWF−/− or Fg−/− mice. Injection of polyI-polyC into Cre+ mice resulted in depletion of pFn in plasma and platelets by over 98% and 80%, respectively. In contrast, there was no depletion of pFn when polyI-polyC was injected into Cre- littermate controls. To avoid contamination with Fg, pFn was purified from Fg−/− mice.

Results: TKO mice had significantly higher mortality (23.1% vs. 9.1%) and longer tail bleeding time than their pFn+ Fg/VWF−/− litter-

mates. Autopsy revealed severe subcutaneous or abdominal bleeding. pFn depletion in Fg−/− mice also increased mortality from 5.5% to 25.6% and prolonged bleeding times; the latter effect was reversed with pFn infusion. Using intravital microscopy, we observed rapid deposition of fluorescently-labeled pFn at sites of vessel injury in wild-type, Fg−/−, Fg/VWF−/−, and β3 integrin−/− mice. pFn deposition preceded significant platelet accumulation, suggesting that pFn is an efficient and rapid hemostatic factor.

Based on thromboelastography, fibrin clots formed in whole blood or platelet-poor plasma from pFn+ mice were significantly stronger than those formed in blood or plasma from pFn−/− mice. Inferior vena cava occlusion after $FeCl_3$ injury was significantly delayed in pFn−/− mice. Fluorescently-labeled pFn was actively recruited into the fibrin network in mouse and human plasma. Under scanning electron microscopy, physiological levels of pFn doubled the diameter of fibrin fibers compared with those formed in pFn−/− plasma, suggesting that pFn contributes to lateral aggregation of fibrin protofibrils.

Interestingly, pFn inhibited platelet aggregation when fibrin was absent. In Fg−/− mice, pFn depletion enhanced aggregation of gel-filtered platelets in response to thrombin and TRAP. By contrast, in VWF−/− mice (with Fg), pFn depletion attenuated the aggregation of gel-filtered platelets in response to thrombin but enhanced TRAP-induced aggregation (which cannot convert Fg to fibrin). Using *ex vivo* perfusion chamber and intravital microscopy, pFn inhibited thrombus formation in Fg−/− mice. Thus, pFn plays a dual role in platelet aggregation based on the presence of fibrin.

Conclusion: pFn contributes to the survival of Fg−/− mice and supports hemostasis via both fibrin-independent and dependent pathways. pFn doubles the diameter of fibrin fibers and enhances the mechanical strength of the clot. In the presence of Fg, pFn augments platelet aggregation, likely because of fibrin-pFn complex formation. By contrast, non-fibrin-linked pFn (at the top of thrombi where thrombin is diluted) inhibits platelet aggregation and prevents excessive thrombosis. Therefore, pFn is likely a crucial supportive factor in hemostasis and a key regulator in thrombosis.

AS 24.3

Inhibition of thrombin-mediated factor V activation as a novel anticoagulant mechanism of fibrinogen ?'

Omarova F[1], Uitte de Willige S[2], Ariëns R[3], Rosing J[1], Bertina RM[4] and Castoldi E[1]

[1]Maastricht University, Maastricht; [2]Erasmus University Medical Center Rotterdam, Rotterdam, the Netherlands; [3]University of Leeds, Leeds, UK; [4]Leiden University Medical Center, Leiden, the Netherlands

Background: Besides its well-known procoagulant function as a precursor of fibrin, fibrinogen also plays a less understood anticoagulant role by binding to thrombin and thereby modulating its activity. The alternatively spliced fibrinogen γ' chain exists as a heterodimer with the main fibrinogen γA chain as γA/γ' fibrinogen. Both γA/γA and γA/γ' fibrinogens bind with low affinity to thrombin exosite I, whereas exclusively γA/γ' fibrinogen binds to thrombin exosite II. The binding is mediated through the anionic carboxyl-terminal end of the fibrinogen γ' chain, which contains two sulfotyrosine and seven acidic residues. This high-affinity interaction has been reported to down-regulate some of the procoagulant activities of thrombin, such as factor VIII (FVIII) activation and platelet aggregation.

Aim: To investigate the thrombin-mediated anticoagulant effect of fibrinogen and particularly of fibrinogen γ' in plasma.

Methods: Thrombin generation was measured by Calibrated Automated Thrombography in whole and defibrinated plasma and in plasma supplemented with synthetic peptides containing the unique amino acid sequence of the fibrinogen γ' carboxyl-terminal end and various modifications of the two tyrosine residues at positions 418 and 422. The peptides were used as a model for the fibrinogen γ' chain domain that binds to thrombin exosite II. The effect of the doubly sulfated peptide on thrombin-mediated factor V (FV) activation was studied in model systems and in plasma.

Results: Total fibrinogen prolonged the lag time of thrombin generation when coagulation was triggered with low tissue factor concentrations, but this anticoagulant effect was lost at higher tissue factor concentrations. The fibrinogen γ' peptides prolonged the lag time and also decreased the peak height of thrombin generation determined at low tissue factor. Tyrosine sulfation, rather than phosphorylation, considerably enhanced the effect of the peptides. The doubly sulfated peptide was the most potent in a dose-dependent manner, whereas a scrambled control peptide was ineffective. Interestingly, the effects of the doubly sulfated peptide on thrombin generation persisted in the presence of an anti-FVIII antibody, a condition where the feedback loops of thrombin on FVIII and factor XI do not contribute to thrombin generation and FV is the only relevant substrate of thrombin. This suggested that the fibrinogen γ' peptide may inhibit thrombin-mediated activation of FV. This was subsequently confirmed in model systems and in plasma, where the fibrinogen γ' peptide strongly reduced the rate of FV activation by thrombin.

Conclusions: Total fibrinogen and the fibrinogen γ' carboxyl-terminal peptide have an overall anticoagulant effect on thrombin generation determined at low procoagulant stimuli. Inhibition of thrombin-mediated FV activation by the fibrinogen γ' peptide is a novel aspect of the anticoagulant activity of fibrinogen γ'.

AS 25 – Contact Activation 2.0

AS 25.1

Role of cell-free DNA in sepsis pathophysiology: novel studies in murine models of sepsis

Mai SHC[1], Fox-Robichaud A[2] and Liaw P[3]

[1]Thrombosis and Atherosclerosis Institute, McMaster University; [2]McMaster University; [3]Thrombosis and Atherosclerosis Institute, Hamilton, ON, Canada

Background: Sepsis is characterized by a dysregulated host response to microbial infection of the blood resulting in the systemic activation of coagulation and inflammation. We have recently observed that high levels of cell-free DNA (cfDNA) released in the circulation is a powerful prognostic marker in severe sepsis patients. However, the potential pathogenic effects of cfDNA itself is unknown.

Aims: Our objective is to investigate the role of cfDNA in experimental sepsis, its association with the inflammatory and procoagulant responses, as well as to explore the potential therapeutic effects of degrading cfDNA.

Methods: Healthy C57Bl/6 male mice were subjected to cecal ligation and puncture (CLP), a sepsis-inducing procedure involving ligation of the cecum distal to the ileocecal valve and two punctures of the ligated cecum (100% at 24 h) or sham surgery (no ligation or puncture). Blood was collected from 0 to 10 h post-surgery and plasma levels of cfDNA and IL-6 were quantified. Additionally, mice subjected to CLP were injected with DNase (0.20 μg/g) and blood and organs were collected 2 h post-injection to quantify plasma levels of cfDNA and IL-6 and to examine organ histology. This was repeated in a lipopolysaccharide (LPS, 0.04 μg/g) model of inflammation.

Results: Baseline levels of cfDNA in healthy mice were 1.1 ± 0.2 μg/mL. At 6 h post-CLP, cfDNA levels increased more than two-fold compared to non-septic mice subjected to sham surgery (5.5 ± 0.4 vs. 2.4 ± 0.2 μg/mL; $P < 0.01$) and remained elevated for 10 h post-CLP. Increases in levels of IL-6 in septic mice accompanied the rapid, time-dependent elevations in cfDNA. Levels of cfDNA and IL-6 in sham-operated, non-septic mice did not change significantly over the 10 h period. Injection of DNase in septic mice resulted in suppressed levels of cfDNA (3.75 ± 0.6 μg/mL DNase-treated vs. 6.35 ± 0.2 μg/mL untreated; $P < 0.01$) comparable to cfDNA levels of nonseptic mice as well as reduced levels of IL-6. In histological studies, photomicro-

graphs of hematoxylin and eosin stained organ sections showed decreased leukocyte infiltration, red blood cell congestion, and microvascular clotting in the lungs and kidneys of septic mice treated with DNase. Similar to observations made in the CLP model, LPS-challenged mice had significant elevations in cfDNA compared to healthy controls (6.24 ± 0.3 vs. 2.1 ± 0.2 μg/mL respectively; $P < 0.01$) which were also suppressed following DNase injection (4.72 ± 0.1 μg/mL; $P < 0.01$). The suppressed levels of cfDNA in DNase-treated septic mice correlated with reductions in IL-6 and improved organ pathology compared to untreated septic mice, suggesting a potential association between cfDNA and inflammatory pathways activated in sepsis.

Conclusions: These studies demonstrate that rapid elevations in cfDNA accompany an early proinflammatory response in experimental sepsis, supporting the importance of early intervention (i.e. administration of resuscitation fluids and antibiotics within 1 h of diagnosis). Furthermore, modifying cfDNA in septic and LPS-challenged mice via treatment with DNase not only causes a reduction in cfDNA levels but may also suppress the inflammatory response and improve organ pathology. These findings suggest that early therapeutic interventions which modulate levels of cfDNA may improve clinical outcome of septic patients.

AS 25.2

Inhibition of factor XII activation reduces experimental thrombus formation in baboons

Leung PY[1], Tucker I[1], Matafonov A[2], Renne T[3], McCarty OJT[4], Gailani D[2] and Gruber A[4]

[1]Aronora, Inc, Portland, OR; [2]Vanderbilt University, Nashville, TN, USA; [3]Karolinska Institutet, Stockholm, Sweden; [4]Oregon Health & Science University, Portland, OR, USA

Background: Factor XI (FXI) activation by activated factor XII (FXIIa) contributes significantly to vascular occlusion in murine thrombosis models. However, the importance of this reaction to thrombosis in primates, including humans, has yet to be established. Indeed, while low FXI levels are associated with reduced risks for arterial and venous thrombosis in humans, a similar relationship between factor XII (FXII) and thrombosis has not been conclusively observed, in contrast to experimental data in mice.

Aims: We sought to identify a role for FXII in primate thrombosis using a novel monoclonal antibody (15H8) that binds to the fibronectin type I domain of FXII and inhibits FXII activation on polyanionic surfaces.

Methods: The hybridoma clone secreting the monoclonal IgG 15H8, which prevents arterial thrombosis in FXII-deficient mice reconstituted with human FXII, was generated by immunizing FXII-deficient mice with human FXII using standard techniques. The antithrombotic effects of 15H8 were evaluated in an established baboon thrombosis model by comparing platelet and fibrin deposition within a thrombogenic device (TD) in 15H8- and vehicle-treated animals. The TD was placed for 1 h in a chronic femoral arteriovenous shunt. The TD consisted of a proximal collagen-coated vascular graft segment to initiate thrombogenesis (4 mm i.d.) and an expansion chamber (9 mm i.d.) 20 mm distal to the graft. The proximal graft segment is intended to model the flow rates of large arteries, while the thrombus chamber creates shear rates more typical of the venous circulation. Impairment of hemostasis was evaluated by template bleeding times and bleeding volumes.

Results: Saturating concentrations of 15H8 in normal human plasma prolonged the aPTT 1.9-fold, while baboon aPTTs were prolonged up to 3.6-fold. An intravenous bolus of 15H8 (6 mg/kg) prolonged the aPTT in baboons by 1.7-fold ($n = 4$) within 10 min, corresponding to a > 99% inhibition of circulating FXII procoagulant activity. The effect lasted for > 24 h. An hour following 15H8 infusion, a $49 \pm 8\%$ reduction in platelet accumulation was observed in the expansion chamber compared to vehicle-treated controls ($P < 0.02$, $n = 4$–9), while fibrin accumulation was reduced by $95 \pm 1\%$. Interestingly, while platelet deposition was not affected within the collagen-coated segment of the TD that models arterial-type thrombosis, fibrin deposition was reduced by $70 \pm 5\%$ ($P < 0.05$) compared with controls. Bleeding times and bleeding volumes were not affected by 15H8 treatment.

Summary/Conclusion: Inhibition of FXII activation produces an antithrombotic effect in our baboon model. 15H8 appears to be more effective at limiting thrombosis on collagen-coated grafts at shear rates typically seen in the venous circulation than under arterial shear. Previously, we showed that inhibition of factor IX activation by activated FXI significantly reduces collagen- or tissue factor-initiated platelet deposition under arterial shear rates in this model. Given this, the present data suggest that activation of FXI by enzymes other than FXII (e.g. thrombin) may be more important for arterial-type thrombus formation. In summary, our data further delineate the role of FXII in thrombosis and hemostasis. Moreover, the results support the hypothesis that pharmacological inhibition of FXII activation may provide safe thromboprophylaxis.

AS 25.3

Blood-borne and wall-derived DNA as a kinetically significant contact pathway activator: DNase inhibits thrombin formation *in vitro* and *in vivo*

Diamond SL, Welsh J, Colace TV, Zhou S and Brass LF

University of Pennsylvania, Philadelphia, PA, USA

Given recent findings of reduced thrombus stability in the Factor XII knockout mouse and the discoveries of platelet-released polyphosphate and neutrophil-released extracellular traps (NETs), we investigated the source and potency of various contact activators. We report that addition of recombinant DNase (rDNase) dramatically delayed thrombin production in recalcified citrated PFP, PRP, and whole blood. Using very low levels of corn trypsin inhibitor (5 μg/mL) added to human whole blood, rDNase (1 mg/mL) delayed thrombin production, while RNase (1 mg/mL) or alkaline phosphatase (0.1 mg/mL) had no effect, with similar outcomes in treated recalcified citrated PRP (no neutrophils observed in PRP wells at 20× magnification). Direct visualization of annexinV-positive platelets revealed the exposure with time of Sytox-Green (a cell impermeable DNA dye) staining nodules as well as detection of ~5 μ long thin strands linked to platelets or in solution, a size consistent with the size of mitochondrial DNA (mtDNA). Platelet mtDNA was elevated (by qPCR) in plasma obtained from convulxin-stimulated PRP and purified platelet mtDNA caused a modest acceleration of thrombin production in recalcified PFP, PRP, and whole blood. This is new evidence for platelet-derived, blood-borne mtDNA as a contact activator following platelet activation. In the arteriole laser injury model using wildtype mouse, rDNase delayed thrombin production (detected with an anti CD41-linked thrombin sensor), delayed platelet accumulation, resulted in less platelet accumulation, and enhanced clot instability. The rDNase caused a 75% reduction ($P < 0.05$, $n = 8$) of wall localized Sytox staining at the injury site and 25% reduction ($P < 0.05$, $n = 11$) of the faint and punctate staining of the thrombus mass. We conclude wall exposed DNA is a major activator of the contact pathway during laser injury, with staining evidence for the existence of clot-derived DNA that was too small to originate from neutrophils. While DNA has been recognized as a contact activator, this evidence provides new insights into its source, locality, and role in the laser injury model *in vivo* as well as its role in the clotting of blood *in vitro*. Understanding the most proximal triggers of contact activation during arterial thrombosis may be particularly relevant to the development of safe anticoagulants with reduced bleeding risk.

AS 26 – Assays for Haemostatic Drugs

AS 26.1

Evaluation of whole blood clotting activity of recombinant factor VIII Fc fusion protein by ROTEM analysis in a multi-center Phase 3 clinical trial

Sommer J[1], Driessler F[1], Miguelino M[2], Powell J[2], Luk A[1], Pierce GF[1] and Jiang H[1]

[1]Biogen Idec Hemophilia, Waltham, MA; [2]UC Davis Cancer Center, Sacramento, CA, USA

Background: The recombinant coagulation factor VIII Fc (rFVIIIFc) fusion protein consists of a single molecule of human factor VIII covalently linked to the dimeric Fc domain of human immunoglobulin G1 (IgG_1). The rFVIIIFc utilizes the FcRn receptor-mediated immunoglobulin cycling pathway to extend its plasma half-life. In a global, multi-center, phase 3 clinical study (A-LONG), rFVIIIFc demonstrated effective prevention and control of bleeding episodes in 1–2× weekly prophylactic dosing intervals.

Aims: To evaluate the whole blood clotting potential of rFVIIIFc in comparison to a currently marketed rFVIII product by *ex vivo* rotation thromboelastometry (ROTEM) of post-infusion samples.

Methods: Thirteen clinical sites (5 US, 5 EU, 1 IL, 1 AU, and 1 JP) performed ROTEM analysis as part of the pharmacokinetic evaluation of 44 subjects treated with rFVIIIFc. All participating sites were trained on a standardized ROTEM procedure and used the same lots of custom reagents, supplies and assay controls. Citrated whole blood samples were rested at ambient temperature for 30–45 min before initiating clot formation by NATEM (recalcification), INTEM (1:300 dilution of the ellagic acid in-tem reagent) or EXTEM (1:10,000 dilution of the recombinant TF ex-tem reagent). Four key ROTEM parameters (clot time [CT], clot formation time [CFT], α-angle, and maximum clot firmness [MCF]) were evaluated relative to FVIII activity determined by the one-stage clotting assay at a central laboratory. Informed consent was obtained from all participating subjects and the study was approved by local site medical ethics committees.

Results: ROTEM results from 16 subjects that had complete pharmacokinetics (PK) profiles for rFVIII and rFVIIIFc, followed by a repeat rFVIIIFc PK profile approximately 3 months later, were included in this report. The 77 rFVIII and 143 rFVIIIFc samples showed a dose-dependent response for CT, CFT and α-angle through the entire range of measurable FVIII activity (0.5% to > 100%). MCF was largely unaffected by the amount of FVIII. Despite significant inter-subject differences in the ROTEM profiles, the mean whole blood clotting activity over time profiles for rFVIIIFc compared to rFVIII closely mirrored the PK extension observed for plasma rFVIIIFc activity. Whole blood clotting activity was, on average, comparable for rFVIII and rFVIIIFc at the first post-dosing time point, while the ROTEM activity seen for Advate 48 h after dosing was comparable to the activity of rFVIIIFc at 72 h. Regression analysis of the integrated ROTEM data vs. FVIII activity showed parallel and comparable ROTEM responses for rFVIIIFc and rFVIII at equivalent FVIII activities.

Summary/Conclusions: *Ex vivo* ROTEM analysis in 16 subjects demonstrated prolonged improvements in clot formation consistent with the reduced rate of plasma clearance observed for rFVIIIFc compared to rFVIII. Equivalent whole blood coagulation potential was demonstrated for rFVIIIFc and rFVIII in a physiologically relevant setting. The comparable ROTEM response for both products throughout the assay range confirms our previous biochemical assessment of rFVIIIFc demonstrating full coagulation potential of the rFVIII fusion protein.

AS 26.2

Activated factor VII: antithrombin complex plasma concentration is an independent predictor of total and cardiovascular mortality in patients with angiographically demonstrated coronary artery disease

Martinelli N[1], Girelli D[1], Baroni M[2], Guarini P[1], Tosi F[1], Pattini P[1], Woodhams B[3], Bernardi F[2] and Olivieri O[1]

[1]University of Verona, Verona; [2]University of Ferrara, Ferrara, Italy; [3]HaemaCon Ltd, Bromley, Kent, UK

Background: Plasma concentration of activated factor VII (FVIIa)-antithrombin (AT) complex has recently been proposed as a marker of intravascular exposure of tissue factor (TF) and, thus, of activation of the extrinsic pathway of coagulation cascade. However, the results of studies investigating the potential relationship between FVIIa-AT complex and coronary artery disease (CAD) are only preliminary so far.

Aims: The aim of this study was to investigate the predictive value of FVIIa-AT complex plasma concentration for total and cardiovascular mortality in the setting of secondary prevention of CAD.

Methods: Within the framework of the Verona Heart Study (VHS), a regional survey aimed to search for new risk factors for cardiovascular disease, we selected a cohort of 510 patients with angiographically proven CAD (mean age 61.8 ± 10.6 years; females 23.7%), who were not taking anticoagulant drugs at time of enrolment and for whom plasma citrate samples for FVIIa-AT complex assay were available. These patients were prospectively followed for a median period of 64 months. Plasma concentration of FVIIa-AT complex was determined by ELISA.

Results: The majority of patients had severe CAD and received surgical or endovascular coronary revascularization during the period 1999–2006 (81.8%). Eight patients had peri-operative deaths and were excluded from subsequent analyses. During follow-up, 105 (20.9%) subjects died, with 68 (13.5%) events attributed to cardiovascular causes. CAD patients who died had a significantly higher plasma concentration of FVIIa-AT complex than those survived ($P = 0.002$). Stratifying the study population on the basis of the FVIIa-AT complex quartiles, we noted an evident increase of both total and cardiovascular mortality for the subjects in the two upper quartiles. CAD patients with plasma concentration of FVIIa-AT higher than the median value (79 pM) had an increase in both total and cardiovascular mortality than those with lower values (26.7% vs. 15.0%, $P = 0.001$ by Log Rank test, and 17.3% vs. 9.7%, $P = 0.006$ by Log Rank test, respectively).

After adjustment for the other predictors of mortality at univariate analysis (i.e. sex, age, number of coronary vessels involved, MI history, hypertension, diabetes, BMI, renal function, and hs-CRP concentration), elevated FVIIa-AT complex (≥ 79 pM) significantly predicted both total and cardiovascular mortality (HR for total and cardiovascular mortality: 2.24 (1.35–3.70) and 1.92 (1.02–3.61), respectively). Such associations remained significant also after adjustment for left ventricular ejection fraction (HR for total and cardiovascular mortality: 1.91 (1.21–3.03) and 1.86 (1.03–3.34), respectively), as well as for the main cardiovascular therapies at discharge, like beta-blockers, ACE-inhibitors, statins, and antiplatelet/anticoagulant drugs (HR for total and cardiovascular mortality: 1.67 (1.08–2.59) and 1.77 (1.01–3.11), respectively).

Conclusions: In this study high plasma concentrations of FVIIa-AT complex were an independent predictor of both total and cardiovascular mortality in patients with angiographically demonstrated CAD, speculatively reflecting a prothrombotic diathesis due to TF-related activation of coagulation cascade. Thus, FVIIa-AT may be a useful prognostic marker in the setting of secondary prevention of CAD.

AS 26.3

Evaluation of a recombinant inactive antithrombin to reverse fondaparinux anticoagulant activity by measuring thrombin generation: an asset compared to other non specific hemostatic agents

Bianchini EP[1], Bourti Y[1], Armand M[2], Fazavana J[1], Saller F[1], LasneD[2] and Borgel D[1]

[1]University of Paris Sud-XI, Chatenay-Malabry, France; [2]Hopital Necker, Assistance Publique – Hôpitaux de Paris, Paris, France

Background: Fondaparinux, a synthetic pentasaccharide mediating its anticoagulant activity through antithrombin (AT) activation, is now widely used for preventive and curative treatment of thrombosis. This drug exhibits advantageous pharmacokinetic and safety profiles but no antidote is still available to reverse fondaparinux overdosing and limit associated blood losses. However, non-specific procoagulant products such as recombinant factor VIIa (rFVIIa) or activated prothrombin complex concentrates (aPCCs), have been tested but with limited evidence of efficacy. To secure the clinical use of fondaparinux, we have already designed a recombinant inactive AT (iAT) that retains its pentasaccharide binding capacity. Such an iAT traps fondaparinux in an inactive complex, and might thus act as a potent reversal agent in situations of fondaparinux overdosing.

Aims: Inactive AT efficiently reverses fondaparinux *in-vitro* and *in-vivo* when assayed by chromogenic anti-factor Xa activity. The goal of this study was to compare the asset of iAT as a specific antidote for fondaparinux, as compared to nonspecific hemostatic agents (rFVIIa and aPCC).

Methods: The impact on coagulation of iAT, rFVIIa and aPCC was evaluated by thrombin generation assay in platelet-poor plasma (PPP) overloaded or not with a supratherapeutic dose of fondaparinux.

Results: The anticoagulant effect of a high dose of fondaparinux (3 mg/L) used to mimic overdosing was evidenced by perturbation of the main thrombogram parameters, in particular by a longer lag time (7.3 ± 0.4 min vs. 2.9 ± 0.3), and both decreased endogenous thrombin potential (ETP) (275 ± 76 nM.min vs. 1741 ± 282) and thrombin peak height (20 ± 5 nM vs. 294 ± 37). As previously shown, addition of increasing rFVIIa concentrations (0.3–2.4 μg/mL) in fondaparinux-overloaded plasma restored a normal lag time though non dose-dependently, while other thrombogram parameters were unchanged. In contrast, aPCC (from 0.5 tio 4 U/mL) shortened the lag time and slightly increased the ETP, which nevertheless remained 2.4-fold lower than the ETP measured in plasma without fondaparinux. Under the same conditions, iAT dose-dependently shortened the lag time, increased the ETP and the thrombin peak height. For example, the estimated ETP in the presence of iAT at concentrations of 0.075, 0.15, 0.3, 0.6, and 1.2 g/L in fondaparinux overloaded plasma were 397 ± 85, 550 ± 77, 900 ± 101, 1331 ± 454, and 1360 ± 380 nM.min, respectively. Strikingly, the same concentrations of iAT in fondaparinux-free plasma had no impact on the thrombin generation curves, whereas rFVIIa only significantly shortened the lag time and aPCC (1 U/mL) both shortened the lag time and greatly increased the ETP by 178%.

Conclusions: This study confirms the potent effect of our recombinant iAT as a specific reversal agent to fondaparinux in a thrombin generation assay. Indeed, iAT normalized thrombin generation curves and parameters measured in fondaparinux-overdosed plasma, Compared to non-specific hemostatic agents, our iAT appears much more efficient to reverse fondaparinux anticoagulant activity and overall could be considered much safer since it appears devoid of any anticoagulant or procoagulant activity by itself.

AS 27 – Platelet Response to Injury

AS 27.1

A talin mutant that disrupts talin-integrin binding in platelets decelerates aIIbβ3 activation without pathological bleeding

Stefanini L[1], Snider A[2], Piatt R[1], Bergmeier W[1] and Petrich B[2]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; [2]University of California San Diego, La Jolla, CA, USA

Background: Tight regulation of integrin affinity is a critical component of thrombosis and hemostasis. The final step of integrin inside-out activation is the binding of the cytoskeletal protein talin to two distinct sites within the integrin β cytoplasmic tail. First, binding of talin to an integrin NPLY sequence provides most of the binding energy. Second, a weaker interaction with the membrane-proximal region (MPR) of the integrin is required for talin-mediated integrin activation. Selective deletion of talin1 from platelets and megakaryocytes ($Tln1^{fl/fl}$Pf4-Cre+) completely prevents agonist-induced activation of α2β1 and αIIbβ3 integrins, impairs thrombus formation and results in profound defects in hemostasis. Interestingly, expression of a talin1 mutant (L325R) that lacks the ability to bind the MPR, but can still bind the NPLY sequence, phenocopies the integrin activation and hemostatic defects observed in mice with talin-deficient platelets. In transfected cells, a talin1 mutant (W359A) with a markedly impaired ability to bind the NPLY region of the β3-integrin tail did not rescue the talin1 knockdown phenotype.

Aim: In this study we sought to analyze the effects of a platelet-specific talin1 mutation (W359A) on thrombosis and hemostasis.

Methods: Homozygous knock-in of talin1(W359A) is embryonic lethal in mice. Thus, $Tln1^{W359A/wt}$ mice were crossed with $Tln1^{fl/fl}$PF4-Cre+ mice to generate $Tln1^{W359A/fl}$PF4-Cre+ ($Tln^{W359A/ko}$) and $Tln1^{wt/fl}$ PF4-Cre+ ($Tln^{wt/ko}$) control mice. aIIbb3 integrin activation and granule secretion of mouse platelets was monitored by flow cytometry and standard aggregometry. Adhesion under static conditions was determined by measuring spreading of ADP-stimulated platelets on fibrinogen-coated slides. For adhesion studies under flow conditions murine whole blood was perfused over fibrillar collagen type I. Thrombosis *in vivo* was studied by applying 5% $FeCl_3$ to the carotid artery for 3 min and by monitoring the flow rate with an ultrasound flow probe. Hemostasis was determined both by tail-bleed and gastrointestinal-bleed assays.

Results: Expression of talin1(W359A) in platelets partially rescued talin1 deficiency. Compared to $Tln^{wt/ko}$ controls, agonist-induced αIIbβ3 activation was reduced by ~50% and both granule release and spreading on fibrinogen were only moderately impaired in $Tln^{W359A/ko}$ platelets. However, kinetic studies demonstrated decelerated αIIbβ3 activation in $Tln^{W359A/ko}$ platelets, which resulted in delayed aggregation under static conditions and reduced thrombus size at low shear rates. Interestingly, adhesion of $Tln^{W359A/ko}$ platelets to collagen at high venous and arterial shear rates was not significantly better than that of talin-deficient cells and $Tln^{W359A/ko}$ mice were completely protected from $FeCl_3$-induced carotid artery occlusion. However, we reproducibly observed a distinct thin layer of platelets adhering to the carotid artery 20 min after injury. Lastly, in contrast to platelet-specific talin-knockout or $Tln^{L325R/ko}$ mice, $Tln^{W359A/ko}$ mice showed no detectable gastrointestinal bleeding and only modestly increased tail-bleeding times compared to littermate controls.

Conclusions: Our studies demonstrate that the talin1(W359A) mutation decelerates, but does not abolish, talin-dependent integrin activation in platelets. Importantly, we also show that the slower kinetics of talin-integrin binding may have beneficial anti-thrombotic effects without increasing the risk of bleeding.

AS 27.2

Tetraspanin Tspan18 regulates GPVI-induced platelet activation by interacting with the store-operated Ca2+ entry channel Orai1

Bailey RL, Colombo D, Haining EJ, Yang J, Lloyd T, Peall A, Watson SP and Tomlinson MG

University of Birmingham, Birmingham, UK

Background: Intracellular Ca^{2+} elevation following platelet activation regulates shape change, granule secretion, integrin activation and phosphatidylserine exposure. Together these events promote platelet adhesion, aggregation and the coagulation cascade at sites of vascular injury. A major means of Ca^{2+} elevation is across the plasma membrane through Orai1 store-operated Ca^{2+} entry channels. Orai1 is particularly important for platelet activation by the collagen receptor GPVI. Mice lacking platelet Orai1 or GPVI are protected against arterial thrombosis and ischaemic stroke, and both proteins are potential anti-thrombotic drug targets. The tetraspanins are a superfamily of 33 transmembrane proteins in humans, of which at least 10 are platelet-expressed, including the previously unstudied Tspan18. Tetraspanins are emerging as important regulators of the trafficking and/or clustering of certain associated receptors. We have previously identified GPVI as tetraspanin-associated, but how tetraspanins regulate GPVI signaling is unknown.

Aims: The aim of this study was to identify tetraspanins that regulate the GPVI signaling pathway, and to subsequently characterize the previously unstudied tetraspanin Tspan18 using knockout mice.

Methods: A panel of tetraspanins was co-expressed with GPVI in a cell line model to determine which could regulate GPVI signaling. The readout was activation of the Ca^{2+}-responsive nuclear factor of activated T cells (NFAT) transcription factor. Cells deficient for various intracellular signaling proteins were used to characterize the mechanism by which the identified tetraspanin, Tspan18, regulated the GPVI signaling pathway. Platelet function was then assessed in the Tspan18 knockout mouse. To address the mechanism of Tspan18 function, its interaction with Orai1 was assessed biochemically.

Results: Expression of the previously uncharacterized tetraspanin Tspan18 in a cell line model promoted GPVI-induced NFAT activation. Moreover, Tspan18 expression in the absence of GPVI was sufficient to activate NFAT, raising the possibility of an effect on Ca^{2+}/NFAT downstream of GPVI. Other platelet tetraspanins did not have this capacity, suggesting a unique function for Tspan18. The active site of Tspan18 mapped to a 61 amino acid portion of the main extracellular region, which is known to mediate specific protein-protein interactions within the tetraspanin superfamily. Tspan18-induced NFAT activation did not require signaling proteins upstream of store-operated Ca^{2+} entry, but did require functional Orai1 channels. The Tspan18 knockout mouse exhibited defective haemostasis, since five-fold more blood was lost than wild-type mice in a tail bleeding assay. Tspan18-deficient platelets were defective in aggregation and secretion in response to the GPVI-specific agonist collagen-related peptide, although the aggregation defect could be overcome at high concentration of agonist. Surface levels of GPVI and other major glycoproteins were normal, as were platelet number and size. Platelet aggregation to thrombin was unaffected by the absence of Tspan18. These observations are similar to those previously reported for mice with Orai1-deficient platelets. Consistent with a role for Tspan18 in regulating Orai1, Tspan18 co-immunoprecipitated with Orai1 but other platelet tetraspanins did not.

Summary/Conclusions: We have characterized a new platelet tetraspanin Tspan18 that positively regulates GPVI signalling via interaction with the store-operated Ca^{2+} entry channel Orai1. The Tspan18-Orai1 complex is a potential anti-platelet drug target for the prevention and treatment of thrombosis.

AS 27.3

Integrin alpha6beta1 is the main receptor for vascular laminins and plays a role in platelet adhesion, activation and arterial thrombosis

Schaff M[1], Maurer E[1], Bourdon C[1], Receveur N[1], Hechler B[1], Georges-Labouesse E[2], Gachet C[1], Lanza F[1] and Mangin PH[1]

[1]UMR_S949, INSERM, University of Strasbourg, EFS-Alsace, Strasbourg; [2]CNRS UMR7104, INSERM U964, University of Strasbourg, IGBMC, Illkirch-Graffenstaden, France

Background: Laminins are major components of endothelial and smooth muscle cells basement membranes, well located to interact with platelets upon vascular injury. Laminin-111 ($\alpha_1\beta_1\gamma_1$) is known to support platelet adhesion but is absent from most blood vessels, which contain isoforms with the α_2, α_4 or α_5 chain. The importance of vascular laminins in platelet functions remains unknown.

Aims: The aim of this study was to evaluate (i) the ability of a series of vascular laminin isoforms to support platelet adhesion and activation under hemodynamic conditions, and (ii) the significance of these interactions in hemostasis and thrombosis.

Methods: Glass microcapillaries coated with recombinant human vascular laminins were perfused with hirudinated blood using a syringe pump and platelet adhesion was monitored by differential interference contrast microscopy. Activation of adherent platelets was evaluated by observing morphological changes and cytosolic Ca^{2+} increases. Concerning the second objective, we generated knock-out mice bearing a platelet-specific deletion of the major laminin receptor, and measured their tail transection bleeding time and thrombotic response upon mechanical-, laser- and chemical-induced arterial injury.

Results: We found that laminin-411 ($\alpha_4\beta_1\gamma_1$), laminin-511 ($\alpha_5\beta_1\gamma_1$) and laminin-521 ($\alpha_5\beta_2\gamma_1$), but not laminin-211 ($\alpha_2\beta_1\gamma_1$), allow efficient human platelet adhesion across a wide range of arterial wall shear rates up to 5000/s. In addition, platelets adhering to laminin-411, laminin-511 and laminin-521 became activated, as indicated by their shape change with filopodia extension and cytosolic Ca^{2+} oscillations. Use of blocking antibodies revealed that platelet/laminin interactions were critically dependent on integrin $\alpha_6\beta_1$. Therefore, to address their *in vivo* significance, we developed a platelet-specific knock-out of integrin α_6 ($\alpha_6^{-/-}$). As expected, integrin $\alpha_6\beta_1$ was not critical for platelet activation in response to a series of agonists (ADP, TxA_2 mimetic, thrombin, PAR-4 agonist peptide, collagen, collagen-related peptide), as indicated by normal aggregation, binding of soluble fibrinogen and P-selectin exposure in $\alpha_6^{-/-}$platelets. In contrast, adhesion of these platelets to vascular laminins under flow was abrogated, whereas it remained unchanged on other subendothelial proteins such as von Willebrand factor, collagen, fibrinogen and fibronectin. Interestingly, compared to their wild-type littermates, $\alpha_6^{-/-}$ mice exhibited a marked inhibition of 69 ± 10% ($n = 6$, $P < 0.05$) in thrombosis induced by endothelium denudation of the common carotid with a guide wire. Following compression of the abdominal aorta with forceps, thrombus formation was likewise reduced by 56 ± 12% ($n = 5$, $P < 0.01$). A more pronounced decrease in thrombosis of 82 ± 3% ($n = 12$, $P < 0.01$) was observed in a model of moderate laser injury removing the endothelial cell layer of mesenteric arterioles. In contrast, $\alpha_6^{-/-}$ mice did not exhibit any protection after a deeper laser lesion exposing the media and adventitia, and following $FeCl_3$ injury of the common carotid artery. The tail bleeding time and volume of blood lost remained unchanged in $\alpha_6^{-/-}$ mice, suggesting normal hemostasis.

Conclusion: This study reveals an unsuspected important contribution of laminins to platelet adhesion and aggregation upon arterial injury depending on the type and severity of lesion. From a clinical point of view, targeting their main receptor, integrin $\alpha_6\beta_1$, could represent an alternative antithrombotic strategy with a potentially low bleeding risk.

AS 28 – Thrombocytopenia

AS 28.1

Impact of an avoid-heparin program on the incidence, clinical consequences and resource use associated with heparin-induced thrombocytopenia (HIT)

McGowan K[1], Makari J[1], Rempel P[2], Bucci C[1], Diamantouros A[1] and Geerts W[1]

[1]*University of Toronto & Sunnybrook Health Sciences Centre;* [2]*Sunnybrook Health Sciences Centre, Toronto, ON, Canada*

Background: Heparin-induced thrombocytopenia (HIT) is a serious complication of heparin, occurring in up to 5% of patients exposed to unfractionated heparin (UFH). In comparison, the risk of HIT among patients exposed to low molecular weight heparin (LMWH) is substantially lower.

Aim: To examine the impact of a hospital-wide HIT reduction strategy, through limiting exposure to UFH and replacing UFH with LMWH, on the incidence of HIT and its consequences.

Methods: A comprehensive 'Avoid-Heparin Program' was implemented at a large university hospital in 2006 as a specific attempt to reduce the burden of HIT and improve patient safety. This involved replacing intravenous and subcutaneous (SC) UFH with SC LMWH for prophylactic and therapeutic indications, and removing UFH from arterial and central venous lines. After 2006, UFH was limited to intraoperative use in cardiovascular surgery and hemodialysis. All cases of suspected HIT from 2003 to 2011 were adjudicated using explicit criteria for negative and positive HIT enzyme-linked immunosorbent assay (ELISA), HIT and HIT with thrombosis (HITT). Outcomes in the pre-intervention phase (2003–2005) were compared to those occurring in the Avoid-Heparin phase (2007–2011). Data from 2006 was not included since this was the program implementation year. There were no changes to the investigation of HIT over the study period.

Results: The annual number of suspected HIT cases decreased 34%, from 85 per 10,000 admissions in the pre-intervention phase to 56 per 10,000 admissions in the Avoid-Heparin phase ($P < 0.001$). The annual number of patients with a positive HIT ELISA decreased 59% from 17 to 7 per 10,000 admissions ($P < 0.001$); adjudicated HIT decreased 73% from 11 to 3 per 10,000 admissions ($P < 0.001$); and HITT decreased 80% from 5 to 1 per 10,000 admissions ($P < 0.001$). Patients with HIT in the pre-intervention phase more frequently developed HITT (43%) than patients with HIT in the Avoid-Heparin phase (20%, $P = 0.044$). The proportion of patients with HIT exposed to LMWH alone was significantly greater in the Avoid-Heparin phase (44%) than in the pre-intervention phase (8%, $P < 0.001$). However, the use of LMWH increased more than six-fold from 2003 to 2011 and the annual rate of LMWH-associated HIT remained constant (at 1/10,000 admissions per year, $P = 1.000$). The hospital expenditure on HIT-safe anticoagulants also decreased 41% in the Avoid-Heparin phase. Patients with HIT in the pre-intervention ($n = 53$) and Avoid-Heparin phases ($n = 25$) had similar characteristics including age, sex, admitting service, duration of heparin exposure and length of stay. We did not identify any other factors that could account for the observed reduction in HIT and HITT.

Summary/Conclusion: Implementation of an 'Avoid-Heparin Program' led to a dramatic decrease in the burden of HIT (suspected HIT, diagnosed HIT and HITT) and in the costs of HIT care. To our knowledge, this is the first study demonstrating the success of a hospital-wide HIT prevention strategy. Our findings suggest a feasible heparin avoidance intervention can improve hospital patient outcomes.

AS 28.2

Platelet-monocyte interactions enhance procoagulant activity in heparin induced thrombocytopenia

Kasthuri RS, Jonas J, Mazepa M, Mackman N, Key NS and Pawlinski R

University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Background: Heparin-induced thrombocytopenia (HIT) is a well recognized complication of heparin therapy. The most feared complication of HIT is the development of thrombosis. HIT is caused by the formation of antibodies against heparin bound to platelet factor 4 (PF4) and the PF4/heparin/antibody (HIT) complexes cause platelet activation via the FcgRIIa receptor. We have previously demonstrated that HIT complexes induce monocyte tissue factor (TF) via the FcgRI receptor.

Aim: The objective of this study was to characterize the role of platelet-monocyte interactions in the HIT complex mediated procoagulant response.

Methods: Peripheral blood mononuclear cells (PBMCs, 1×10^6 per condition) and platelet rich plasma (PRP, 25×10^6 platelets per condition) were isolated from citrated blood donated by healthy volunteers. PBMCs and/or PRP aliquots were incubated with PF4 (10 μg/mL), heparin (1 U/mL), and the PF4-heparin specific antibody KKO (100 μg/mL) at 37°C between 30 min and 6 h based on the experiment. Procoagulant activity (PCA, pg/mL) was measured using a one-stage clotting assay.

Results: Incubation of PBMCs with PRP for 6 h resulted in an increase in PCA compared to PBMCs alone (114 ± 34 vs. 6 ± 1 pg/mL; $n = 4$, $P = 0.02$). Incubation of PBMCs with PF4, heparin and KKO (HIT complex) resulted in significantly increased PCA compared to control ($224 +/- 63$ vs. $6 +/- 1$ pg/mL; $n = 4$, $P = 0.014$). Pre-incubation of PRP with the HIT complex for 30 min followed by incubation with PBMCs did not lead to significant increase in PCA compared to incubation of PBMCs and PRP without the HIT complex (120 ± 50 vs. 114 ± 34 pg/mL; $n = 3$). Combining PBMCs with PRP and incubating them with the HIT complex for 6 h resulted in a further increase in PCA (1114 ± 411 pg/mL; $n = 4$) compared to HIT complex and PBMCs alone. In preliminary experiments, pre-incubation of PRP with the anti-FcgRII antibody IV.3 before combining with PBMCs and incubating for 6 h decreased the PCA by 70% (1704 vs. 504 pg/mL). The addition of a P-Selectin blocking antibody in the PRP+PBMC+ HIT complex experiment did not decrease the PCA compared to PRP+PBMC+ HIT (1704 vs. 2015 pg/mL).

Conclusion: HIT complexes are known to cause activation of both monocytes and platelets. Interestingly, activation of platelets by the HIT complex and subsequent incubation with PBMCs did not cause significant increase in PCA. This suggests that platelet activation in itself doesn't lead to monocyte activation in HIT. On the other hand, when PBMCs and platelets were combined together prior to exposure, the HIT complex caused marked increase in PCA, much greater than the effect of both HIT complexes and LPS on PBMCs. The effect of platelets on the PCA was significantly decreased by blocking FcgRIIa but not by blocking P-Selectin. This suggests that platelet activation enhances the activation of coagulation caused by HIT complexes and that this platelet-monocyte interaction in HIT is not mediated by P-Selectin.

AS 28.3

A mutation in ANKRD18A is associated with a severe congenital thrombocytopenia

Morgan V[1], Lowe GC[1], Motwani J[2], Williams M[2], Simpson M[3], Kirby G[1], Maher ER[1] and Watson SP[1]

[1]*University of Birmingham;* [2]*Birmingham Children's Hospital, Birmingham;* [3]*King's College, London, UK*

Background: Inherited thrombocytopenias are a group of heterogeneous disorders which are associated with bleeding of all types of

severity depending both on the reduction in platelet count and whether there is co-existing altered platelet function. The condition can be associated with abnormal bleeding ranging from severe bleeding diatheses recognised early in life to mild bleeding which can remain undetected even to advanced adulthood. Here we describe two cousins from a consanguineous family with severe thrombocytopenia and serious clinical bleeding including intracerebral haemorrhage.

Aims: In this study, we used a whole exome-sequencing approach to elucidate the genetic basis of a severe form of congenital thrombocytopenia in two cousins from a consanguineous family.

Methods: We studied a consanguineous family that included two cousins with severe thrombocytopenia. The proband was aged 3 years with a platelet count of 3×10^9/L when first entered into the study. His affected cousin was aged 7 years when recruited into the study and has a baseline platelet count of 15–20 $\times$ 10^9/L. To identify the causative mutation in this family we sequenced the whole exome of the two affected individuals with the SureSelect human AllExon 50 Mb kit (Agilent Technologies) and sequencing on the HiSeq 2000 (Illumina) with 100 bp paired-end reads. To examine whether the mutation within *ANKRD18A* led to hypofunction, we first measured the abundance of *ANKRD18A* mRNA by real time quantitative RT-PCR (qRT-PCR) in the two patients and compared to healthy controls. To analyse expression of *ANKRD18A,* quantification of gene expression was performed using the ABI Prism 7900HT Sequence Detection System. To investigate platelet function in the two patients we initially measured the levels of the surface glycoproteins CD42b (GPIbα), CD41 (αIIb) and GPVI by flow cytometry. Furthermore PRP was stimulated with ADP, collagen-related peptide (CRP) and PAR-1 peptide and the expression of P-selectin and binding of fluorescent fibrinogen was assessed by flow cytometry on an Accuri C6 flow cytometer.

Results: Whole exome sequencing performed in the two patients identified a homozygous in frame deletion mutation (c.2401_2403delGAA) in the ankyrin repeat domain 18A gene (*ANKRD18A*). The mutation removed a glutamic acid residue at position 801 of a coiled-coil domain of the protein (p.Glu801del). RT-PCR analysis in the two affected individuals revealed loss of *ANKRD18A* mRNA expression compared to control samples demonstrating an unstable mutant transcript. In addition to a severely low platelet count, platelet function testing demonstrated a marked impairment of platelet activation by a range of agonists.

Summary/Conclusions: In summary, these findings identify a novel gene that underlies thrombocytopenia and defines the genetic basis of the severe thrombocytopenia in this family. *ANKRD18A* belongs to the same family of proteins that has recently been discovered to be a major cause of a dominant form of thrombocytopenia (THC2). This study led to the identification of mutations in *ANKRD26 gene*, encoding ankyrin repeat domain 26. Therefore the discovery of *ANKRD18A* mutations further implicates ankyrin repeat domain containing genes in the global regulation of platelet formation and possibly platelet function.

AS 29 – Genetics in Coagulation

AS 29
Anticoagulant pathways: genotype-phenotype relationships

Castoldi E

Maastricht University, Maastricht, the Netherlands

The protein C pathway is a pivotal anticoagulant mechanism which is responsible for the proteolytic inactivation of coagulation factors Va (FVa) and VIIIa (FVIIIa), the essential cofactors of the prothrombinase and tenase complexes, respectively. Several genetic and acquired risk factors for venous thromboembolism (VTE), such as the deficiencies of protein C and protein S, the FV Arg506 Gln (FV Leiden) and prothrombin G20210A mutations, elevated FVIII levels, pregnancy and oral contraceptive use, directly or indirectly hamper the inactivation of FVa and/or FVIIIa by activated protein C (APC). Not surprisingly, a poor anticoagulant response of plasma to APC (APC resistance) is the most common risk factor for VTE. In our laboratory, we use a thrombin generation-based assay to determine plasma APC resistance. In this assay, thrombin generation is measured at ~10 pM tissue factor in the absence and presence of added APC, and the ratio between the endogenous thrombin potentials (ETP) determined in the presence and absence of APC is taken as a measure of plasma APC resistance. Thrombin generation is a global assay that probes all three phases of coagulation (initiation, propagation and termination) and reflects the overall tendency of a plasma sample to clot. Several retrospective and prospective studies have shown a correlation between the ETP or peak height of thrombin generation, especially if determined in the presence of APC, and VTE risk, making thrombin generation a promising intermediate phenotype to discover new (genetic) determinants of hypercoagulability and possibly VTE. In this lecture I will illustrate this concept with practical examples. In particular, I will show that: 1) thrombin generation determined in the absence and presence of APC varies widely among different FV Leiden carriers and is a marker of VTE risk; 2) some of this inter-individual variability can be explained by common genetic variation in haemostasis-related genes; and 3) the genetic dissection of thrombin generation parameters in patient populations may help identify new candidate genes that contribute to VTE risk.

AS 29.1
Fibrinogen ?′ increases the sensitivity to activated protein C in normal and FV Leiden plasma

Omarova F[1], Uitte de Willige S[2], Simioni P[3], Ariëns R[4], Bertina RM[5], Rosing J[1] and Castoldi E[1]

[1]Maastricht University, Maastricht; [2]Erasmus University Medical Center Rotterdam, Rotterdam, the Netherlands; [3]University of Padua Medical School, Padua, Italy; [4]University of Leeds, Leeds, UK; [5]Leiden University Medical Center, Leiden, the Netherlands

Background: Activated protein C (APC) inhibits coagulation by proteolytically inactivating activated factor V (FVa) and activated factor FVIII (FVIIIa). An insufficient response of plasma to APC (APC resistance), which is often due to the FV Leiden mutation, is the most common risk factor for venous thrombosis (VT). In a recent study of 188 FV Leiden carriers we observed an unexpected relationship between carriership of the fibrinogen γ gene (*FGG*) haplotype 2 (H2) and thrombin generation determined at high tissue factor in the presence of APC. The endogenous thrombin potential (ETP_{+APC}) was 397 ± 100 nM.min in *FGG* H2 homozygotes, 338 ± 91 nM.min in heterozygotes and 230 ± 62 nM.min in non-carriers ($P < 0.001$). *FGG* H2, a known risk factor for VT, is associated with reduced levels of the alternatively spliced fibrinogen γ' chain. The latter binds and inhibits thrombin *via* a high-affinity interaction with thrombin exosite II. Occupation of exosite II by the highly anionic carboxyl-terminal peptide of the fibrinogen γ' chain has been shown to interfere with the ability of thrombin to activate both FVIII and (Omarova et al., this congress) FV.

Aims: To investigate the effect of total fibrinogen and fibrinogen γ' on plasma APC resistance.

Methods: Thrombin generation was measured by Calibrated Automated Thrombography in the absence and presence of exogenous APC in: (i) whole and defibrinated plasma, (ii) congenitally fibrinogen-deficient plasma reconstituted with the purified fibrinogen isoforms (γAγA or γAγ'), and (iii) pooled plasma from normal individuals or heterozygous FV Leiden carriers in the presence of a synthetic fibrinogen γ' carboxyl-terminal peptide. The ratio of the ETPs determined in the presence and absence of APC was taken as a measure of plasma APC resistance.

Results: Whole plasma was less APC-resistant than defibrinated plasma, suggesting that (total) fibrinogen improves the response of plasma to APC. Reconstitution experiments in fibrinogen-deficient

plasma indicated that this phenomenon is mainly attributable to the γA/γ' fibrinogen isoform, with γAγA fibrinogen having only a minor effect. The synthetic fibrinogen γ' carboxyl-terminal peptide (added to plasma at a final concentration of 250 μM) considerably increased the APC sensitivity not only of normal pooled plasma, but also of pooled plasma from FV Leiden heterozygotes. These effects were specific, as a scrambled control peptide was ineffective. Moreover, the APC-sensitizing action of the fibrinogen γ' peptide was not abolished by the addition of an anti-FVIII antibody, indicating that the effect of fibrinogen γ' on the APC response is not (exclusively) mediated by FVIII, but probably also by FV.

Conclusions: Total fibrinogen and especially fibrinogen γA/γ' increase the APC sensitivity of normal and FV Leiden plasma. This APC-sensitizing effect can be reproduced by the carboxyl-terminal peptide of the fibrinogen γ' chain, suggesting that the underlying mechanism is due to the inhibition of thrombin-mediated activation of FV and FVIII, rather than to a stimulation of the APC-mediated inactivation of FVa and FVIIIa. The fibrinogen γ' peptide might form the basis for pharmacological interventions to counteract plasma APC resistance.

AS 29.2

The functional effect of pleotropic mutations on Antithrombin

Aguila S, Navarro-Fernández J, Bohdan N, De La Morena-Barrio ME, Padilla J, Miñano A, Vicente V, Corral J and Martínez-Martínez I

Centro Regional de Hemodonación, Hospital Morales Meseguer, UMU, IMIB, Murcia, Spain

Background: Antithrombin is a serine protease inhibitor with a key role in hemostasis and its deficiency significantly increases the risk of thrombosis. Two types of antithrombin deficiency have been described: type I with no mutant antithrombin in plasma, and type II, with a plasma variant that has reduced anticoagulant activity. This group of deficiencies is sub-classified according to the localization of the mutation and its functional consequence: II-a, and II-b affects the heparin-binding site and the reactive center loop, respectively. The type II-c or pleiotropic deficiencies include mutations located in C-sheet that impair the heparin affinity and the inhibitory activity by not well defined mechanisms. Recently, we described an abnormal glycosylation of a pleiotropic mutation (K241E) that explained the impaired heparin affinity.

Aim: To evaluate potential effects of different natural pleiotropic mutations on the glycosylation of antithrombin and their functional effects.

Methods: We selected pleiotropic mutations identified in patients with antithrombin deficiency located in each one of the strands of the C-sheet: K241E, M251I, M315K, F402L and P429L. Recombinant mutants produced in HEK-EBNA cells in a β-antithrombin context (S137A) were purified by heparin affinity chromatography and anion exchange. Then, we evaluated differences on size in SDS gel under reducing conditions, and the glycan alteration by treatment with *N*-glycosidase F. We also determined heparin affinity by intrinsic fluorescence. Finally, functional assays with FXa and thrombin in presence or absence of heparin were done.

Results: All pleiotropic mutants presented two isoforms that were purified by anion exchange due to their different isoelectric points, except for M315K, which only produced one isoform. Treatment with *N*-glycosidase F verified that these differences are caused by distinct glycosylation. For every mutant the glycoform with less electrophoretic mobility (V1) had reduced heparin affinity, which for the M251I mutant reached six-fold lower affinity than the recombinant β wild-type antithrombin. Moreover, these V1 glycoforms also had severely affected the reactivity with target proteases (FXa and FIIa) in presence and absence of heparin. In contrast, the V2 glycoform showed the same electrophoretic mobility and similar heparin affinity that recombinant β wild-type antithrombin. Moreover, this V2 glycoform also had an impaired inhibitory activity but it was partially compensated by activation with heparin.

Conclusions: Our study shows a common glyosylation defect for every tested natural pleiotropic mutation affecting C-sheet, apart from M315K, probably because the localization of this residue, close to the reactive center, might not affect the normal interaction with glycosyl transferases involved in the maturation of the *N*-glycan, that seems to allow other mutations. However, mutants with two glycoforms showed a proportion of protein undegoing an abnormal glycosylation. In these cases, V1 with high glycan content had reduced heparin affinity and a significantly impaired anticoagulant function. In contrast, V2 had normal glycosylation and heparin affinity. Thus, although the inhibitory activity of V2 glycoform is impaired as a consequence of the mutation, the activation with heparin restores partially the inhibitory capacity.

AS 29.3

Genetic variation in the annexin V gene and the risk for pregnancy related venous thrombosis

Dahm AEA[1], Tiscia G[2], Grandone E[2], Skretting G[1] and Per Morten S[1]

[1]Oslo University Hospital, Oslo, Norway; [2]Atherosclerosis and Thrombosis Unit, I.R.C.C.S. 'Casa Sollievo della Sofferenza', San Giovanni Rotondo, Foggia, Italy

Background: Annexin A5 is a natural anticoagulant mainly expressed by placental trophoblasts. It is assumed to have thrombomodulary functions as it shields phospholipid layers from coagulation complexes. There is evidence that anti-Annexin A5 antibodies can interfere with the Annexin A5 crystallization on the phospholipid layers and thereby promote pregnancy losses and/or thrombosis in the anti-phospholipd antibody syndrome. Recently, it has been demonstrated that the M2 haplotype within the Annexin A5 gene (*ANXA5*) promotor could be responsible for a diminished transcriptional activity. In the general population, some studies have shown that the M2 haplotype is associated with recurrent fetal loss, pregnancy-related hypertensive disorders as well as venous thrombosis (VT).

In developed countries, VT is a leading cause of maternal morbidity and death during pregnancy and puerperium, and occurs in approximately 1/1000 pregnancies. The mechanism behind pregnancy related VT is considered multicausal, but risk factors for ante- and postnatal VT differ, indicating different pathophysiological mechanisms.

Aim: To investigate if the M1 or M2 haplotypes or other genetic variations in *ANXA5* was associated with pregnancy related VT.

Methods: We investigated women in the Norwegian VIP study which is a population based case-control study of VT in pregnancy or within 3 months post partum (cases) and women without pregnancy related VT (controls). Informed consent was obtained from all women and the study was approved by the regional medical ethics committee. The M1 and M2 haplotypes were analysed by direct sequencing of a PCR-amplified 491 bp fragment of the *ANXA5* promotor. In addition, tag SNPs were selected for *ANXA5* from the CEU population of the Hapmap project with an r2 of 0.80 and minimum allele frequency of 0.10. DNA samples from 313 cases and 353 controls were investigated. Odds ratios were calculated for each haplotype with the wild type as the reference and for each tag SNP with the most common genotype as reference. Antenatal and postnatal VT were analysed separately.

Results: Women homozygous for the M2 haplotype had an odds ratio of 2.8 (95% confidence interval 0.83–9.2) for antenatal VT. For the other haplotypes the odds ratios for both antenatal and postnatal VT were close to 1.

The tag SNP rs17384348 had an odds ratio for antenatal VT of 1.5 (95% confidence interval 0.8–2.7). The other tag SNPs had odds ratios close to 1 for both antenatal and postnatal VT.

Conclusion: All in all, neither the M1/M2 haplotypes nor the tag SNPs in *ANXA5* were convincingly associated with pregnancy related VT.

AS 30 – Thrombus Resolution and Stroke

AS 30

The effects of DNA and histones on fibrin clot structure-function and on the regulation of fibrinolysis

Longstaff C[1], Varjú I[2], Sótonyi P[2], Szabó L[3], Krumrey M[4], Hoell A[5], Bóta A[6], Varga Z[6], Komorowicz E[2] and Kolev K[2]
[1]*NIBSC, South Mimms, UK;* [2]*Semmelweis University;* [3]*Institute for Materials and Environmental Chemistry, Budapest, Hungary;* [4]*Physikalisch-Technische Bundesanstalt;* [5]*Helmholtz-Zentrum Berlin, Berlin, Germany;* [6]*Institute of Molecular Pharmacology, Budapest, Hungary*

Background and Aims: Neutrophil extracellular traps (NETs) are networks of DNA, histones and other proteins, released by neutrophils and are recognised as mediators between immunity, inflammation and haemostasis. They have been shown to promote clotting and form a scaffold with fibrin within clots which increases the likelihood of unwanted thrombosis. However, little is known of the effects of DNA and histones on the mechanical stability of fibrin and resistance to fibrinolysis, the subjects of the present study.
Methods: An array of biophysical techniques and binding studies were applied to investigate the effects of DNA and histones on fibrin structure and stability. These included electron microscopy (EM) and confocal microscopy (CM), rheology, isothermal titration calorimetry (ITC), small angle X-ray scattering (SAXS) and thromboelastography. Fibrinolysis assays, with tissue plasminogen activator (tPA) and plasminogen, in a variety of formats were included to understand the kinetics of plasminogen activation and of fibrin breakdown.
Results: DNA, histones or DNA+histones could have strong and sometimes opposing effects on fibrin structure and stability to mechanical stress. This may be important physiologically as we found surgically removed arterial thrombi stained positively for DNA and histones either separately or in complex. Rheology studies showed DNA added to fibrin produced weak, floppy clots, whereas histones or DNA+histones produced firmer clots requiring more shear stress to be disassembled. EM studies showed histones and DNA+histones in clots resulted in significantly thicker fibrin fibres. Fibrinolysis was also affected by DNA and histones. Setting tPA activity in the absence of DNA or histones to 100%, fibrinolytic activity of tPA with 70 μg/mL DNA was 85.4 ± 6.6% and 146.8 ± 8.2% with 50 μg/mL histones. These results were in agreement with experiments tracking the progress of a fluorescent tPA chimera (tPA-GFP) through red AlexaFluor fluorescently-conjugated fibrin by CM. The rate of movement of the lysis front in clots with no additions was set to 100% and was 50 ± 3% in the presence of DNA and was 161 ± 3% in the presence of histones or DNA+histones. However, important differences were seen in studies of gross changes in clot structure during lysis. Time lapse photography showed dramatically slower clot lysis (~3 times longer) in the presence of DNA+histones. ITC data indicated that DNA and histones both bind to large FDP suggesting a mechanism whereby DNA-histones bind to FDP to maintain clot structure during lysis, significantly delaying complete dissolution until FDP are reduced to smaller fragments which bind to DNA-histones only weakly. DNase mixed with tPA reverses this delay. Heparin was able to break down fibrin-DNA-histone complexes, as evidenced in SAXS studies, also enhancing clot lysis rates.
Conclusions: DNA and histones affect fibrin structure and properties, plasminogen activation and fibrinolysis in a number of distinct ways. However, profound effects were observed with DNA+histones which modify clot structure and markedly delay clot lysis. DNA and histones released by neutrophils or other apoptotic cells found in the pro-inflammatory environment of atherosclerotic plaques may regulate fibrinolysis *in vivo*. New therapeutic strategies including DNase or non-anticoagulant heparins added to plasminogen activators may improve thrombolysis.

AS 30.1

A new effective strategy for thrombolysis in ischemic stroke: low-dose tPA in combination with MMP-10

Orbe J[1], Roncal C[1], Rodriguez JA[1], Salicio A[1], Montaner J[2], Rosell A[2], Martinez de Lizarrondo S[3], Vivien D[3] and Paramo JA[1]
[1]*CIMA, University of Navarra, Pamplona;* [2]*Vall d'Hebron Hospital, Barcelona, Spain;* [3]*Inserm, Caen, France*

Background: Early reperfusion using tissue-type plasminogen activator (tPA) is the only therapeutic strategy to treat focal cerebral ischemia with proven efficacy in stroke patients. Intracerebral haemorrhage is one of the major complications of t-PA administration. t-PA has also been linked to neurotoxicity. Therefore, there is an unmet need for new strategies to improve tPA-induced thrombolysis.
Aim: Based on our previous data showing a profibrinolytic effect of matrix metalloproteinase-10 (MMP-10) in ischemic stroke model (Orbe et al., Circulation 2011), we wanted to determine if combined therapy of tPA and MMP-10 improves the beneficial effect of tPA.
Methods: We used a murine ischemic stroke model induced by the local injection of thrombin into the middle cerebral artery, to analyze the effect of different tPA doses (1–10 mg/Kg) or tPA combined with recombinant MMP-10 (6.5 μg/Kg) on the infarct size. *In vitro* cultures were also performed to determine the effect of tPA+MMP-10 on endothelial cells (permeability assay) and neurons (excitotoxicity assay).
Results: We observed that 10 mg/Kg of tPA plus MMP-10 significantly reduced the infarct size in the thromboembolic ischemic stroke model compared with tPA alone. Moreover, a 10-fold reduction in tPA dose in the presence of MMP-10 produced the same effect on infarct size than full-dose of tPA+MMP-10 ($P < 0.05$) without increasing haemorrhage. *In vitro* data showed that MMP-10 reduced the tPA endothelial permeability and improved neuronal excitotoxicity of tPA.
Conclusions: These data suggest that the combination tPA/MMP-10 could be a new strategy for thrombolysis in ischemic stroke, allowing significant reduction of the tPA dose and similar decrease in infarct size.

AS 30.2

Kinase activity of TRPM7 enhances PLC? Two mediated calcium responses in platelets and plays an important role in arterial thrombosis and stroke

Braun A[1], Chen W[1], Chubanov V[2], Morowski M[1], Kraft P[1], Gotru SK[1], Hermanns HM[1], Stoll G[1], Gudermann T[2] and Nieswandt B[1]
[1]*University of Würzburg, Würzburg;* [2]*Walther-Straub-Institute, Munich, Germany*

Background: Transient receptor potential melastatin-like 7 channel (TRPM7) has been identified as a constitutively active divalent cation selective channel which regulates intracellular Mg^{2+} concentration in vertebrates. In addition, the C-terminus of TRPM7 is covalently linked to an α-type Ser/Thr kinase domain which is able to phosphorylate its own residues and several substrates including phospholipase C (PLC) γ2. Interestingly, the activation mechanism and the physiological role of the kinase domain still remain elusive. TRPM7 has been shown to play an important role in the pathogenesis of ischaemic stroke and its expression in brain tissue was found to be upregulated under ischaemic conditions, whereas knock-down of TRPM7 resulted in enhanced viability of neurons under hypoxia. TRPM7 seems to exhibit an ambivalent role in cation homeostasis; hence under normal physiological conditions Mg^{2+} influx through TRPM7 can support cell survival, while under pathophysiological conditions the channel or its kinase domain might enhance Ca^{2+} influx leading to cell death. TRPM7 function in platelet physiology and thrombosis has not been investigated so far.
Aims: We hypothesized that the kinase domain of TRPM7 and its signalling mechanism might regulate Ca^{2+} mobilization and Ca^{2+} influx during platelet activation and thrombus growth.

Methods: To identify the physiological importance of the TRPM7 kinase *in vivo*, a *Trpm7ΔKIN* mouse line was generated by introducing a point mutation in the *Trpm7* gene, resulting in an amino acid substitution at position 1646 from lysine to arginine. The K1646R mutation inhibits Mg^{2+}-ATP binding in the catalytic site of the kinase domain, leading to the complete blockade of TRPM7 kinase activity. *Trpm7ΔKIN* platelets were analyzed using a wide range of *in vitro* and *in vivo* platelet functional assays.
Results: We report the first experimental evidence that *Trpm7ΔKIN* mice display a marked signalling defect in platelets. Inositol triphosphate (IP_3) production, Ca^{2+} mobilization and Ca^{2+} influx were severely impaired upon activation of the immunoreceptor tyrosine based activation motif (ITAM)-coupled collagen receptor, GPVI. These results indicated that the kinase activity of TRPM7 is essential to enhance ITAM-PLCγ2-mediated Ca^{2+} responses. Impaired TRPM7 signalling also led to altered integrin activation, degranulation and aggregation responses to GPVI agonists *in vitro* and impaired thrombus formation under flow *ex vivo*. In line with these findings, *in vivo* experiments showed that *Trpm7ΔKIN* mice were significantly protected from arterial thrombosis and ischaemic brain infarction.
Conclusions: These results establish the physiological role of TRPM7 kinase as a key modulator of Ca^{2+} store release and SOCE in platelets, and highlight the role of this new signalling mechanism in the pathogenesis of thrombosis and ischaemic stroke.

AS 31 – Coagulation and Complement

AS 31
Coagulation and complement

Levi M
University of Amsterdam, Amsterdam, the Netherlands

The blood coagulation system and the complement system are connected in many ways. Coagulation proteases, such as thrombin, but also factor Xa, IXa and XIa, can directly activate complement factors, although the biological and clinical relevance of this action *in vivo* is not clear. Factor XIIa is known to activate complement factor I, leading to the initiation of the classical complement pathway. Conversely, C1 inhibitor does not only block complement factor I but is also the most important inhibitor of factor XIIa and kallikrein. In patients with C1-inhibitor deficiency (leading to hereditary angio-edema) attacks of angio-edema are associated with minor activation of coagulation but have major impact on fibrinolysis. An interesting role of thrombin activatable fibrinolysis inhibitor (TAFI) in complement regulation has been established. TAFI is activated upon binding of thrombin to the endothelial surface receptor thrombomodulin and acts as an important inhibitor of C3a and C5a, thereby rendering another important connection between coagulation and inflammation. Lastly, C4b binding protein serves a binding protein for free protein S, interfering with the regulation of coagulation by physiological anticoagulants.

AS 31.1
Human megakaryocytes and platelets contain complement C3 and C5 and release it upon interaction with *Escherichia coli*

Arbesu I[1], Fischer MB[2] and Mannhalter C[3]
[1]*Medical University of Vienna;* [2]*Department of Blood Group Serology and Transfusion;* [3]*Department of Laboratory Medicine, Medical University of Vienna, Vienna, Austria*

Background: Platelets link coagulation, inflammation and infection. Following exposure to bacteria and a complement dependent activation, platelets can contribute to defense against pathogens. It is known that complement proteins, especially C3, are important for protection from endotoxin shock, and individuals with C3 deficiency are more susceptible to bacterial infections. In sepsis, C3 activation, leading to high C3b levels, is involved in the development of septic shock. In haemolytic uremic syndrome with Shiga toxin producing *E. coli* infection, platelet microparticles carrying high levels of surface bound C3 and C9 are found. Currently, it is assumed that the complement proteins are bound to platelets from plasma.
Aim: We studied whether complement proteins on platelets are only derived from plasma or are synthesized in megakaryocytes and stored in platelets intracellularly. We hypothesized that platelets contain complement proteins and, upon contact with gram-negative bacteria, platelets release complement factors and their activation products to support defense against the bacteria.
Methods: Mature megakaryocytes (MK) generated from cord blood CD34+ cells and platelets obtained from platelet concentrates were exposed to heat killed (HK) *E. coli* 018: K1 in the absence of plasma or other sources of complement proteins. Platelets and MKs were tested for complement C3 and C5 by Western blot and immunocytochemistry. The release of complement proteins was evaluated by ELISA, the presence of C3 and C5 mRNA was analyzed by real time PCR (RT-PCR). The effect of platelets on viability of *E. coli* 018: K1 (pathogenic) and *E. coli* K12 C600 (non-pathogenic) was tested following incubation with platelets before growing the bacteria on culture plates.
Results: RT-PCR analyses showed the presence of C3 and C5 mRNA in MKs and platelets. Proteins migrating at 110, 100, 75, 64, 45 and 38 kD were detectable in platelet concentrates by Western blot with C3 antibody. Exposure of platelets and MK to *E. coli* 018: K1 lead to secretion of C3a and C5a, and ELISA results revealed a 10-fold increased release of C3a and a 100-fold increase of C5a compared to platelets incubated with buffer. Higher expression of C3 after contact with bacteria was also found by confocal microscopy. Activated C3 released from platelets was immediately bound to bacteria. Growth of *E. coli* K12 C600 was completely abolished following platelet contact, while the growth of *E. coli* 018: K1 was not affected. Increased levels of C3a or C5a were not induced by *E. coli* 055:B5 LPS.
Conclusion: Our data indicate that complement C3 and C5 mRNA and protein are present in megakaryocytes and platelets. Contact of washed platelets with *E. coli* leads to activation of C3 and C5 and generation of C3a, C3b, C3d and C5a. The lacking effect of LPS indicates that the activation of complement in platelets is not primarily mediated via TLR4. Already 30 min contact between platelets and bacteria seems to be sufficient to inhibit the growth of *E. coli* K12 C600. The underlying mechanisms have yet to be elucidated and the relevance for the pathogenicity of *E. coli* needs to be evaluated.

AS 31.2
Polyphosphate suppresses complement activation

Wat J[1], Krisinger MJ[1], Foley JH[1], Lei V[1], Smith SA[2], Morrissey JH[2] and Conway EM[1]
[1]*University of British Columbia, Vancouver, BC, Canada;* [2]*University of Illinois at Urbana-Champaign, Urbana, IL, USA*

Background: In response to vascular injury, coagulation and complement are simultaneously activated to limit blood loss and restrict pathogen invasion, respectively. Although it is reasonable to consider that complement and coagulation are co-regulated, it is only recently that the molecular mechanisms have started to be delineated.
Initiation of coagulation is achieved by exposure of blood to tissue factor or an anionic surface, resulting in a proteolytic cascade that leads to generation of thrombin and a fibrin clot. Complement activation is initiated via the classical, lectin or alternative pathways, whereupon the pathways merge, ultimately leading to cleavage of C5 to yield C5a and C5b. C5b complexes with C6 (C5b,6), which initiates the terminal pathway by sequentially binding to C7, C8 and multiple C9 molecules.

This resultant C5b-9, the membrane attack complex (MAC), becomes integrated into the membrane of the cell that is targeted for destruction.

Recent studies have shown that polyphosphate (polyP), anionic strings of phosphate ions that are released from granules of activated platelets, has important procoagulant properties. With increasing evidence of links between complement and coagulation, we sought to evaluate whether polyP also modulates complement activation.

Aim: To evaluate the effect of polyP on complement activation.

Methods: Binding of polyP to complement components was evaluated by electrophoretic mobility shift assays. Complement-mediated hemolytic activity was quantified by measuring lysis of rabbit or chicken erythrocytes. The terminal pathway was initiated with C5b,6 in the presence of C7, C8 and C9 or human serum. Different polymer lengths and concentrations of polyP were added prior to initiation of complement. As controls, polyP polymers were digested with calf intestinal alkaline phosphatase (CIAP) into monomers (P_1). Concentrations of polyP were expressed as monomeric phosphate equivalents.

Results: We determined that polyP binds to alterative pathway components factor H and factor B, and to C5, C5b,6 and C6 of the terminal pathway. Total hemolytic activity was dampened by increasing concentrations of long-chained polyP ($P_{>1000}$) as compared with P_1. Long-, medium- and short-chain polyP ($P_{>1000}$, $P_{40–160}$, and $P_{<30}$) interfered with terminal pathway activation in a concentration-dependent manner, but the $P_{>1000}$ and $P_{40–160}$ were more effective, i.e., the concentration of $P_{>1000}$ or $P_{40–160}$ to achieve half-maximal inhibition (IC_{50}) was ~10 μM with total inhibition at ~200 μM. In contrast, an IC_{50} with $P_{<30}$ could not be achieved even with 5 mM polyP. The ability of polyP to inhibit terminal pathway activation was absent once the C5b-7 complex formed, suggesting that polyP binding to C5b,6 may alter its ability to form a fully functional MAC. Pretreatment of polyP with CIAP restored hemolytic activity.

Summary/Conclusions: In addition to interacting with factors that regulate coagulation, polyP binds to several proteins in the complement system, including those that initiate and propagate the terminal pathway. All polyP preparations tested inhibited hemolytic activity in terminal pathway assays with $P_{>1000}$ being the most effective. The physiological relevance of polyP in response to injury requires further study, but our findings are consistent with an important role in protecting host cells from complement-mediated damage.

AS 31.3

The lectin like domain of Thrombomodulin is involved in the defense against pyelonephritis

Lattenist L, Teske G, Claessen N, Florquin S and Roelofs JTH
Academic Medical Center, Amsterdam, the Netherlands

Background: Urinary tract infections (UTI), frequently caused by *E. coli*, are among the most common bacterial infections, affecting 50% of women worldwide at one point of their life and causing considerable paediatric problems. Among UTI acute pyelonephritis forms a substantial health issue and can lead to end stage renal failure.

Thrombomodulin (TM) is a cell surface-expressed protein, mainly expressed on vascular endothelium but also on some epithelium such as urothelium. TM is part of a natural anticoagulation pathway that limits the action thrombin. Binding of thrombin to TM inhibits the thrombin-mediated conversion of fibrinogen into fibrin. Furthermore the thrombin-TM complex activates the protein C which has anticoagulant, anti-inflammatory and cytoprotective activities. The TM protein consists of several domains of which the lectin and EGF-like domains are crucial for TM structure and function.

Aim: In the current study we wanted to investigate the role played by thrombomodulin in a model of acute pyelonefritis.

Methods: We used two TM transgenic mouse strains: TMpro/pro mice, which bear a mutation in the EGF-like domain making them unable to activate protein C, and TMled/led mice which lack the lectin-like domain of TM which is critical for its anti-inflammatory and cytoprotective properties. These mice were subjected to pyelonephritis model by intravesical inoculation of $1x10^9$ CFU of *E. coli* 1677. Mice were sacrified after 24 and 48 h after inoculation. Kidneys and the bladder were harvested and homogenized in sterile saline for determination of bacterial outgrowth on blood agar plates. Circulating numbers of leukocytes were counted using a haemocytometer.

Results: TMpro/pro mice did not show any differences in renal and bladder bacterial loads, nor in blood leukocytes compared to WT mice.

In contrast, TMled/led mice showed more severe disease than WT mice. TMled/led mice showed significantly more bacterial outgrowth in bladder homogenates at 24 and 48 h after inoculation compared to WT mice ($P < 0.01$ and $P < 0.05$ respectively). Also, TMled/led mice had significantly more bacteria in kidney homogenates at 48 h after inoculation ($P < 0.05$) and showed elevated blood leukocyte counts at 24 h after inoculation than WT mice ($P < 0.05$).

Conclusion: We conclude that the lectin-like domain of thrombomodulin is critically involved in host defense against *E. coli* induced acute pyelonephritis.

AS 32 – Treatment of Von Willebrand Disease

AS 32.1

Long-term correction of von Willebrand disease via Sleeping Beauty transposon-mediated gene therapy

De Meyer SF[1], Verhenne S[1], Pareyn I[1], Deckmyn H[1], Izsvak Z[2] and Vanhoorelbeke K[1]
[1]KU Leuven Kulak, Kortrijk, Belgium; [2]Max Delbruck Center for Molecular Medicine, Berlin, Germany

Background: Von Willebrand disease (VWD) is the most common inherited bleeding disorder. Severe VWD (type 3) is characterized by complete absence of the hemostatic protein von Willebrand factor (VWF). Current treatment of severe VWD is limited to the administration of exogenous VWF concentrates derived from plasma. Given the relatively short half-life of VWF (8–12 h), only a short-term therapeutic effect can be achieved, often requiring multiple subsequent treatments. Gene therapy for this monogenic bleeding disorder is an interesting treatment alternative with long-term therapeutic potential. We previously showed that the liver is an attractive target for ectopic expression of physiologically active VWF.

Aim: The aim of this study was to achieve long-term correction of murine severe VWD via non-viral gene therapy.

Methods: We constructed two Sleeping Beauty transposon vectors containing full-length murine VWF under the control of either the ubiquitous CAG promoter or the hepatocyte-specific alpha-1 antitrypsin promoter. Each transposon, together with a plasmid encoding the optimized Sleeping Beauty transposase SB100x, was directed to the liver of VWF-deficient mice via hydrodynamic gene delivery. At regular intervals after gene delivery, we measured VWF antigen levels in plasma. Correction of the bleeding diathesis was investigated using a tail-clipping bleeding assay.

Results: Use of the transposon containing the CAG promoter resulted in a sustained long-term (> 1 year) expression of VWF in VWF-deficient mice, although VWF levels were low (< 5% of normal wild-type level). Integration of the murine VWF cDNA into the mouse liver genome was confirmed using splinkerette PCR. Higher levels of sustained VWF expression were observed using the transposon with the more potent alpha-1 antitrypsin promoter. Three months after gene delivery, plasma levels remained 75.8 ± 17.6% ($n = 5$) of wild-type values in male mice while VWF expression was lost within 3 weeks in mice that received the VWF transposon vector but no transposase plasmid. At this timepoint, tail-clipping bleeding times were corrected in treated male mice. This phenotypic correction was confirmed by the observation that the blood loss volume was

significantly lower in treated mice when compared to VWF-deficient control mice. Female animals had significantly lower levels of VWF after treatment, resulting in less blood loss volume but not in correction of bleeding time.

Conclusion: We herewith present the first proof-of-concept for long-term treatment of VWD by non-viral gene therapy. Ongoing follow-up studies will establish how long phenotypic correction can be maintained.

AS 32.2

Determinants, frequency, types, and management of bleedings in severe VWD type 3: final results of the retro/prospective analyses in 86/52 Italian patients

Federici AB[1], Castaman G[2], Bucciarelli P[3], Oliovecchio E[4], Baronciani L[3], Mazzucconi MG[5], Morfni M[6], Morfni M[6], Rocino A[7], Schiavoni M[6] and Peyvandi F[3]

[1]University of Milan, Milan; [2]S. Bortolo Hospital, Vicenza; [3]AB Bonomi Hemophilia Thrombosis Center, Milan; [4]Unversity of Perugia, Perugia; [5]University of Rome, Rome; [6]Hemophilia Center, Firenze; [7]Pellegrini Hospital, Napoli, Italy

Background: VWD3 is the most rare (1–5 cases/million) and severe form of VWD because is due to virtually complete deficiency of the von Willebrand factor (VWF). VWD3 is of major interest because of severe clinical presentation, need for replacement therapy with VWF/FVIII concentrates, risk of occurrence of anti-VWF inhibitors in a few cases. Even though VWD3 has been known since its original description in 1926, detailed information on the determinants of bleeding are not available so far.

Aims and design of the study: To evaluate possible predictors of bleedings requiring VWF/FVIII concentrates in VWD3 patients, data were collected by Members of the Italian Association of Hemophilia Centers (AICE) using standard protocols. 6/20 Italian Centres could also follow-up for 1 year patients with confirmed VWD3 diagnosis.

Methods: Inclusion criteria were VWF:Ag < 3 U/dL with FVIII:C < 20 U/dL and autosomal-recessive inheritance. Bleeding score (BS) was calculated at enrolment. Gene mutations were searched for in all available DNA.

Results: In the retrospective analysis, among cases originally reported, only 86/114 (75.4%) patients met the inclusion criteria and were characterized by the following demographic, clinical-lab parameters [median(range)]: gender (M/F) = 42/44; age = 38 (6–71); BS = 14 (3–35); FVIII:C = 3 (1–20); anti-VWF-inhibitors = four from three families. Molecular diagnosis was available in 54/86 (59.5%) cases with the following gene defects(pt-n): large-deletion (4); small-deletions-insertions (14); nonsense (9); splice-site (8); missense mutations (19). Mucosal bleedings (64%) were more frequent than hematomas-hemarthrosis (24%). In the retrospective study 77/86 (89.5%) VWD3 had been already exposed to VWF/FVIII concentrates. In the prospective observational study, 52/86 (60.5%) VWD3 were followed-up by 6/20 Centres and 27/52 (88%) were treated in a year for 72 spontaneous bleeding events. BS of VWD3 bleeders (16 [5–35]) was significantly ($P = 0.01$) higher than that (10 [3–22]) of non-bleeders; BS > 10 (HR = 6.8, CI = 3.8–12.3) and FVIII < 5 U/dL (HR = 4.1, CI = 2.4–7) were associated with high risk of bleeding. VWD3 patients with BS < 10 and FVIII > 15 had very few bleeding events. On the other hand, BS > 10 could identify VWD3 patients with higher frequency and severity of events requiring intensive therapy (8100 [3500–25,400] VWF:RCo IU/event) with VWF/FVIII concentrates. Patients with anti-VWF inhibitors were off therapy during this follow-up.

Discussion and Conclusions: these retro/prospective studies show for the first time that also VWD3 can be very heterogeneous. BS and FVIII levels are good predictors of bleeding. An international and multicenter project (3WINTERS-IPS) has been recently organized (2011–2016) to collect more information about clinical and molecular markers associated with increased risk of bleeding and of anti-VWF inhibitors in a larger cohort of at least 250 patients with VWD3.

AS 32.3

High rate of postpartum hemorrhage in women with von Willebrand disease or carriership of hemophilia, despite specialized care

Stoof CM[1], Van Steenbergen HW[2], Sanders YV[1], Cannegieter SC[2], Duvekot J[1], Leebeek FWG[1], Kruip JHA[1] and Eikenboom HCJ[2]

[1]Erasmus University Medical Center, Rotterdam; [2]Leiden University Medical Center, Leiden, the Netherlands

Background: In the general Dutch population the incidence of severe postpartum hemorrhage (PPH) is 5%. It is likely that this incidence is higher in women with bleeding disorders, as the increase of coagulation factors during pregnancy, such as von Willebrand factor and factor VIII, may be insufficient for adequate hemostasis. It is known that pregnancy and delivery are associated with a high risk of bleeding in women with bleeding disorders. Therefore, pregnant women with bleeding disorders require specialized peripartum care to prevent PPH. It is generally accepted that coagulation factors < 0.50 IU/mL are an indication for prophylactic replacement therapy with factor concentrate or desmopressin during delivery.

Aims: to study the incidence of PPH in women with von Willebrand disease (VWD) and hemophilia carriers managed in Hemophilia Treatment Centers (HTC).

Methods: We included pregnancies in women with VWD or hemophilia carriers treated in two Dutch HTCs between 2002 and 2011. We collected information about pregnancy outcome, i.e. blood loss during or after delivery, need for red blood cell transfusion, and mode of delivery. Primary PPH was defined as blood loss ≥ 500 mL, severe PPH as ≥ 1000 mL within 24 h postpartum. Analyses were performed separately for all pregnancies and for first pregnancies only. As results did not essentially differ, only the former are presented. The study was not subject to the Medical Research Involving Human Subjects Act and was approved by the Medical Ethics Committee.

Results: We included 201 pregnancies in 141 women. Mean age at time of delivery was 31 ± 4.7 years. Median parity was 1 (10–90th percentile: 0–2). Sixty-eight women had VWD (58 type 1, 10 type 2) and 73 women were hemophilia carriers (60 hemophilia A, 13 hemophilia B). Seventy-nine percent (158/201) of deliveries were vaginal and 21% (42/201) were caesarean sections (11% elective, 10% emergency). Of 180 pregnancies data on the amount of milliliters blood loss during or after delivery were available. Thirty-six percent (65/180) of deliveries were complicated by primary PPH, 10% (18/180) by severe PPH. No difference in PPH incidence was seen between women with VWD and hemophilia carriers. Coagulation factor levels were measured at 25–40 weeks of gestation. In 26 pregnancies these levels were < 0.50 IU/mL and consequently prophylactic replacement therapy was given. Despite replacement therapy, 50% (13/26) of deliveries in these patients still resulted in PPH, 15% (4/26) in severe PPH. These PPH incidences were higher compared to deliveries in which no prophylactic replacement therapy was given according to the guidelines, i.e. 34% (52/154) for all PPH and 9% (14/154) for severe PPH. Compared to pregnancies with factor level ≥ 1.00 IU/mL at 25–40 weeks of gestation (before correction with factor concentrate), pregnancies with factor level < 0.50 IU/mL had a seven-fold increased risk of severe PPH.

Summary/Conclusion: The incidence of severe PPH is high in women with VWD and in carriers of hemophilia, despite specialized care in a HTC. The high rate of PPH in pregnancies managed with prophylactic factor replacement therapy indicates that current management of deliveries in women with bleeding disorders needs to be improved.

AS 33 – Major Bleeding

AS 33
Bleeding and thrombosis in patients with liver disease

Lisman T

University Medical Centre Groningen, Amsterdam, the Netherlands

Patients with chronic or acute liver diseases frequently acquire a complex disorder of hemostasis secondary to their disease. These hemostatic changes include thrombocytopenia and platelet function defects, decreased levels of pro- and anticoagulant proteins, and alterations in plasma levels of the fibrinolytic system. These changes have long been believed to result in a hypocoagulable status. Recent laboratory studies have shown that the prohemostatic defects in patients with liver diseases are, at least in part, compensated for. Specifically, the thrombocytopenia is compensated for by substantially elevated levels of von Willebrand factor, decreased levels of procoagulants are balanced by decreased levels of anticoagulants, and defects in profibrinolytic systems are balanced by changes in the regulatory mechanisms of the fibrinolytic system. The hemostatic system in patients with liver disease thus appears to be in a 'rebalanced' state due to concomitant changes in pro- and antihemostatic pathways. This new hemostatic balance, however, is unstable and can easily tip towards either a hypo- or a hypercoagulable status. Careful analysis of the clinical phenotype of these patients supports the theory of a 'rebalanced' hemostatic system. Patients with liver diseases do not have an overt bleeding diathesis, as many patients can undergo major surgical procedures such as liver transplant surgery without the requirement for transfusion or prohemostatic therapy. In addition, both bleeding complications as well as thrombotic episodes frequently occur in patients with liver diseases. Nevertheless, the most important bleeding complication in patients with chronic liver disease (i.e. variceal bleeding) is unrelated to defective hemostasis, but rather depends more on local vascular abnormalities and portal hypertension leading to increased vascular pressure. Management strategies of bleeding complications that are related to defective hemostasis are still incompletely defined, and no laboratory tests to predict bleeding complications in these patients is available. Despite laboratory indications of a hypocoagulable status such as prolongations in the PT and APTT, patients with liver disease are not protected against venous thrombosis. In addition, thrombosis of the portal vein is common in patients with advanced chronic liver disease, and results in clinical deterioration. Prevention and treatment of thrombosis of patients with liver diseases is complicated by multiple factors including (i) a (perceived) bleeding risk, (ii) Uncertainty of dosing regimens or drug targets (e.g. the target INR of a patient that requires vitamin K antagonists but already has a prolonged INR as a result of the liver disease is unclear), (iii) issues with monitoring tests (assessment of the INR or of anti-Xa levels is inaccurate in patients with liver diseases), (iv) The anticoagulant potency of some of the available drugs appear different in patients with liver disease compared to individuals with intact liver function. Clinical studies on safety, efficacy, and monitoring of both pro- and antihemostatic strategies in patients with liver disease are thus urgently required.

AS 33.1
Comparison of three different prothrombin complex concentrates efficacy, in reversal of anti-vitamin K effect in patients under oral anticoagulant treatment: an *in vitro* study

Rossetto V, Sartori MT, Gavasso S, Fadin M, Campello E, Spiezia L and Simioni P

Padua University, Padua, Italy

Background: Intra-cranial and major haemorrhages in patients undergoing anticoagulant treatment are life-threatening events that require rapid reversal of anticoagulation with target INR < 1.5.

Aims: To compare '*in vitro*' efficacy of three different prothrombin complex concentrates (PCC) in reversing INR and in restoring thrombin generation and ROTEM® profiles in anticoagulated blood or plasma samples. Two of them, 'PCC-A' and 'PCC-B' were four factors containing PCC. The third, 'PCC-C', was a three factors containing PCC.

Methods: Primarily, we tested three different concentrations of PCC (0.5, 1 and 1.5 U/mL of plasma) to detect the lower dose sufficient to restore a normal INR. The lower dose was found to be 0.5 U/mL. In a second phase *n*. 60 anticoagulated blood samples, both whole blood and plasma, were collected: (i) *n*. 20 with INR 1.5–2; (ii) *n*. 20 with INR 2–3.5; (iii) *n*. 20 with INR > 3.5. In each plasma sample, coagulation factors concentrations, INR, PTT and thrombin generation were measured at baseline (t_0) and after the addition of 0.5 U/mL of each of the three different PCC (t_1). Finally, ROTEM® profiles were evaluated in whole blood samples at t_0 and t_1.

Results: The four factors PCC (PCC-A and PCC-B) were able to restore a normal INR value independently from the INR at baseline. On the contrary, PCC-C restored an INR value < 1.5 only when the INR t_0 value was 1.5–2. Moreover, when INR value at baseline was 2–3.5 the mean INR value at t_1 was 1.64 (range 1.4–2.5), and when INR value at baseline was > 3.5 the mean INR corrected value was 1.88 (range 1.7–2.3). PCC-A determined a significantly ($P < 0.0001$, in both cases) lower factor IX activity (FIX act) at t_1 (increase vs. basal of 96.4%, range 40–155.4) than PCC-C (170%, range 101–273.6%) and PCC-B (164.3%, 106.6–270.6). Differently from PCC-A and PCC-B, PCC-C did not restore Factor VII activity. PCC-C completely restored thrombin generation profile in all degrees of anticoagulation (mean Peak increase vs. basal 453.1%, 96.7–1250.6) with performance comparable to PCC-B (483.4, 152.1–1433.6). PCC-A failed to restore normal thrombin generation even at lower levels of anticoagulation (INR < 2). In particular, with PCC-A was observed only a small increase of Peak compared to basal condition (38.5%, −82.3 to 495.6). No significant differences were observed as for ROTEM profiles among the three PCC tested.

Conclusions: INR is rapidly corrected by low doses of PCC-A and PCC-B independently of basal INR while PCC-C gives only a partial INR correction at higher degrees of anticoagulation. This is most likely due to the lack of FVII in PCC-C. TG is completely restored by low doses of PPC-B and PCC-C while PCC-A has a paradoxical behavior evidenced by a prolongation of PTT and CT-INTEM and absent TG restoration *in vitro*.

On the basis of TG profiles, it can be observed that PCC-B and PCC-C are good tools to rapidly reverse anticoagulation. Data concerning PCC-A need to be carefully evaluated and correlated with the real *in vivo* efficacy.

AS 33.2
Liver cirrhosis is associated with hypercoagulability, decreased clot strength and normal fibrinolysis

Kleinegris MC[1], Habets CAM[1], Van De Sande AJP[1], Henskens YMC[2], Ten Cate-Hoek AJ[1], Van Deursen C[3], Spronk HMH[1], Koek GH[2] and Ten Cate H[1]

[1]*Cardiovascular Research Institute Maastricht, MUMC+;* [2]*Maastricht University Medical Center, Maastricht;* [3]*Atrium Medical Center, Heerlen, the Netherlands*

Background: In patients with cirrhosis substantial changes in the haemostatic system occur, making them prone not only to bleeding but also to thrombotic events. Conventional coagulation tests support the theory of a combined hypocoagulable and hyperfibrinolytic state. However, recent studies postulate that in cirrhosis pro-haemostatic changes compensate these antihaemostatic changes, thus 'rebalancing' the coagulation system.

Aim: To gain better insights in the coagulation and fibrinolytic capacity in patients with increasing severity of liver cirrhosis we performed the thrombin generation assay (TGA) combined with tPA-induced fibrinolysis by rotational thromboelastometry ('tPA-ROTEM').

Methods: Blood (citrated, 0.105 M) was obtained from 71 patients with all-cause liver cirrhosis. Cirrhosis severity was assessed by means of the Child Pugh (CP) score (CP-A $n = 52$, CP-B $n = 14$, CP-C $n = 5$). A panel of coagulation parameters was assessed. TG was determined by means of the calibrated automated thrombogram in platelet poor plasma using a 1 pM Tissue Factor trigger in the absence or presence of thrombomodulin (parameters: lag time [LT], peak height [PH] and endogenous thrombin potential [ETP]). tPA-ROTEM was determined in recalcified citrated whole blood triggered with either 35 pM TF or 35 pM TF and 125 ng/mL tissue plasminogen activator (tPA). The following parameters of clot formation and clot lysis were analyzed: coagulation time (CT), α-angle, clot formation time (CFT), maximal clot firmness (MCF), lysis onset time (LOT), lysis time (LT) and fibrinolysis velocity (FV). Statistical analysis of potential differences between CP-groups was performed using the Kruskal-Wallis test.

Results: With increasing CP-score the classic coagulation tests (PT, aPTT) showed a significant prolongation while the coagulation parameters antithrombin, protein C and fibrinogen showed, as expected, a significant decrease. In the TGA we found a significant decrease of the median LT with increasing CP-score (CP-A: 6.83 min vs. CP-C: 4.00 min, $P < 0.05$). Despite relatively high normalized ETP and PH values, no significant differences between the CP-groups were observed with ETP being: CP-A 146%, CP-B 167% and CP-C 174%, and PH: CP-A 200.5%, CP-B 265.6%, CP-C 261.7%. To evaluate the protein C pathway, TM was added to the TGA resulting in a significantly lesser reduction of the ETP in the CP-C group in comparison to the CP-A group (7.2% vs. 24%, resp. $P < 0.05$). Parameters that reflect stable clot formation in the tPA-ROTEM showed significant alterations with increasing disease severity. In the measurements without added tPA there was a decrease of the α-angle ($P < 0.05$), increase of the CFT ($P < 0.05$), decrease in the MCF ($P < 0.05$), None of the tPA-ROTEM parameters of clot degradation (LOT, LT and FV) showed significant differences between the different CP-groups (data not shown).

Conclusion: Thrombin generation demonstrated a hypercoagulable profile in patients with liver cirrhosis. This hypercoagulability is most likely due to the reduced levels of the anticoagulant factors antithrombin and protein C. tPA-ROTEM analysis however, showed diminished clot strength with increasing cirrhosis severity, resulting in a less stable clot. Fibrinolysis on the other hand was comparable between the different CP-groups. Taken together our data therefore do not support the theory of a combined hypocoagulable and hyperfibrinolytic state.

AS 33.3

Prolonged shock phase in a pig model with multiple injuries is associated with a decreased onset of tPA induced fibrinolysis

Zentai C[1], Spronk HMH[2], Van Oerle R[2], Ten Cate H[2], Rossaint R[1] and Grottke O[1]

[1]RWTH Aachen University Hospital, Aachen, Germany; [2]Maastricht University Medical Center, Maastricht, the Netherlands

Background: Current concepts of trauma induced coagulopathy indicate that prolonged shock leads to an acivation of the protein-C pathway with anticoagulation and induce hyperfibinolysis in severley injured patients. However, large animal models investigating this mechanisms are largely missing.

Aims: In a pilot pig study with multiple injury we elaborated the effects of a prolonged shock phase on coagulation parameters as compared to non-shock animals receiving volume resuscitation.

Methods: After local ethical approval trauma was induced in 10 anaesthetized pigs. Multiple injury was inflicted by the fracture of both femurs and a lung contusion using a captive bolt gun followed by blunt liver injury (Injury Severity Score: 27). Following a shock phase of 30 min animals received either no volume (group: NV, $n = 5$) or Ringer's solution (group: RS, $n = 5$) to maintain a mean arterial pressure of 55–60 mmHg. Thromboelastometry (ROTEM), including a modified method for fibrinolysis ('tPA-ROTEM' with parameters lysis onset time (LOT) and Lysis Index after 30 min (LI.30)), and thrombin generation (TG) were monitored for 4 h and blood loss was measured. Statistical analysis was performed using ANOVA with Tukey *post hoc*. A $P < 0.05$ value was considered as statistical significant.

Results: Severity of inury was confirmed both by macroscopical analysis and a significant drop in cardiac output (CO) (baseline: 4.3 ± 0.6 L/min; 30 min post injury: 1.3 ± 0.14 L/min). Fluid resuscitation led to an increase of CO (3.1 ± 0.8 L/min) whereas in non-resuscitated animals CO remained low (1.6 ± 0.2 L/min). Due to haemorrhagic shock lactate levels (baseline: 1.7 ± 0.2 mM) significantly increased over time in NV animals 8.3 ± 2.9 mM and remained stable in RS animals (1.7 ± 0.6 mM). After injury, tPA-ROTEM induced fibrinolysis (both groups, baseline: LOT: 355 ± 66 s; LI.30: 4.4 ± 0.1%) was significantly reduced in the NV group (240 min post inury: LOT: 982 ± 74 s; LI.30: 81 ± 9.7%). In contrast, tPA induced fibrinolysis in RS animals remained constant (240 min post injury: LOT: 399 ± 37 s; LI.30: 10 ± 4.4%). TEM analysis showed a decrease of clot formation over time (both groups, baseline: 79 ± 0.5 mm) with significantly reduced values in the RS group (67 ± 4 mm; NV group: 72 ± 2 mm, $P < 0.05$). Plasma thrombin generation without exogenous trigger and in the presence of a tissue factor inhibitor was enhanced upon infliction of trauma. The endogenous thrombin potential (ETP) increased from 92 ± 65 nM.min at baseline to 203 ± 86 nM.min at 30 min after trauma. This increase in contact activated coagulation continued upto 4 h after trauma (ETP: 182 ± 54 nM.min) and attenuated at 6 h after trauma (ETP: 80 ± 60 nM.min).

Conclusions: Severe haemorrhagic shock over 4 h with elevated shock parameters following multiple injury induced a contact activation mediated hypercoagulable state, without alterations in global haemostasis (ROTEM) or signs of hyperfibrinolysis. In contrast, omitted volume resuscitation led to an enhancement of clot stability. This observation conflicts current ideas of shock induced hyperfibrinolysis and protein-C activated systemic anticoagulation, which may be explained by lower protein-C levels in pigs as compared to humans.

AS 34 – Venous Thrombosis and Cancer

AS 34.1

The value of CT-scanning for detection of occult cancer in patients with unprovoked venous thromboembolism. The D'Acquapendente study

Piccioli A[1], Bernardi E[2], Dalla Valle F[1], Visonà A[3], Tropeano F[4], Bova C[5], Bucherini E[6], Falanga A[7] and Prandoni P[1]

[1]Padua University Hospital, Padova; [2]ULSS 7 Pieve di Soligo, Conegliano; [3]ULSS 8 Asolo, Castelfranco V.to; [4]Hospital of Pordenone, Pordenone; [5]Hospital of Cosenza, Cosenza; [6]Hospital of Faenza, Faenza; [7]Ospedali Riuniti di Bergamo, Bergamo, Italy

Background: Patients with unprovoked venous thromboembolism (VTE) may harbor occult cancer. Literature shows that the risk of malignancy after unprovoked VTE ranges from 2% to 12%. Cancer may be identified by baseline screening (history, physical, lab-testing, chest X-ray) in up to 4% of these patients; nonetheless, overt malignancy may occur in up to 10% within 2 years in those with normal findings.

Aims: To assess if an extensive diagnostic strategy based on CT-scan yields a higher cancer detection rate than a non-standardized approach based on physicians' preferences, we embarked in a prospective multicenter randomized open-label clinical trial in patients with a first episode of unprovoked VTE and a normal baseline screening.

Methods: Consecutive patients at their first episode of symptomatic unprovoked VTE were eligible for inclusion. VTE was deemed unprovoked when occurring in patients without known malignancy, trauma, recent surgical procedures/immobilization, family history of VTE, thrombophilia, estrogen use, pregnancy/childbirth. Patients with a history of VTE, younger than 18 years, pregnant, unable to attend follow-up visits and those who underwent torso CT-scan within 3 months of presentation, were excluded. Only patients with a normal baseline screening, who undersigned informed consent, were randomized. Patients in the CT-group were scheduled for mandatory thoracic, abdominal and pelvic CT-scan plus hemoccult. Patients in the CCP-group underwent any diagnostic testing at the discretion of the attending physician, except for CT as first-line imaging. Patients with a normal work-up were followed-up for up to 2 years. The main endpoint of the study was the difference in the cancer detection rate between the two strategies. Secondary endpoints were the sensitivity of the diagnostic strategies, using the incidence of cancer during follow-up as a reference; and the cancer-related mortality.

Results: Between September 2006 and May 2008, 242 patients had a first diagnosis of unprovoked VTE, and 205 (84.4%) were included. Malignancy was identified in 10/205 (4.9%) by baseline screening; thus 195 patients were randomized. Cancer was diagnosed in 10/98 (10.2%) patients of the CT-group, and in 8/97 (8.2%) of the CCP-group, yielding a 2% absolute difference of cancer detection-rate (95% CI −7.2 to 11.1%). During follow-up, cancer developed in 2 (2.2%) patients of the CT-group and in 2 (2.2%) of the CCP-group. Therefore, the sensitivity of the CT strategy was 83.3% (95% CI 55.2–95.3%), while that of the CCP strategy was 80% (95% CI 49.0–94.3%). Overall, 7 (7.1%) patients of the CT-group and 11 (11.3%) of the CCP-group died, with 2 and 4, respectively, as a result of cancer; yielding a −2.1% absolute difference of cancer-related mortality (95% CI −8.0 to 3.8%, OR 0.48, 95% CI 0.04–3.48; $P = 0.665$ by 2-tailed Log-rank test).

Conclusions: A CT-based screening approach yields an early cancer detection rate comparable to a non-standardized approach based on physicians' preferences, and does not impact on overall and cancer-related mortality. Noteworthy, most (6/8, 75%) cancers in the CCP-group were identified by ultrasonography, which may represent a similarly effective non-invasive alternative to CT for cancer screening in patients with unprovoked VTE.

AS 34.2

A risk scoring model for cancer-associated venous thromboembolism is predictive for overall survival in patients with cancer

Ay C, Reitter E-M, Riedl J, Wagner O, Zielinski C and Pabinger I
Medical University of Vienna, Vienna, Austria

Background: Patients with cancer are at high risk of venous thromboembolism (VTE), a complication associated with increased risk of mortality. A simple and multi-factorial risk scoring model was developed by Khorana et al. (*Blood* 2008; 111:4902–7) to improve prediction of VTE in patients receiving chemotherapy. This risk scoring model was confirmed by several groups to reliably stratify also broader populations of cancer patients according to their VTE risk and identify those patients at the highest risk. We hypothesized that cancer patients who are at risk of VTE may also have higher mortality rates and poor prognosis of their disease.

Aim: The aim of the present study was to evaluate whether the risk scoring model for cancer-associated VTE developed by *Khorana* et al. is able to predict mortality and overall survival in cancer patients.

Methods: We assessed the 'Khorana-Score' in a prospective and observational cohort study of patients with newly diagnosed cancer or progressive disease after remission that were included in the Vienna Cancer and Thrombosis (CATS), an ongoing study initiated in year 2003. The primary endpoint of the study was occurrence of objectively confirmed VTE and the secondary was death within a maximum follow-up period of 2 years. According to the Khorana-Score and our validation of this risk model (Ay et al. *Blood* 2010; 116(24):5377–82) assignment of points for five parameters was done: site of cancer (2 points for very high-risk site, 1 point for high-risk site), platelet count of 350×10^9/L or more, hemoglobin < 10 g/dL, leukocyte count more than 11×10^9/L, and body mass index of 35 kg/m^2 or more (1 point each). Cox-regression and Kaplan–Meier analyses were applied to investigate the association of risk scores with risk of mortality and overall survival.

Results: We included 1544 patients with different types of cancer (45% women, median age: 62 [25–75th percentile: 52–68] years). During a median observation time of 563 days, death was reported in 649 (42%) patients. The Khorana-Score was significantly associated with risk of mortality (hazard ratio [HR] per 1 score increase: 1.56 [95% confidence interval: 1.45–1.68], $P < 0.001$). In multivariable Cox-regression analysis including age, sex and VTE, compared to patients with a score 0 ($n = 466$) the HR for risk of mortality was 1.61 ([1.28–2.02], $P < 0.001$) in those with score 1 ($n = 489$), 2.80 ([2.24–3.51], $P < 0.001$) in score 2 ($n = 405$) and 4.01 ([3.09–5.21], $P < 0.001$) in those with score ≥ 3 ($n = 184$). The overall survival probabilities for patients with score 0, 1, 2 and ≥ 3 were 87%, 78%, 65% and 58% after 1 year and 67%, 55%, 38% and 27% after 2 years, respectively (Log-rank test: $P < 0.001$).

Summary/Conclusion: The Khorana-Score had been externally validated in several studies to predict risk of developing VTE. In our current analysis, we were able to demonstrate that this simple risk scoring model predicts also risk of mortality and overall survival in patients with cancer, independently of VTE occurrence. This may support clinical decision strategies with regard to thromboprophylaxis and anticancer treatments.

AS 34.3

Mechanistic insights into zymogen protein C protection against cancer progression

Crudele JM[1], Van Sluis GL[2], Margaritis P[1], Siner JI[1], Maurer J[1], Zhou S[1], Esmon CT[3], High KA[1], Spek CA[4] and Arruda VR[1]
[1]*Children's Hospital of Philadelphia, Philadelphia, PA, USA;*
[2]*Amsterdam Medical Center, Amsterdam, the Netherlands;*
[3]*Oklahoma Med. Rsch. Foundation, Oklahoma City, OK, USA;*
[4]*Cemm, Amsterdam Medical Center, Amsterdam, the Netherlands*

Background: Cancer is frequently associated with activation of coagulation, and a procoagulant state facilitates tumor metastasis. Recent studies have suggested that the activated protein C (aPC) pathway plays a role in modulating tumor metastasis. Notably, we have uncovered that the inactive precursor, zymogen PC (zyPC), exhibits a robust protective effect against metastasis.

Aim: The aim of this study was therefore to explore mechanisms through which zyPC prevent metastatic cancer progression in a murine cancer model.

Methods: Liver directed adeno-associated viral vectors (AAV) were utilized to achieve a wide range of sustained expression of wildtype (WT) or mutant murine zyPCs. Mice expressing stable levels of zyPCs after AAV administration and control mice receiving PBS were injected intravenously with 2.5×10^5 murine melanoma B16F10 cells. After 3 weeks the numbers of pulmonary tumors were determined.

Results: Expression of zyPC-WT in normal C57BL/6s decreased the rates of metastasis in a dose-dependent manner compared to controls ($P < 0.01$). These effects were noted even in mice with only a two-fold increase in zyPC levels. Conversely, when PC-deficient mice (residual 3%) were administered B16F10s without zyPC-expression, they did not survive 3 weeks, while their normal littermates did. These data demonstrate the protective role of zyPC in tumor progression. We then tested modified zyPCs to identify the critical functions responsible for our observations. zyPC-R15Q is unable to dock to the thrombin-thrombomodulin complex and cannot be converted to aPC. Compared to PBS controls, mice expressing zyPC-R15Q still showed a decrease

in the number of tumor foci ($P < 0.001$) similar to the zyPC-WT ($P = 0.28$). Additionally, mice expressing zyPC-S195A, which has a mutation in its serine protease active site, also showed a significant decrease in the number of tumor foci compared to PBS controls ($P < 0.05$). As with the R15Q, mutating the S195 did not affect the ability of zyPC to protect against metastasis ($P = 0.22$). These data suggest that zyPC protection is not dependent upon local activation of zyPC to aPC and aPC's anticoagulant function. Next, we tested the importance of the main PC cellular receptors in our model. Binding to endothelial protein C receptor (EPCR) enhances activation of PC. zyPC-expressing mice that received anti-EPCR antibody that blocks PC binding still had a significant reduction in tumor rates compared to PBS controls ($P < 0.01$). Moreover, mice expressing zyPC had similar levels of protection whether they received the anti-EPCR antibody or an isotype control ($P = 0.31$). EPCR binding not only increases activation of PC, it also mediates the cytoprotective effect by clustering with and facilitating the activation of the signaling protease-activated receptor (PAR) 1. PAR1 −/− mice expressing zyPC had reduced rates of metastasis compared to PAR1 −/− PBS controls ($P < 0.01$). The zyPC protection in PAR1 null mice was comparable to that in PAR1+/− littermate controls ($P = 0.619$). PAR4 is an alternative PAR found on murine platelets. PAR4 −/− mice were also protected by zyPC expression ($P < 0.01$) similar to their +/− littermate controls ($P = 0.14$).

Conclusion: Collectively, these findings suggest a distinct mechanism by which zyPC modulates tumor progression independent of anticoagulant function, EPCR, PAR1 or PAR4.

AS 35 – Clot Structure

AS 35
Determinants of clot stability

Wolberg A

University of North Carolina, Chapel Hill, NC, USA

Fibrinogen (340 kDa) circulates at 2–5 mg/mL (~6–15 μM) as a hexameric homodimer consisting of two sets each of three polypeptide chains (A , B , γ). Following vascular disruption or dysfunction, biochemical and biophysical cross-talk between extravascular and intravascular cells, plasma procoagulant and anticoagulant proteins, and blood flow promote generation of thrombin, which proteolytically cleaves N-terminal peptides from fibrinogen monomers. Fibrin, the polymerized, insoluble product generated by assembly of fibrin monomers into fibers, exhibits remarkable extensibility and elasticity and is essential for the formation and stability of both hemostatic and thrombotic clots. Clinical and epidemiological studies have consistently correlated abnormal fibrin clot characteristics with disease; coarse, open fibrin networks that are susceptible to fibrinolysis are associated with bleeding, whereas dense fibrin networks that are resistant to fibrinolysis are associated with thrombosis. Major determinants of fibrin network characteristics (fiber thickness, branching, density, and susceptibility to lysis) include the concentrations of fibrinogen and thrombin present during fibrin formation. At a constant thrombin concentration, increasing fibrinogen concentrations produce denser, highly-branched fibrin networks. Accordingly, in both humans and mice, reduced fibrinogen levels are associated with bleeding; whereas, elevated fibrinogen in congenital hyperfibrinogenemia, pregnancy, and inflammation is associated with both arterial and venous thrombosis. Similarly, at a constant fibrinogen concentration, low thrombin concentrations produce coarse, un-branched networks of thick fibrin fibers; whereas, high thrombin concentrations produce dense, highly-branched networks of thin fibers. Consequently, therapeutic approaches to modify thrombin generation or activity though the use of hemostatic agents in bleeding patients (e.g. patients with hemophilia) or anticoagulants in patients at risk for thrombosis have important implications for fibrin formation and quality, and therefore, clot stability. Platelets mediate clot stability by both supporting procoagulant activity and inducing integrin-mediated clot retraction, which consolidates clots and protects against fibrinolysis. Additional determinants of fibrin network properties include the levels of alternatively-spliced or post-translationally-modified fibrinogen, polyphosphates, and fibrin(ogen)-binding proteins (e.g. factor XIII). These elements both alter fibrin formation, and modify fibrin's susceptibility to fibrinolysis. Finally, the pattern of blood flow during fibrin formation profoundly affects fibrin structure. Fibrin networks formed under static conditions exhibit an isotropic fiber distribution; whereas, networks formed under flow are anisotropic, with fibers aligned with flow vectors. Anisotropy of fibers within a clot is expected to modulate the clot's interactions with cells and fibrinolytic enzymes. Growing appreciation of the complexity of these interactions increasingly warrants the use of assay systems that incorporate multiple aspects of clot formation, including *in situ* thrombin generation in a plasma milieu that incorporates physiologically-relevant fluid flow.

AS 35.1
Fibrinogen a-chain and ?-chain play specific roles in fibrin clot formation and structure

Duval C[1], Ridger VC[2], Philippou H[1] and Ariëns R[1]

[1]*University of Leeds, Leeds;* [2]*University of Sheffield, Sheffield, UK*

Background: Factor XIII (FXIII) plays a major role in stabilising fibrin clots by cross-linking fibrinogen (Fbg) γ- and α-chains. To date, few studies have investigated the individual roles of α- and γ-chains in fibrin clot formation and structure. Investigation of the role of α-chain in clot stiffness at individual fibres (Helms et al., 2012) and whole clot (Standeven et al., 2007) levels, have shown that α-chain cross-linking partly increases stiffness of individual fibrin fibres and of the whole fibrin clot respectively.

Aims: The aims of the present study were to investigate the effects of α-chain and γ-chain cross-linking on fibrin clot formation and structure.

Methods: FbgWT and Fbg3X (γQ398N/Q399N/K406R, eliminates all γ-chain cross-linking) were produced as previously described (Standeven et al., 2007). All experiments were performed with the following: 0.5 mg/mL fibrinogen, 0.1 U/mL thrombin, 5 mM $CaCl_2$. Fibrin formation and lysis were studied by turbidity (± 0.24 μM plasminogen and 100 pM tPA). Fibrin structure was studied by confocal (+1% AlexaFluor488 fibrinogen), and electron microscopy. Microscale fibrin viscoelasticity was analysed by magnetic tweezers. FXIII-A_2B_2 (3.7 μg/mL) was added for cross-linking.

Results: Turbidity experiments showed that in the absence of FXIII FbgWT clots had a 1.33-fold higher maximal absorbance compared to Fbg3X, indicating that Fbg3X formed denser clots with thinner fibres than FbgWT. FXIII induced an increase in maximum absorbance (FbgWT: 1.21-fold; Fbg3X: 1.18-fold) over a prolonged period of time for both fibrinogens (WT: 2.76-fold; Fbg3X: 2.13-fold). Lysis experiments showed similar lysis rates for both fibrinogens (FbgWT: -2.30×10^{-4} U/s; Fbg3X: -2.32×10^{-4} U/s), which were reduced by FXIII (FbgWT: -1.97×10^{-4} U/s; Fbg3X: (-1.96×10^{-4} U/s). Confocal microscopy showed that Fbg3X formed a denser clot (64 fibres/200 μm) with thinner fibres compared to FbgWT (40 fibres/200 μm). Fibres in clots formed with FbgWT (2.5 min) appeared quicker than Fbg3X (3.0 min) in the absence of FXIII. Both fibres appearance times were reduced in the presence of FXIII (FbgWT: 2.0 min; Fbg3X: 2.5 min). Electron microscopy showed that without FXIII, both fibrinogens formed curly fibres. In the presence of FXIII, fibres appeared straighter for both FbgWT and Fbg3X. Magnetic tweezers showed a similar clot stiffness (storage modulus) between the two fibrinogens in the absence of FXIII, but the loss modulus was significantly increased by two-fold in clots formed with Fbg3X compared to FbgWT, indicating that the former are more likely to deform. When FXIII was added, clot stiffness was significantly increased for clots formed by FbgWT (1.3-fold), but not Fbg3X; and clot non-elastic

deformation was significantly decreased in clots formed by FbgWT (1.5-fold), but not Fbg3X.
Summary/Conclusion: In this study, we found that fibrinogen α-chain cross-linking plays a role in a time-dependent increase in fibre thickness. Furthermore, α-chain cross-linking decreases lysis rate and straightens fibres. Our findings also show that fibrinogen γ-chain cross-linking influences fibre density, increases clot stiffness and decreases clot elasticity. These data extend our knowledge regarding the role of α-chain and γ-chain cross-linking in fibrin fibre morphology and fibrin micro-elastic properties.

AS 35.2
Multiscality of the structure and mechanics of fibrin clots

Kurniawan NA and Koenderink GH
FOM Institute AMOLF, Amsterdam, the Netherlands

Background: Blood clots form from three-dimensional mesh of the protein fibrin. These fibrin networks consist of branched fibers, are highly extensible and can be stretched up to four times its original length. Such extraordinary mechanical properties are important in resisting blood shear flow *in vivo* and render fibrin clots one of the most resilient naturally-occurring biopolymer networks.
Aims: Although recent works have started to explore the elastic properties of fibrin fibers and networks, the link connecting the mechanics and the underlying structure of fibrin is still missing. In particular, we seek to unravel how the remarkable mechanics of the fibrin clots derive from the self-assembled structures at the fiber and molecular levels.
Methods: We combine mechanical measurement using rheology and quantitative structural characterization using confocal and electron microscopy, as well as light and X-ray scattering, to study the physical and structural origins of fibrin clotting and extensibility at multiple length scales.
Results: Like many other biopolymer networks, fibrin clots stiffen nonlinearly with stress. Interestingly, however, we find that the rheological response shows multiple plateau-stiffening steps depending on protein concentration, a behavior unique to fibrin. Comparison with theoretical predictions reveals that the stiffening regimes correspond to different deformation modes at fiber and network level. Moreover, the presence of Factor XIII is found to alter the polymerization kinetics, time-dependent response, and network stiffness in the linear regime, but not beyond. Although the network microstructure is not significantly affected, the coupling between fibrils can vary with both fibrin and Factor XIII concentrations, and this manifests macroscopically in the ability of the clots to withstand mechanical strain and stress.
Summary/Conclusions: By dissecting the relation between structure and mechanics of fibrin clots at different length scales, we find that structural hierarchy plays a major role in determining the integrity and behavior of clots. A better understanding of the structure-mechanics interconnection can not only shed important light on the molecular origins of fibrin behavior and regulation in thrombosis, but also provide guidance in designing haemostatic materials, particularly in surgical settings and tissue engineering.

AS 35.3
Dissolution of tPA-resistant thrombi in occlusive intracranial thrombosis

Gauberti M[1], Le Béhot A[2], Lemarchand E[2], Montagne A[2], Maubert E[2], Vivien D[2] and Orset C[2]
[1]Inserm; [2]Inserm U919, Caen, France

Background: Large artery intracranial occlusive disease is now considered as the most common subtype of ischemic stroke. Unfortunately currently available fibrinolytic treatments, such as tissue-type plasminogen activator (tPA), glycoprotein (Gp) IIb/IIIa inhibitors and anticoagulants, are poorly efficient to promote reperfusion following *in situ* intracranial thrombosis (ICT).
Aims: In the present study, our aims were to determine the most efficient pharmacological strategy to restore vessel patency after ICT and thus to further understand the molecular mechanisms involved in such type of thrombus formation.
Methods: We developed an original model of ischemic stroke in mice, by inducing occlusive thrombosis of the middle cerebral artery using topical application of $FeCl_3$. In this model, cerebral blood flow was continuously monitored using laser Doppler flowmetry and the arterial status was assessed post-treatment using magnetic resonance angiography. To dissect the mechanisms driving occlusive thrombosis, we used different experimental approaches including transgenic mice, pharmacological inhibitors of platelet receptors, recombinant proteins, F(ab) from monoclonal antibodies and two-photon microscopy.
Results: We demonstrated that the thrombi resulting from occlusive thrombosis are resistant to fibrinolytics (such as rtPA), GpIIb/IIIa inhibitors and anticoagulants. In contrast, administration of inhibitors of the GpIba-von Willebrand Factor (VWF) axis resulted in efficient thrombus dissolution and dramatically improved stroke outcome (68% reduction of the ischemic lesion size), without inducing bleeding complications. From a mechanistic point of view, we demonstrated that during the last steps of thrombus formation, the very-high pathological shear rate in the narrowing arterial lumen promotes GpIba-VWF-dependent platelet cross-linking. Our study provides evidence that this unique mechanism of platelet aggregation is critical to achieve arterial lumen closure. Accordingly, inhibitors of the GpIba-VWF axis induce specific dissolution of the last-formed platelet aggregates and restore vessel patency after occlusive thrombosis.
Conclusion: GpIba-VWF interaction drives arterial lumen closure during occlusive thrombosis. Therefore, inhibition of the GpIba-VWF axis represents a new therapeutic strategy to restore vessel patency after stroke or myocardial infarction.

AS 36 – Structure-Function of Factor V

AS 36
Molecular Basis of Factor V Procofactor Activation

Camire RM
Children's Hospital of Philadelphia, Philadelphia, USA

Most coagulation factors circulate in blood as inactive precursors and must transition to an active form to participate in blood clotting. Despite its significance, mechanisms that underpin these molecular and structural conversions have proven difficult to pinpoint especially for coagulation factor V (FV). Factor V circulates in blood as an inactive procofactor and cannot participate to any significant degree in its macromolecular enzyme complex. Following proteolytic removal of a central B-domain activity is generated indicating that the conversion of the procofactor to FVa must result in structural changes that impart cofactor function. A key focus of my laboratory is to decipher these molecular processes and provide new biophysical and structural insight into how FV is preserved as an inactive procofactor. This molecular process undoubtedly plays critical regulatory roles, evolved to maintain normal hemostasis since FVa has a tremendous influence on thrombin generation. Over the past few years we have shown that proteolysis of FV functions to dismantle and release autoinhibitory sequences within the B-domain termed the procofactor regulatory region. Understanding how this evolutionary conserved region functions, where it binds, how it disengages from FV following activation, and how this region is regulated by a variety of physiological ligands are major research areas in the laboratory.

AS 36.1

Alternatively spliced factor V isoform in the east Texas bleeding disorder inhibits coagulation by binding and increasing tissue factor pathway inhibitor alpha (TFPIa) plasma levels

Dahlbäck B[1], Vincent LM[2], Tran S[1], Bensend TAT[2], Milewicz DM[2] and Dahlbäck B[1]

[1]Lund University, Malmö, Sweden; [2]University of Texas Health Science Center at Houston, Houston, TX, USA

Background: The autosomal dominantly inherited East Texas bleeding disorder (OMIM 605913) has been linked to the coagulation FV gene (*F5*) and all affected individuals carry an A2440G variant in exon 13 encoding the large B domain activation fragment. The disease is moderately severe and all affected family members have prolonged prothrombin time (PT) and/or activated partial thromboplastin time (APTT). However, they have normal concentrations of all coagulation factors, including FV.

Aim: The aim was to elucidate the pathogenic molecular mechanisms resulting in the inherited bleeding phenotype.

Methods: The family spans over 4 generations and has 22 known affected members. All participants gave written informed consent. The Institutional Review Board and the Center for Protection of Human Subjects at the University of Texas HealthScience Center at Houston approved this study (MS-02-157). Total blood RNA was reverse transcribed using *F5* gene exon 13 specific primers and subjected to real-time PCR. The FV-Short splice variant was targeted using exon 13 specific reverse and forward primers. FV- and TFPI- isoforms in plasma were tested with western blotting using mono- and polyclonal antibodies against FV and TFPI. Thrombin Generation of plasma, in presence of tissue factor and negatively charged phospholipid membranes, was monitored with fluorogenic substrate. Different isoforms of FV and TFPI in patient plasma were immune depleted using various FV- and TFPI- antibodies. FV- and TFPI- isoforms were quantified with several ELISAs using domain-specific monoclonal antibodies.

Results: We now demonstrate that A2440G causes up-regulation of an alternative spliced form of the FV transcript that results in an in-frame deletion of 702 amino acids of the large activation fragment of FV, the B domain. The novel ~250 kDa FV isoform (FV-Short), which can be fully activated to FVa by thrombin, is present in all A2440G carriers' plasma (n = 16), but is also present at much lower concentrations in non-carriers' plasma (n = 20). FV-Short inhibits coagulation through an indirect mechanism involving tissue factor pathway inhibitor alpha (TFPIα). In affected family members, FV-Short forms a complex with TFPIα. As a result, the TFPIα plasma concentration in affected individuals is increased approximately 10-fold when compared to unaffected individuals' plasma, suggesting that the TFPIα-FV-Short complexes are retained in circulation. The TFPIα-FV-Short complexes are demonstrated to efficiently inhibit thrombin generation of both intrinsic and extrinsic coagulation pathways.

Conclusions: The A2440G FV gene mutation results in up-regulation of a previous unidentified, alternatively spliced transcript of FV, which yields a FV-Short protein (Δ702 amino acids residues) that binds and retains TFPIα in the circulation. The FV-Short-TFPIα complex acts to inhibit activation and propagation of coagulation, leading to the East Texas bleeding disorder. This is the first autosomal dominant bleeding disorder due to a gain of function mutation in the *F5* gene. The identification of TFPIa as the active inhibitory compound in the affected family members opens possibilities for future therapeutic intervention in the affected family members as TFPI inhibitors are presently under development.

AS 36.2

Site-specific glycan trimming in megakaryocyte-endocytosed factor V

Tracy PB, Jemings ME II, Stringer KM, Silveira JR, Wood JP and Blanchard A

University of Vermont, Burlington, VT, USA

Background: Coagulation factor V exists as two phenotypically- and functionally-distinct pools in whole blood: 75–80% is found in the plasma, while the remaining 20–25% is stored within α-granules of platelets, and appears to be the more physiologically-relevant pool. As platelet-derived factor V originates *via* megakaryocyte endocytosis of plasma-derived factor V, we hypothesize that the unique functional characteristics expressed by platelet-derived factor V are a result of its processing within megakaryocytes subsequent to its endocytosis. This processing includes glycosylation, as Thr^{402} is glycosylated in platelet-derived, but not plasma-derived factor V, suggesting that endocytosed factor V is intracellularly transported to the Golgi network for O-glycosylation. In addition, since glycans account for 13% to 25% of the molecular mass of factor V, and glycosylation is known to affect several plasma-derived factor V/Va activities, we hypothesize further that glycosylation differences between the plasma- vs. platelet-derived pools contribute to their functional differences.

Aims: Our initial goal was to characterize potential N-linked glycosylation sites in the heavy and light chains of plasma-derived factor Va. Subsequent to the identification of those sites, as well as analyses of their composition and determination of any microheterogeneity of the attached glycan chains, our next goal was to determine any donor-dependent differences between the platelet- and plasma-derived factor Va pools.

Methods: Electrospray ionization-liquid chromatography mass spectrometry was performed on proteolytically-derived peptides from purified heavy and light chains of both plasma- and platelet-derived factor Va. Confocal microscopy was used to determine the co-distribution of endocytosed factor V with the Golgi-specific enzyme, α-mannosidase.

Results: Of the nine potential N-linked glycosylation sites within the factor Va heavy chain, two glycans were confirmed (Asn269 and Asn432) and characterized, an additional three were identified (Asn23, Asn27 and Asn439) but only one was characterized (Asn439). Three sites were not glycosylated (Asn354, Asn526, and Asn639) and a last site remains unidentified. Regarding the factor Va light chain, the glycan on Asn2181 was reconfirmed and glycan chains were identified and characterized on the two potential sites remaining (Asn1675, Asn1982). While glycan chains composed of either high mannose carbohydrates or sialic acid-containing complex carbohydrates were observed in factor V purified from plasma pooled from seven donors, little, if any, heterogeneity was apparent at each individual glycosylation site, suggesting that the composition of glycans is relatively consistent between individuals. When individual donor's platelets/plasma were analyzed, again little heterogeneity was observed with one exception. Whereas plasma-derived factor Va contained high-mannose glycans with either 6, 7, 8, or 9 mannose residues at Asn1982, platelet-derived factor Va glycans at the same site had only 4, 5, or 6 mannose residues. This trimming process was site-specific, as neither the high-mannose glycan at Asn269, nor the complex glycans at Asn432, Asn439, Asn1675, and Asn2181 incurred substantial modification from what is observed in plasma-derived factor Va. Subsequent, confocal microscopy studies demonstrated the co-distribution of megakaryocyte-endocytosed factor V with Golgi-specific, α-mannosidase.

Summary/Conclusions: These combined data suggest that factor V endocytosed by megakaryocytes undergoes retrograde transport to the Golgi network where site-specific glycan trimming occurs.

AS 36.3

Functional characterization of a structural element unique to venom factor V from the Australian common brown snake Pseudonaja textilis

Verhoef D[1], Camire RM[2], Reitsma PH[1] and Bos MHA[1]

[1]*Leiden University Medical Centre, Leiden, the Netherlands;* [2]*Children's Hospital of Philadelphia, Philadelphia, PA, USA*

Background: The venom of the Australian snake *Pseudonaja textilis* (pt) contains a robust prothrombin activator homologous to the human coagulation factors V (FV) and Xa (FXa). To effectively escape hemostatic regulation, this venom-derived prothrombinase-like complex has been subject to remarkable gain-of-function adaptations. We previously revealed that the constitutively active FV subunit (pt-FV) not only bypasses the requirement for a membrane surface to achieve high affinity FXa binding, but is also functionally resistant to activated protein C (APC).

Aim: Here we examined the functional linkage between these distinct procoagulant properties and a disulfide bond covalently connecting the A2-A3 domains This structural element is nonconserved throughout vertebrate evolution and exclusive to pt-FV.

Methods: To assess its functional implications in human FV, we introduced the disulfide bond into constitutively active human FV-810 (Pro811-Gy1491 deleted) by substituting the appropriate residues to Cys. In a second variant, we additionally exchanged human A3 region Tyr1756-His1778 for the homologous snake region Phe994-Pro1016, which we hypothesize to promote disulfide linkage in pt-FV based on its unique sequence. Alternatively, we eliminated the disulfide bond in pt-FV by substituting the Cys residues involved for Ser. The recombinant FV variants were stably expressed in BHK cells and purified to homogeneity using ion-exchange chromatography.

Results: All purified FV variants demonstrated full cofactor activity in a PT-based clotting assay. SDS-PAGE analysis prior to and following thrombin-activation demonstrated that in both human FV variants approximately 50% of the molecules had successfully incorporated a covalently linked heavy and light chain. This suggests that formation of the disulfide bond is impaired in human FV. Furthermore, introduction of the *Pseudonaja textilis* A3 sequence into human FV does not promote disulfide linkage under the conditions employed. Using a purified prothrombinase assay, no gain-of-function was observed since the membrane-dependent and -independent cofactor function of the variants was identical to FV-810. Incubation of all human FV variants with physiological concentrations of APC (10 nM) resulted in full proteolysis and loss of cofactor activity. As such, human FV function was not significantly improved following partial introduction of the disulfide bond. In pt-FV, full elimination of the disulfide link was confirmed by SDS-PAGE analysis. However, we observed no loss in cofactor activity of this variant, irrespective of the availability of anionic membranes. Furthermore, pt-FV lacking the disulfide bond was completely active following incubation with high concentrations of APC, even though the heavy chain was fully proteolyzed. This strengthens the assumption that noncovalent interactions stabilize fragments generated by APC.

Conclusion: Taken together, these data indicate that the disulfide bond exclusively found in venom-derived pt-FV is not a functional requirement for its powerful procoagulant properties. Accordingly, transferring this structural element to human FV did not alter cofactor function nor any of the other protein characteristics studied. This concurs with the three-dimensional coordination of the A3 region replaced in human FV, which is a solvent-exposed loop and may therefore tolerate structural rearrangement. Whether its venom counterpart imposes conformational constraints essential to other aspects of the FV life cycle remains to be determined.

AS 36.4

Regulatory sequence 1000 to 1008 of human coagulation factor V maintains the procofactor in a quiescent state

Wiencek JR[1], Na M[1], Hirbawi J[2] and Kalafatis M[1]

[1]*Cleveland State University;* [2]*Cleveland Clinic-Lerner Research Institute, Cleveland, OH, USA*

Background: Human factor V (fV) circulates in blood as a single chain inactive procofactor with a M_r 330,000 consisting of multiple domains (A1-A2-B-A3-C1-C2) at a concentration of 20 nM. The sequential cleavage of fV by thrombin at Arg^{709}, Arg^{1018}, and Arg^{1545} is physiologically necessary to remove the heavily glycosylated B-domain, and produce factor Va (fVa) which is composed of the light and heavy chains. fVa binds to factor Xa (fXa) on a phospholipid membrane in the presence of divalent metal ions to form the prothrombinase complex. A comparative sequence analysis of fV among mammals revealed that amino acid sequence 1000–1008 of the B domain contains seven conserved basic amino acids and could play a major part in inhibiting the interaction of fVa with fXa.

Aim: To investigate the functional importance of the basic amino acid region 1000–1008 within fV.

Methods: We constructed three mutant recombinant fV molecules as follows: fV^{Q3} all activation sites (R709/R1018/R1545) were mutated to glutamine, $fV^{\Delta B9}$ had region 1000–1008 deleted and $fV^{\Delta B9/Q3}$ was a combination of both mutations. All recombinant molecules were expressed as full-length derivatives in mammalian COS-7 cells and were purified to homogeneity. The molecules were assessed for clotting activity using fV-deficient plasma and for cofactor activity in the presence of fXa and saturating concentrations of recombinant fV molecules prior and following incubation with thrombin. The ability of the molecules to be activated was investigated and visualized through Western blotting techniques.

Results: Kinetic analyses revealed that fV^{Q3} was severely impaired in its interaction with fXa before and after incubation with thrombin. In contrast, $fV^{\Delta B9}$ and $fV^{\Delta B9/Q3}$ had similar affinity for fXa when compared to wild type (fVa^{WT}) before and after activation by thrombin. Two-stage clotting assays revealed that while fV^{Q3} was devoid in clotting, $fV^{\Delta B9/Q3}$ had clotting activity comparable to fVa^{WT}. Under similar experimental conditions prothrombinase assembled with recombinant $fV^{\Delta B9/Q3}$ had a K_m that was comparable to the K_m of prothrombinase assembled with fVa^{WT} while the k_{cat} was decreased by ~20-fold. Increasing the concentration of $fV^{\Delta B9/Q3}$ within the mixture resulted in a 57-fold increase in the K_m and a four-fold increase in the k_{cat} of prothrombinase. Western blotting of the reaction mixture during the process of the experiment confirmed that $fV^{\Delta B9/Q3}$ remained intact during the course of the assay whereas $fV^{\Delta B9}$ became activated.

Conclusions: Our data demonstrate that amino acid sequence ^{1000}KTRKKKKEK^{1008} controls spontaneous binding of fV to fXa. Overall the data reveal that the amino acid stretch 1000–1008 and B region of the procofactor keep the molecule in a quiescent state by both covering the fXa binding domain and by impeding the productive interaction of prothrombin with the COOH-terminus of the heavy chain of fVa. Our data demonstrate that the clotting activity of $fV^{\Delta B9/Q3}$, which is a measure of its physiological *in vivo* activity, was indistinguishable from the clotting activities of fVa^{WT} or fVa^{PLASMA}. Thus, it becomes obvious that even a small mutation within the 1000–1008 region of the B domain could have profound and devastating clinical implications for normal hemostasis.

AS 37 – Signal Transduction

AS 37.1

Role of Class I PI3K a and β in platelet activation and functions: new potential antithrombotic targets?

Gratacap M-P[1], Severin S[1], Laurent PA[1], Chicanne G[1], Hechler B[2], Gachet C[2], Guillermet-Guibert J[1], Vanhaesebroeck B[3] and Payrastre B[1]

[1]Inserm U1048, Toulouse Cedex 4; [2]UMR-S949 Inserm, Université de Strasbourg, Strasbourg, France; [3]Institute of Cancer, Queen Mary University of London, London, UK

During platelet activation, class I phosphoinositide 3-kinases (PI3Ks) generate lipid second messengers (D3-phosphoinositides) which are important players in the organisation and the regulation of intracellular signalling processes. Using a selective inhibitor of class I PI3Kβ, TGX221, it has been suggested that targeting this isoforme could be a potentially interesting antithrombotic strategy (Jackson et al. *Nat Med*. 2005). Due to the lack of tools, the role of α isoform of class I PI3K has remained unclear in platelet activation. However, recent studies using pharmacological inhibitors suggest that both PI3Kα and β are required, in a non redundant way, for full platelet activation by collagen (Gilio et al. *J. Biol. Chem*. 2009).

To analyse the respective role of PI3Kα and β during platelet activation and thrombosis, we have generated two mice lines expressing an inactive form of these isoforms selectively in the megakaryocyte lineage (*PF4*-Cre/p110$\alpha^{flox/flox}$ and *PF4*-Cre/p110$\beta^{flox/flox}$).

Using the *PF4*-Cre/p110$\beta^{flox/flox}$ mouse model, we demonstrated that PI3Kβ plays a critical role downstream of GPVI and $\alpha_{IIb}\beta_3$ integrin. This isoform also contributes to platelet activation induced by GPCR. *Ex vivo* and *in vivo* approaches show that PI3Kβ is not mandatory for primary haemostasis but regulates thrombus growth and stability mainly under high shear rates. *PF4*-Cre/p110$\beta^{flox/flox}$ mice are protected against occlusive thrombus formation in the $FeCl_3$ carotid injury model. The mice line presenting conditional invalidation of PI3Kα shows that this isoforme is partially implicated in signalling downstream of GPVI but not downstream of GPCR. *Ex vivo* and *in vivo* experiments reveal a role for this PI3K in thrombus growth but not in thrombus stability or the control of bleeding time.

Altogether, these results reveal different role for PI3Kα and β during platelet activation and thrombus formation *in vitro* and *in vivo*. PI3Kβ appears as an interesting antithrombotic target since inhibition of this isoform protects mice from occlusive thrombus without increasing the hemorrhagic risk.

AS 37.2

The Epac1-Rap1 pathway regulates Weibel-Palade body exocytosis from endothelial cells through the activation of Rac1 via PREX-1.

Van Hooren WEM, Fernandez-Broja M, Meijer AB, Bierings R and Voorberg J

Sanquin, Amsterdam, the Netherlands

Background: Vascular endothelial cells provide a dynamic interface between circulating blood and underlying tissues that is critically involved in maintaining vascular integrity and homeostasis. A significant number of haemostatic components and inflammatory mediators originate from endothelial cell-specific, cigar-shaped organelles called Weibel-Palade bodies (WPBs). WPBs function as storage vesicles for von Willebrand factor (VWF), a multimeric adhesive glycoprotein crucial for platelet plug formation, the leukocyte receptor P-selectin and a number of bioactive compounds that include the chemoattractants IL-8 and eotaxin-3. WPBs release their content following stimulation with agonists increasing intracellular Ca^{2+}, like thrombin, or agonists increasing intracellular levels of cAMP, such as epinephrine. The physiological importance of the cAMP-mediated pathway is illustrated by the rise in VWF levels in patients with von Willebrand's disease and mild haemophilia A following administration of the vasopressin analogue desmopressin (DDAVP).

Aim: Previously, we have shown that the exchange protein activated by cAMP, Epac1 and its substrate, the small GTPase Rap1 are involved in cAMP-mediated release of WPBs. In this study, we explored whether Rac1 and other potential downstream-effectors of Rap1 are involved in cAMP-mediated WPB release.

Methods: Studies were performed in primary human umbilical vein endothelial cells. Activation of the small GTP binding protein Rac1 was monitored by its ability to bind to the CRIB domain of the serine/threonine kinase PAK1. Downstream-effectors of active Rap1 were identified by a proteomic screen using a GST-fusion of the Ras binding domain of RalGDS. Functional involvement of candidate proteins in WPB release was determined by RNAi mediated knockdown of gene expression.

Results: We identified the PI3K-dependent Rac exchange factor 1 (PREX-1) using a pulldown for putative downstream targets of activated Rap1 in endothelial cells. We subsequently explored whether Rac1 is activated in response to agonists that induce WPB release. Incubation of endothelial cells with epinephrine and forskolin but also the Epac1-specific cAMP-analogue Me-cAMP-AM and protein kinase A (PKA)-specific Bnz-cAMP-AM results in the activation of the small GTPase Rac1. Epinephrine and forskolin-induced Rac1 activation is partially abolished in Epac1 depleted cells. Additional treatment with the PKA inhibitor (PKI) completely abolishes the activation of Rac1. Depletion of Rac1 employing RNAi resulted in reduced epinephrine-induced VWF secretion. Also the Rac1 inhibitor EH $t_1$864 reduced both Rac1 activation and epinephrine-induced WPB release. These findings show that Rac1 modulates WPB release. RNAi-mediated downregulation of PREX-1 resulted in a reduced activation of Rac1 in response to Me-cAMP-AM. After silencing of PREX-1, endothelial cells required higher concentrations of epinephrine to induce VWF secretion. Also, the PI3K inhibitor Ly294002 reduced epinephrine-induced WPB release further implicating PREX-1 in WPB release.

Summary/Conclusions: Taken together our findings suggest that Epac1-Rap1-mediated WPB release proceeds through activation of Rac1 by PREX-1, thereby regulating release of haemostatic, inflammatory and angiogenic components from WPBs.

AS 37.3

Endoplasmic reticulum stress in diabetic nephropathy is mechanistically linked to coagulation protease-activated protein C signaling

Thati M[1], Wang H[1], Gröne HJ[2], Nawroth PP[3] and Isermann B[1]

[1]Otto-von-Guericke-Universität Magdeburg, Magdeburg; [2]German Cancer Research Center; [3]University of Heidelberg, Heidelberg, Germany

Background/Aim: Diabetic nephropathy (DN) is a multifactorial disease associated with substantial changes in the haemostatic system. A hallmark of diabetes induced haemostatic dysfunction is impaired thrombomodulin (TM) dependent-protein C (PC) activation. Impaired PC activation triggers glomerular podocyte and endothelial cell dysfunction, thus promoting DN. The intracellular mechanism through which loss of TM and PC activation contributes to DN is not known. Here we show that the haemostatic mediator activated PC (aPC) regulates cellular homeostasis by inhibiting hyperglycemia induced endoplasmic reticulum (ER)-stress in DN.

Methods: Hyperglycaemia was induced in wild-type (wt) mice or mice with altered activity of the TM-PC system (loss of function secondary to impaired PC activation [$TM^{Pro/LacZ}$] or gain of function with higher plasma levels of aPC [APC^{high}]). Subsets of diabetic mice were treated with the chemical chaperone tauroursodeoxycholic acid (TUDCA) to inhibit ER-stress. After 26 weeks of persistent hyperglycaemia

markers of DN were determined and tissue samples were isolated for *ex vivo* analysis. Supplementary *in vitro* assays were performed in podocytes and endothelial cells.
Results: Persistent hyperglycaemia in wt mice caused severe ER-stress and DN. *Ex vivo* analysis of transcription factors regulating the ER-stress response showed an increase of the ER-stress markers C/EBP homologous protein (CHOP) and activating transcription factor 6 (ATF6), while nuclear translocation of the highly conserved transcription factor X-box binding protein-1 (XBP1) was reduced in DN. These changes were aggravated in diabetic $TM^{Pro/LacZ}$ mice which has impaired protein C activation. Conversely, in a mouse model with constitutively higher aPC levels (APC^{high} mice) nuclear levels of XBP1 were normalized and expression of ATF6 and CHOP was reduced despite persistent hyperglycaemia. Restoring aPC levels or deletion of CHOP reverses the pathological ER-stress alterations in diabetic $TM^{Pro/LacZ}$ mice. In addition, podocyte specific inducible expression of active form of ATF6 aggravated DN. Pharmacological inhibition of ER-stress by using TUDCA normalized nuclear levels of XBP1, inhibited CHOP/ATF6 expression, and protected against DN in diabetic wt and $TM^{Pro/LacZ}$ mice. *In vitro* hyperglycaemia inhibited nuclear translocation of XBP1 in endothelial cells and podocytes, the two cellular components of glomerular filtration barrier. In agreement with *in vivo* observations, hyperglycaemia induced impaired nuclear translocation of XBP1 resulted in sustained activation of ER-stress markers CHOP/ATF6. Likewise, knock down of XBP1 in podocytes and endothelial cells aggravated ER-stress and hyperglycaemia induced cellular apoptosis. Activated PC directly promotes the nuclear translocation of XBP1 in these cells, which is required to inhibit hyperglycaemia induced ER-stress. Deletion of XBP1 in podocytes or endothelial cells abolished the cytoprotective effect of aPC. Furthermore, aPC regulates the interaction of PI3K regulatory subunit p85α with XBP1 which is known to mediate its nuclear translocation and diminished hyperglycaemia induced ER-stress.
Conclusion: These studies demonstrate that hyperglycemia induced ER-stress is causally linked to DN and establish a novel mechanistic link between haemostatic system and ER function in regulating cellular homeostasis in chronic kidney disease.

AS 37.4
Junctional adhesion molecule-A suppresses platelet integrin aIIbβ3 signaling by recruiting Csk to the integrin-c-Src complex

Naik MU and Naik UP
University of Delaware, Newark, DE, USA

Background: Dysregulation of the endogenous negative regulators present within the platelet may aid the thrombotic complications seen in various diseases. How endogenous negative regulators suppress platelet functions is not well understood. We have recently shown that junctional adhesion molecule-A (JAM-A), a member of the CTX (Cortical Thymocyte marker of the Xenopus) family is expressed on platelets. Using gene-targeted Jam-A null mice, we showed that *Jam-A* knockout mice show a prothrombotic phenotype, as assessed by significantly ($P < 0.00001$) shortened tail bleeding time, decreased carotid vessel occlusion time, ($P < 0.002$) and significantly increased susceptibility to pulmonary thromboembolism ($P < 0.008$). Platelet functional studies revealed that Jam-A null platelets hyperaggregate to physiological agonists. Furthermore, integrin inside-out signaling events were not affected, although outside-in signaling, such as platelet spreading and clot retraction, were significantly enhanced ($P < 0.0001$) in Jam-A null platelets compared to wild-type (WT).
Aim: To determine the molecular mechanism through which JAM-A suppresses platelet function.
Methods: We used gene-targeted Jam-A null mouse platelets. Wild-type (WT) mouse platelets were used as controls. Co-immunoprecipitation studies were used to evaluate association. Site-directed mutagenesis and GST pull-down assays were used to assess interaction.
Results: We found that outside-in signaling events such as Y^{773} phosphorylation of integrin b_3 subunit and Y^{418} phosphorylation of c-Src were significantly enhanced in Jam-A null platelets. Interestingly, we also found the absence of inhibitory Y^{529} phosphorylation of c-Src in resting Jam-A null platelets compared to WT, suggesting that C-terminal Src kinase (Csk), which is responsible for phosphorylation of Y^{529} may be absent from the integrin-Src complex. When analyzed for the presence of Csk, we found that in WT platelets, Csk, was abundantly present in the integrin $a_{IIb}b_3$ immunoprecipitate, but was completely absent in the integrin immunoprecipitate of the Jam-A null platelet lysates, suggesting that JAM-A may be responsible for the recruitment of Csk to the integrin complex in resting platelets. We also found that JAM-A associates with integrin $a_{IIb}b_3$ in resting platelets, which dissociates upon platelet activation. Concomitantly, Csk was also found to associate with JAM-A in unactivated platelets and dissociates upon platelet activation. Since Csk contains an SH2 domain, it is possible that Csk binds phosphotyrosine residue on its binding partner. In order to understand how Csk binds to JAM-A, we determined if JAM-A is tyrosine phosphorylated. We found that JAM-A is tyrosine phosphorylated in resting platelets and is rapidly dephosphorylated upon platelet activation. This tyrosine phosphorylation appears to be necessary for the association of Csk since Y^{280}-F mutant of JAM-A failed to associate with Csk, but not the integrin. In addition, recombinant SH2-domain of Csk efficiently pulled down endogenous tyrosine-phosphorylated JAM-A.
Summary: The results presented here strongly suggest that tyrosine-phosphorylated JAM-A is an endogenous negative inhibitor of integrin signaling and thus thrombosis. JAM-A recruits Csk to the integrin-c-Src complex, where Csk negatively regulates c-Src activation and thus suppresses the initiation of thrombus growth by attenuating outside-in signaling. Upon agonist stimulation, JAM-A is dephosphorylated on the tyrosine, allowing the dissociation of Csk from the integrin complex and thus facilitating outside-in signaling.

AS 38 – Blood Coagulation Tests

AS 38.1
Endothelial cell-based fluorogenic thrombin generation assay for the evaluation of the protein C anticoagulant system

Coll E, Robles-Carrillo L, Reyes E, Francis JL and Amirkhosravi A
Florida Hospital, Orlando, FL, USA

Background: *In vivo* thrombin generation (TG) is regulated by cooperation between the vascular endothelium and the pro- and anticoagulant systems in blood, such as the thrombin/endothelial cell (EC)-dependent activation of the protein C anticoagulant pathway that ultimately leads to inactivation of factors Va and VIIIa. *In vitro*, TG is assessed most commonly in platelet-poor plasma by a fluorogenic substrate-based thrombin generation assay (TGA) in microtiter plates. While this assay can accurately measure the kinetics of TG in plasma (including, Peak thrombin [PT], and endogenous thrombin potential [ETP]), it does not assess the influence of the EC-dependent protein C pathway on TG. As a result, the assay has a limitation in the assessment of the hypercoagulable patient.
Aim: In the present study, by introducing a surrogate endothelium to the TGA, we aim to enable activated protein C-induced inactivation of factors Va and VIIIa in the assay system.
Methods: Wells of flat-bottomed microtiter plates were coated with 4×10^4 quiescent EA.hy926 endothelial-like cells which consistently express thrombomodulin (TM) and the endothelial protein C receptor (EPCR). The concentration of active TM associated with EA.hy926 in the assay well (determined by a chromogenic assay) was ~0.5 nM. Tissue factor (TF)-initiated thrombin generation was evaluated in normal pooled plasma (NP), and in protein C-deficient (PCd), protein S-deficient (PSd), and heterozygous factor V Leiden (fVL) plasmas, in the presence or absence of EC.

Results: Thrombin generation in NP was inhibited in the presence of EC as evidenced by a 56% reduction in PT and 39% reduction in ETP. However, in PCd, PSd and fVL plasmas, endothelial-induced suppression of TG was blunted. Specifically, only relatively small reductions were observed in PT (31% in PCd, 13% in PSd, 23% in fVL) and ETP (11% in PCd, 7% in PSd, and 18% in fVL). Furthermore, the blunted inhibition of TG observed in PCd, PSd and fVL plasmas, was proportionally reversed when these plasmas were mixed with different percentages of NP or by the addition of protein C or S to PCd or PSd plasmas. In separate experiments in the absence of EC, we noted that while similar results were obtained in the presence of the soluble form of thrombomodulin, the concentration required (30 nM) was ~60 times higher than that offered by the EC monolayer. This suggests that protein C activation occurs more efficiently in the presence of EA.hy926 cells. The contribution of EC-derived tissue factor pathway inhibitor (TFPI), to the endothelial cell-induced inhibition of TG was ~15%.

Summary: By introducing an EC monolayer to the TGA, and measuring TG kinetics in the presence or absence of cells, we have adapted the assay to assess the contribution of the protein C anticoagulant system to TG in a physiologically relevant manner. This novel approach not only enables the functions of the endothelial-dependent PC pathway by expressing TM and EPCR, but also may provide other endothelial components relevant to TG (such asTFPI). This approach to TG assessment may therefore have both research and clinical applicability.

AS 38.2

Defining time in therapeutic range for clinicians: Frequency of dose changes and INR testing as surrogate markers for adequate vitamin K antagonist management

Kimpton M, Le Gal G, Kherani S and Carrier M

The Ottawa Hospital Research Institute, Ottawa, ON, Canada

Background: The RELY trial has shown that dabigatran (150 mg BID) is superior to vitamin K antagonist (VKA) for stroke prevention in patients with atrial fibriallation. The quality of VKA management was reported using the time in therapeutic range (TTR). A subgroup analysis of the RELY trials has shown that dabigatran is no longer superior to VKA in patients with TTR over 65%. Therefore, numerous national drug coverage agencies and private insurance companies have decided to only financially cover new anticoagulants if patients have TTR $\leq$ 65%. The calculation of the TTR is difficult and not readily available in daily clinical practice. Clinicians need to have a simple and convenient way to identify patients on VKA with TTR $\leq$ 65% who would benefit from coverage for these new anticoagulants.

Aim: We sought to predict a TTR $\leq$ 65% using a surrogate method of measurement (Number of changes in VKA dosing and INR testing) that can be used by primary care physicians.

Method: A cross-sectional study including patients on VKA actively being followed for anticoagulation management using the DAWN software was conducted. Consecutive patients who had received a minimum of 9 months of VKA therapy with a target INR between 2.0 and 3.0 were enrolled into the study. The TTR for each patient was calculated using the linear interpolation of the Rosendaal method. The number of dose changes and the number of INR tests done over the last 6 months were recorded.

Results: A total of 1381 were included in the analyses. The median age was 63 ($\pm$ IQR 52–75) and the median duration of anticoagulation was 1287 days ($\pm$ IQR 764–2268), most patients were anticoagulated for secondary prevention of venous thromboembolism (83.4%) or for atrial fibrillation (11.9%). The mean TTR was 81% ($\pm$ IQR 70–90). Both the number of dose changes and the number of INR tests were independent predictors of TTR (Spearman's correlation coefficient: 0.62 and 0.58 [$P < 0.001$]). Patients were stratified according to their mean TTR (TTR $\leq$ 65% [$n = 238$] and TTR > 65% [$n = 1142$]). In patients with TTR > 65%, the median number of dose changes and the number of INR test done within the previous 6 months were 1 (IQR 0–3) and 7 (IQR 5–9) respectively. In patients with TTR $\leq$ 65%, the 6-month median number of dose changes was 5 (IQR 3–7) and the number of INR tests done was 12 (IQR 9–15). The combination of $\geq$ 3 doses changes and/or $\geq$ 9 INR testing done within 6 months had a sensitivity of 87% (95% CI: 82–90%), specificity of 63% (95% CI: 60–65%) to identify patients with TTR < 65%. The NPV was 96% (95% CI: 94–97%).

Conclusion: Both the number of dose changes and the number of INR tests can be used as surrogate markers of TTR. Therefore, these surrogate markers may offer a simple and clinically relevant way for clinicians to identify which patients on VKA would benefit from coverage for the new anticoagulants.

AS 38.3

Prothrombin fragment 1+2 in urine; a new way of analysing blood coagulation activity

Wexels F[1], Dahl OE[2], Borris LC[3], Pripp AH[4], Haslund A[1], Gudmundsen TE[1], Laszlo F[1], Seljeflot I[4] and Lassen MR[5]

[1]Vestre Viken Hospital Trust, Drammen, Drammen; [2]Innlandet Hospital Trust, Brumunddal, Brumunddal, Norway; [3]Århus University Hospital, Århus, Denmark; [4]Oslo University Hospital, Oslo, Norway; [5]University of Copenhagen, Glostrup, Glostrup, Denmark

Background: D-dimer may be used as a pretest to exclude deep vein thrombosis (DVT) and thus reduce the number of patients requiring imaging evaluations. A test based on spot urine could be more simple in several clinical situations. Prothrombin fragment 1+2 (F1+2) is excreted in the urine where it can be measured with an enzyme-linked immuno-sorbent assay. Several studies show an association between F1+2 levels in urine (uF1+2) and postoperative DVT.

Aims: We wanted to assess if levels of uF1+2 were associated with radiological confirmed DVT in symptomatic non-selected patients.

Methods: Patients aged $\geq$ 18 years with suspected DVT were included over a 2.5 year period. The study was conducted in accordance with the Declaration of Helsinki and approved by the regional Ethics Committee. Before the radiological procedure a urine sample (10 mL) was collected. Imaging was conducted with B-mode compression ultrasound and supplemented with venography when inconclusive. A commercial available ELISA kit (Enzygnost F1+2, Monoclonal) and a BEP 2000® analyzer (both Dade Behring, Marburg, Germany) were used for measuring uF1+2 levels. All patients were followed up for at least 3 months to detect new venous or arterial thromboembolic events or other conditions causing thrombin activity. Data analyses were conducted using SPSS version 19 (IBM, Armonk, New York, USA). Statistics were given as percent and number of patients or median with 25–75 percentile as appropriate. The non-parametric Mann-Whitney U test was used to assess differences in uF1+2 levels. The results were considered statistically significant if the two-sided P-value was $\leq$ 0.05.

Results: Median age of the 534 (260 men and 274 women) included patients was 60 (range 18–93) years and 108 (20.2%) patients had imaging verified DVT. Venography was performed in 52 (9.7%) patients due to inconclusive ultrasound. Median levels of uF1+2 was 28.1 pM and the DVT positive patients had statistically significant higher levels of uF1+2 than those without DVT (56.8 vs. 24.3 pM, $P < 0.001$).

Summary/Conclusions: We found that the urine levels of F1+2 was statistically significantly higher in patients with radiologically confirmed DVT compared to those without DVT. This indicates that F1+2 in urine can be used to determine increased procoagulant activity in patients with suspected DVT.

AS 38.4

Real-time dynamic measurement of hemostasis and fibrinolysis and detection of hemostatic and prothrombotic blood disorders by T2 magnetic resonance

Cines DB[1], Lebedeva T[1], Kowalska MA[1], Cuker A[1], Weisel JW[1], Whitten J[1], Skewis LR[2], Papkov V[2] and Lowery TJ[2]

[1]University of Pennsylvania, Philadelphia, PA; [2]T2 Biosystems, Lexington, MA, USA

Background: There is no single currently available test to rapidly identify and assess impaired hemostasis, hypercoagulable states and fibrinolysis. This is in part because of difficulties in measuring integrated reactions in whole blood with one platform. T2 magnetic resonance (T2MR) is a new approach that allows for monitoring these processes in real time by measuring relaxation times of the hydrogen nuclei within the sample. The time-resolved signals generated with this method provide dynamic information about the physical states of complex samples, such as changes that occur in the blood during hemostasis.

Aims: Apply a novel detection method, T2MR, to monitor the dynamics of clot formation and fibrinolysis across a range of hemostatic conditions.

Methods: We used a small, portable instrument to measure changes in T2MR signal that continuously report on the dynamically changing microscopic environment of water during coagulation and clot contraction in whole blood. In these foundational studies, we measured 34 μL blood samples from consented normal adult donors continuously over 20 min using T2MR. We tested clotting of recalcified citrated whole blood initiated by the addition of thrombin or kaolin. To assess the sensitivity of this platform to platelet activity, we measured samples activated with ADP or arachidonic acid in the presence and absence of 2-methylthioadenosine 5′-monophosphate (2-MeSAMP) or aspirin. Results were confirmed by standard platelet aggregometry. Fibrinolysis in whole blood was induced by addition of different concentrations of tissue plasminogen activator (tPA) before, during or after clot formation.

Results: At normal platelet counts (150,000–300,000/μL) and normal hematocrit (HCT) (38–48%), the T2MR signals resolved into two peaks corresponding to: (i) water trapped within a retracted clot and (ii) water in the surrounding liquid, i.e. serum. Platelet counts < 50,000/μL or addition of aspirin or 2-MeSAMP eliminated the signal peak originating from clot contraction. Higher platelet counts (300,000–1,300,000/μL) and high thrombin concentrations (2 U/mL) generated a third, even more highly ordered peak. The third peak was confirmed to correspond to a tightly packed fibrin clot enriched in red blood cells (RBCs) with D2O exchange experiments and scanning electron microscopy. The signals also revealed the procoagulant influence of RBCs on clot formation/contraction over a wide range of HCTs (20–73%). Addition of tPA coincident with thrombin generated diverse species of fibrin/fibrin degradation products reflected in the dynamics of clot contraction and dissolution. Addition of tPA after clot contraction revealed heterogeneity in the susceptibility of clots formed under normal and procoagulant conditions to lysis.

Summary/Conclusions: These studies show that the dynamics and properties of clot formation and lysis across a range of hemostatic conditions can be characterized with T2MR measurements. This approach may be applicable to the study, diagnosis, and management of a spectrum of disorders of hemostasis, thrombosis and fibrinolysis. Additional studies will be needed to develop a more complete understanding of the biochemical events measured by T2MR and to more fully explore its clinical utility.

AS 39 – Regulation of Platelet Function

AS 39.1

Src-like adapter proteins (SLAPs) are critical negative regulators of GPVI/ITAM-signalling in arterial thrombosis and ischaemic stroke

Cherpokova D[1], Bender M[1], Morowski M[1], Kraft P[2], Akbar S[3], Sultan C[3], Dragone L[4], Watson SP[5], Tomlinson MG[3] and Nieswandt B[1]

[1]University Hospital and Rudolf Virchow Center; [2]University of Würzburg, Würzburg, Germany; [3]School of Biosciences, University of Birmingham, Birmingham, UK; [4]University of Colorado, School of Medicine, Denver, CO, USA; [5]Centre for Cardiovascular Sciences, University of Birmingham, Birmingham, UK

Background: The central activating platelet collagen receptor *glycoprotein* (GP) VI has been established as an attractive potential target for antithrombotic therapy as its blockade or antibody-induced deficiency provided powerful protection from experimental arterial thrombosis and acute ischaemic stroke without affecting platelet haemostatic functions. GPVI signals through an *immunoreceptor tyrosine-based activation motif* (ITAM) in a similar manner to the *T*- and *B-cell antigen receptors* (TCR, BCR).

The *Src-like adapter protein* (SLAP) and the closely related SLAP2 constitute a family of haematopoietic adapter proteins that are involved in the regulation of TCR and BCR surface expression levels and signalling via interaction with the phosphorylated ITAMs of their signalling complexes. However, the function of SLAP and SLAP2 in platelets, and in particular their effects on GPVI, are unknown.

Aims: The aim of this study was to investigate the role of SLAP and SLAP2 in platelet biology.

Methods: Mice deficient in SLAP and SLAP2 were generated and platelet function was analysed by flow cytometry, aggregometry, flow adhesion assays and biochemical methods. In addition, SLAP and SLAP2 were expressed in a cell line model system to study GPVI/ITAM signalling *in vitro*. The role of SLAP and SLAP2 *in vivo* was assessed in models of arterial thrombosis and ischaemic stroke.

Results: *Slap*/*Slap2*″**◆**/″**◆** mouse platelets displayed markedly increased integrin activation, granule release, aggregation and procoagulant activity upon stimulation with GPVI/ITAM″**◆**specific agonists. In contrast, activation responses to soluble agonists operating via G protein-coupled receptors were normal. The negative regulatory function of both adapters was confirmed in a heterologous system where overexpression of either SLAP or SLAP2 could almost completely inhibit GPVI signalling in response to collagen. Furthermore, SLAP/SLAP2-deficiency was associated with enhanced and sustained tyrosine phosphorylation of different proteins involved in the GPVI/ITAM″**◆**signalling cascade, including FcR γ-chain, Syk, LAT and PLCγ2. This effect was not based on the elevated GPVI expression levels observed in *Slap*/*Slap2*″**◆**/″**◆** platelets as it was fully preserved in *Slap*/*Slap2*″**◆**/″**◆**/*Gp6*+/− mice which exhibited reduced GPVI expression levels compared to the wild-type. *In vivo*, *Slap*/*Slap2*″**◆**/″**◆** mice displayed faster occlusive thrombus formation in the $FeCl_3$-injured carotid artery and a dramatically worsened outcome in a model of ischaemic stroke. This was evident by increased infarct volume and neurologic deficits in *Slap*/*Slap2*″**◆**/″**◆** mice compared to the wild-type 24 h after 30 min of transient middle cerebral artery occlusion.

Summary/Conclusion: Our results establish SLAP and SLAP2 as critical inhibitors of platelet GPVI/ITAM signalling, which has major pathophysiological significance in the setting of arterial thrombus formation and ischaemic stroke.

AS 39.2

Connexin40 regulates platelet function and thrombosis

Vaiyapuri S[1], Moraes LA[1], Sage T[1], Ali MS[1], Mahaut-Smith MP[2], Simon AM[3] and Gibbins JM[1]

[1]University of Reading, Reading; [2]University of Leicester, Leicester, UK; [3]University of Arizona, Tucson, AZ, USA

Background: Connexins are membrane proteins that assemble into connexons or hemichannels on the plasma membrane to facilitate the transport of small signalling molecules (up to ~1000 Da) between the interior and exterior of isolated cells. Upon docking, hemichannels form gap junctions between adjacent cells allowing direct intercellular communication. The presence of multiple connexins is recently reported on platelets, small circulating blood cells that maintain haemostasis and their inappropriate activation leads to thrombosis, a trigger for heart attack and strokes. The mechanistic phenomenon on the functions of various connexins in regulating platelet function is yet to be explored.
Aims: This study was performed to determine if connexin40 (Cx40) has a role in the regulation of platelet function and to establish whether Cx37 and Cx40 are able to function independently in these cells.
Methods: Human platelets were tested in the presence or absence of a selective peptide inhibitor of Cx40, ^{40}Gap27 on various functional assays such as aggregation, fibrinogen binding and granule secretion. Plasma clot retraction was also tested in the presence of ^{40}Gap27. To assess the effects of Cx40 deletion, platelets from *Cx40−/−* mice were analysed in comparison with those from *Cx40+/+* mice using aggregation, fibrinogen binding, granule secretion and clot retraction assays. To explore, if Cx40 function independently from Cx37, the platelets from *Cx40−/−* were analysed in the presence and absence of ^{37,43}Gap27 and similarly platelets from *Cx37−/−*were analysed using ^{40}Gap27.
Results: The Cx40 selective inhibitor, ^{40}Gap27 inhibited CRP-XL- (a GPVI selective agonist) and thrombin-induced human platelet aggregation, fibrinogen binding and granule secretion in concentration-dependent manner. Inhibition of Cx40 also resulted in reduced clot retraction, a process driven by outside-in signalling by integrin αIIbβ3 on the platelet surface. Deletion of Cx40 in mice also resulted in retarded platelet function and clot retraction. The ability of ^{40}Gap27 to inhibit the function of *Cx37−/−* (but not *Cx40−/−*) platelets, and conversely ^{37,43}Gap27 to inhibit *Cx40−/−* (but not *Cx37−/−*) platelets, suggests that Cx40 and Cx37 are able to function independently in platelets.
Conclusions: This study indicates that multiple members of the connexin family of proteins, beyond the previously characterised Cx37, are likely to be of importance in the regulation of platelet function, haemostasis and thrombosis.

AS 39.3

CalDAG-GEFI deficiency protects mice from FcγRIIa-mediated thrombotic thrombocytopenia induced by CD40L and β2GPI immune complexes

Amirkhosravi A[1], Boulaftali Y[2], Robles-Carrillo L[1], McKenzie SE[3], Meyer T[1], Francis JL[1] and Bergmeier W[2]

[1]Florida Hospital, Orlando, FL; [2]University of North Carolina, Chapel Hill, NC; [3]Thomas Jefferson University, Philadelphia, PA, USA

Introduction: Platelet activation via Fcγ receptor IIa (FcγRIIa) is implicated in the pathogenesis of thrombotic complications triggered by immune complexes (ICs) resulting from autoimmune disease or the administration of therapeutic antibodies. We previously showed that ICs of antigen and antibodies targeting CD40 ligand (CD40L) or β2 Glycoprotein I (β2GPI) induce thrombocytopenia and thrombosis in mice transgenic for human FcγRIIa (hFcR) but not wild-type control mice (which lack FcγRIIa). *In vitro*, platelet aggregation downstream of FcγRIIa was dependent on signaling by the calcium-sensing guanine nucleotide exchange factor, CalDAG-GEFI, and the Gi-coupled receptor for ADP, P2Y12.
Aim: Here we studied the signaling response required for IC-mediated thrombocytopenia and thrombosis (ITT) in mice. Specifically, we evaluated ITT in hFcR transgenic mice deficient in CalDAG-GEFI and/or treated with the P2Y12 inhibitor clopidogrel bisulfate.
Methods: Pre-formed anti-CD40L ICs (M90+rCD40L) or anti-β2GPI (β2pAb+β2GPI) ICs were injected intravenously into hFcR/CalDAG-GEFI$^{+/+}$ or hFcR/CalDAG-GEFI$^{-/-}$ mice with or without clopidogrel pre-treatment. Inhibition of platelet P2Y12 by clopidogrel was confirmed by flow cytometry ex vivo. Animals were observed for symptoms of shock for 30 min, during which time core body temperature was monitored. Platelet counts were obtained before and 30 min after IC injection. Lungs were harvested at 30 min for assessment of thrombosis by histology or by near-infrared imaging (mice pretreated with Alexa-800-labeled anti-P-selectin antibody).
Results: CD40L and β2GPI ICs both rapidly induced severe symptoms of shock and marked reduction in body temperature in hFcRmice along with profound thrombotic thrombocytopenia. hFcR/CalDAG-GEFI$^{-/-}$ mice were almost completely protected from CD40L IC-induced thrombocytopenia/thrombosis and shock. Clopidogrel had a small effect on IC-induced ITT in hFcR and hFcR/CalDAG-GEFI$^{-/-}$ mice. CalDAG-GEFI deficiency also conferred marked protection from β2GPI IC-induced ITT. However, significant thrombocytopenia/thrombosis and hypothermia was still observed in clopidogrel treated hFcR/CalDAG-GEFI$^{-/-}$ mice, suggesting that β2GPI ICs can trigger platelet activation in the absence of these major signaling pathways.
Summary/Conclusions: Our studies demonstrate that clinically relevant ICs cause platelet FcγRIIa-dependent thrombocytopenia and thrombosis in hFcR mice. We further show that signaling by CalDAG-GEFI, but not by P2Y12, is critical for IC-induced platelet activation *in vitro* and *in vivo*. Thus, CalDAG-GEFI may be a promising target for the intervention of IC-associated, FcγRIIa-mediated thrombotic conditions.

AS 39.4

Platelet ITAM signaling is critical for maintenance of vascular integrity during inflammation

Boulaftali Y[1], Hess PR[2], Getz TM[1], Stolla M[3], Mackman N[1], Owens AP III[1], Ware J[4], Kahn ML[2] and Bergmeier W[1]

[1]University of North Carolina Chapel Hill, Chapel Hill, NC; [2]University of Pennsylvania, Philadelphia, PA; [3]Thomas Jefferson University, Philadelphia, PA, USA; [4]University of Arkansas for Medical Sciences, Little Rock, AR, USA

Background: Blood platelets, long recognized for their importance in primary hemostasis, have recently been identified as critical regulators of vascular integrity during inflammation and cancer. Interestingly, the contribution of platelets to the maintenance of vascular integrity in inflammation seems to be independent of their ability to form a clot.
Aim: To identify signaling molecules critical for the contribution of platelets to vascular integrity in inflammation.
Methods: We here describe a novel method for the generation of mice with platelet-specific signaling defects, which is based on the adoptive transfer of platelets into thrombocytopenic (TP) mice. Depletion of circulating platelets was achieved in transgenic mice with antibodies that recognize hIL-4R, a heterologous antigen expressed on circulating platelets in these animals. Platelets from various knockout mice or inhibitor-treated wild-type (WT) platelets were transfused into TP mice and tested for their ability to support vascular integrity in a reverse passive Arthus reaction (rpA) model and LPS-induced inflammation in the lung. Hemoglobin (Hb) content in skin tissue and bronchoalveolar lavage (BAL) was used to quantify hemorrhage at sites of inflamamtion.
Results: Inflammation-induced hemorrhage was significantly increased in TP mice compared to controls. Vascular integrity at sites of

inflammation was not impaired in TP mice transfused with 8×10^8 WT platelets before challenge. Unexpectedly, platelets defective in GPCR signaling, a crucial component of platelet plug formation and hemostasis, were indistinguishable from WT platelets in their ability to support vascular integrity in both models of inflammation. In contrast, genetic deletion of *Clec2* or inhibition of GPVI (inhibitory antibody JAQ1), the only ITAM receptors expressed on mouse platelets, significantly reduced the ability of platelets to prevent inflammation-induced hemorrhage. Moreover, transfusion of JAQ1-treated *Clec2−/−* platelets or platelets lacking SLP-76, an adapter protein critical to ITAM signaling, into TP mice had no significant effect on vascular integrity during inflammation.

Summary/Conclusions: By generating mice with multiple platelet-specific signaling defects, we demonstrate that vascular integrity in inflammation depends on both ITAM receptors, GPVI and CLEC2, as well as the adapter protein SLP-76. Our studies highlight potential complications associated with novel antiplatelet drugs targeting the ITAM signaling pathway, which may lead to bleeding at sites of inflammation.

AS 40 – Thrombotic Micro-Angiopathies

AS 40.1

A novel CD46 gene mutation in a patient with normal ADAMTS13 activity and microangiopathy

Rossio R[1], Lotta LA[2], Pontiggia S[1], Donadelli R[3], Piras R[3], Garagiola I[1], Ghiringhelli Borsa N[1], Mikovic D[4], Cugno M[1] and Peyvandi F[1]

[1]Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico; [2]Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, Milano; [3]Mario Negri Institute for Pharmacological Research, Ranica, Bergamo, Italy; [4]Blood Transfusion Institute of Serbia Svetog Save 39 11000, Belgrade, Serbia

Background: The differential diagnosis and etiologic classification of the two main forms of thrombotic microangiopathy, thrombotic thrombocytopenic purpura (TTP) and atypical hemolytic uremic syndrome (HUS), remain challenging. TTP is usually characterized by the severe deficiency of the von Willebrand factor (VWF) cleaving protease, ADAMTS13. Atypical HUS is characterized by hyperactivation of the alternative complement-system. The prevalence of severe ADAMTS13 deficiency in TTP is particularly high in patients with idiopathic disease and absence of renal involvement, reaching 75–80% in some cohorts. In a small fraction of patients with a diagnosis of idiopathic TTP and absent (or minor) renal involvement, ADAMTS13 activity may be only slightly reduced or normal at acute disease presentation. The pathophysiological mechanisms underlying microvascular thrombosis in these patients are unknown.

Aims: To investigate etiology in a 27-year-old woman with a diagnosis of TTP with minor renal involvement and normal ADAMTS13 activity at presentation.

Methods: The patient was referred to the Milan TTP registry (URL: www.ttpdatabase.org) with a diagnosis of TTP (thrombocytopenia, microangiopathic hemolytic anemia and no overt renal failure). Blood samples were collected both at acute episode before starting any transfusional therapy and during remission. We measured ADAMTS13 antigen, activity, VWF- and complement system-related plasmatic parameters. Mutations in six complement-system genes (*CFH, CFI, CD46, CFB, THBD* and *C3*) were searched for by PCR and Sanger sequencing. The protein coding area of the genome (i.e. the exome) was sequenced by target-capture and sequencing on Illumina HiSeq 2000. The role of a novel mutation of the *CD46* gene was studied by expression of MCP on leucocytes by fluorescence-activated cell sorter (FACS).

Results: A 27-year-old woman with thrombocytopenia (platelet counts: 14×10^9/L; normal values [n.v.]: 150–450 $\times 10^9$/L), microangiopathic hemolytic anemia (hemoglobin: 8.9 g/dL; n.v.: 11.5–16 g/dL), and slightly increased serum creatinine (117 μM; n.v.: 53–106 μM), was diagnosed as TTP and was treated with plasma-exchange. Remission was achieved after 7 daily exchange procedures. Large multimers of von Willebrand factor were depleted and complement system was activated during acute disease, while ADAMTS13 activity was normal. Sequencing of six complement system genes revealed a novel splice-site mutation of *CD46*. Exome sequencing revealed 12 nonsynonymous changes in 11 genes encoding proteins implicated in the pathophysiology of thrombotic microangiopathies, including the novel *CD46* mutation. The mutation was predicted to create an alternative splice site within the open reading frame of exon 4, resulting in the in frame deletion of six aminoacids of the encoded complement membrane-cofactor. Studies on mRNA isolated from the patient and from family members carrying the mutation showed the presence of abnormal transcripts bearing the deletion. Low surface expression of MCP on PBMC was confirmed by FACS.

Summary/Conclusions: This study shows that complement system gene mutations may be implicated in the occurrence of TTP with normal ADAMTS13 at presentation, even when there are little signs of renal involvement.

AS 40.2

Complement activation and cytokine response in TTP

Westwood JP[1], Heelas O[1], Langley KM[1], Machin SJ[1] and Scully M[2]

[1]University College London; [2]University College London Hospital, London, UK

Background: Thrombotic Thrombocytopenic Purpura (TTP) is a microangiopathy associated with organ dysfunction and a high level of morbidity and mortality. Complement dysregulation and subsequent overactivation of complement effector proteins (including the anaphylatoxins C3a and C5a) is established in atypical Haemolytic Uraemic Syndrome (aHUS), and responds clinically to C5 inhibition. However, the role of complement in TTP is unknown.

Aims: We carried out a prospective study investigating the role of complement anaphylatoxins C3a and C5a in patients with TTP during acute episodes, and in remission, and compared these with normal controls. For both acute and remission groups we also investigated the cytokine response (Th1/Th2/Th17- involving IL-2, IL-4, IL-6, IL-10, TNF, IFN-γ and IL-17a) and association with disease state.

Methods: EDTA plasma was obtained from 21 patients (12F, 9M) with acute TTP, ADAMTS13 activity < 5% and positive anti-ADAMTS13 IgG antibodies (median IgG 59%, range 8–180%). Also, EDTA Plasma from 50 patients (34F, 16M) previously treated for acute TTP, now in clinical remission (normal ADAMTS13 activity and a platelet count > 150×10^9/L). Paired EDTA plasma was obtained from 12 patients (6F, 6M) for whom both acute and remission samples were available. Measurement of complement anaphylatoxins C3a (NR 32.5–56.1 ng/mL) and C5a (NR 1.7–13.6 ng/mL) was performed using BD™ Human Anaphylatoxin Kit, (BD Biosciences, San Jose, CA, USA) using a Cytometric Bead Array (CBA) method. Serum was obtained from acute and remission patients, enabling the measurement of cytokines, using BD™ Human Th1/Th2/Th17 Kit, (BD Biosciences, San Jose, CA, USA) also incorporating the CBA method.

Results: In acute TTP, median C3a and C5a were significantly elevated compared to patients in remission, C3a 66 vs. 38.5 ng/mL ($P < 0.001$) and C5a 17 vs. 10 ng/mL ($P < 0.001$), respectively. For the 12 patients with paired acute and remission samples, median C3a levels were significantly higher during the acute episode than in remission, C3a 45.5 vs. 35.8 ng/mL ($P = 0.041$); there was a non-significant difference in C5a levels 15.2 vs. 10.6 ng/mL ($P = 0.084$). Compared to controls, remission median C5a levels were significantly higher 10 vs. 5.81 ng/mL ($P = 0.001$); however remission C3a levels were lower than controls 38.5 vs. 43.7 ng/mL ($P = 0.046$). Within the acute TTP group, there was no significant difference in C3a or C5a levels for patients

requiring ITU admission vs. those not requiring ITU care or patients with or without neurological features at presentation. Both median IL-6 and IL-10 levels were significantly higher in the acute vs. remission groups, IL-6: 8 vs. 2 pg/mL ($P = 0.002$), IL-10: 6 vs. 2 pg/mL ($P < 0.001$). C3a levels were strongly correlated with both anti-ADAMTS13 IgG ($r_s = 0.731$, $P = 0.002$) and IL-10 ($r_s = 0.627$, $P = 0.012$) levels.

Summary/Conclusion: These results suggest anaphylatoxin levels in TTP vary between acute and remission cases, and highlight the possibility that the complement response seen acutely may relate to both the degree of anti-ADAMTS13 IgG antibody level and cytokine (IL-10) levels. Complement inhibition at presentation in the acute phase may have therapeutic potential.

AS 40.3

Plasmin cleavage of von Willebrand factor; a physiological and therapeutic bypass for ADAMTS13 deficiency and thrombotic microangiopathy

Tersteeg C, Smeets MWJ, Roest M, Pasterkamp G, De Groot PG and Maas C

UMC Utrecht, Utrecht, the Netherlands

Background: ADAMTS13 controls Von Willebrand Factor (VWF) multimer size through continuous proteolysis. This prevents spontaneous platelet agglutination on ultra-large VWF multimers and formation of pathological microthrombi. ADAMTS13 deficiency is often caused by inhibiting autoantibodies and can result in microangiopathy. This is treated by plasmapheresis, which is inefficient and costly. Enigmatically, a complete congenital or persistent acquired ADAMTS13 deficiency does not lead to continuous thrombotic disease.

Hypothesis: Plasmin, the key enzyme of the fibrinolytic system, can serve as a physiological backup enzyme for the degradation of unfolded VWF multimers in absence of ADAMTS13. We base this hypothesis on the following evidence: 1) Plasmin can cleave VWF under purified conditions 2) Plasmin activity is reported in ADAMTS13 deficient persons. 3) uPA triggers plasmin activation on activated endothelial cells, but is redundant for the clearance of fibrin.

Results: Plasminogen activation, either induced by uPA/uPAR or streptokinase, leads to rapid degradation of endothelial-cell tethered strings of platelet-decorated VWF. In the presence of plasmin, ristocetin-induced platelet agglutinates form normally, whereafter they are fully degraded. In contrast, plasmin acivity does not reduce aggregate formation on collagen surfaces at arterial shear rates. These findings indicate that platelet-VWF complexes are preferred substrates for plasmin degradation. Plasminogen binds to immobilized VWF in a lysine-dependent manner through multiple binding sites, one of which resides in the A1 domain. Patients with acute TTP episodes have elevated levels of PAP-complexes, indicating plasminogen activation.

Conclusions: We propose that during reduced or absent activity of ADAMTS13, plasmin serves as a natural backup for the degradation of pathologically large VWF multimers. As streptokinase is able to degrade platelet-decorated VWF strings on endothelial cells, as well as platelet VWF-agglutinates, induction of plasmin activity may have therapeutic value in the treatment of VWF-mediated microangiopathies. Especially when neutralizing autoantibodies cause ADAMTS13 deficiency, this bypassing strategy may prove useful.

AS 40.4

The phenotype of ADAMTS13 mutation 4143_4144insA – a study of 11 homozygous cases in Norway

Von Krogh AS[1], Kremer Hovinga JA[2], Waage A[1], Tjønnfjord GE[3] and Quist-Paulsen P[4]

[1]Norwegian University of Science and Technology, Trondheim, Norway; [2]Inselspital, Bern University Hospital, Bern, Switzerland; [3]Oslo University Hospital, Oslo; [4]St Olavs Hospital Trondheim University Hospital, Trondheim, Norway

Background: Patients with congenital thrombotic thrombocytopenic purpura (TTP) suffer recurrent acute attacks of microangiopathic haemolytic anaemia and thrombocytopenia due to an inherited severe deficiency of von Willebrand factor cleaving metalloprotease ADAMTS13. However, time of onset and severity of the disease, in terms of number of acute attacks, end-organ damage, and dependency on regular plasma infusions vary widely among patients. Effort has been put down to determine to what extent different genotypes correspond to different clinical phenotypes. The fact that more than 100 different mutations have been reported in congenital TTP, most of them in compound heterozygous state, represents an obstacle in this work. In Norway, we have a particularly high prevalence of patients homozygous for the common mutation 4143_4144insA.

Aim: To study the clinical phenotype of Norwegian patients homozygous for mutation 4143_4144insA and compare it with previously published cases with the same mutation.

Methods: The study combined retrospective review of participating patients' medical records, and literature searches. Ethical review board approval and patients' informed consents were obtained.

Results: There were five (46%) females, and six males from eleven different families of non-consanguineous marriages. Median age at inclusion in the study was 30 years (range 5–63). Seven patients (64%) had symptoms of TTP in the neonatal period, although diagnosed years later. Two patients (18%) had disease onset during childhood, and two (18%) in adulthood. Mean and median age at first TTP attack requiring plasma therapy was 25 and 22 years, respectively (range 3–52). Five patients (46%) received regular prophylactic plasma infusions, and two (18%) only on special occasions. The average amount of plasma required per month was 4 units (range 2–6). Two patients (18%) had five or less TTP attacks, seven patients (64%) had between six and nine, and two patients (18%) had ten or more documented acute attacks. Three patients had complications in pregnancy related to TTP, one had a mild behavioural developmental disorder, one had chronic renal insufficiency, one had neurological sequelae, and six had no complications. Only two patients were correctly diagnosed with TTP at their first presentation of disease. Other diagnoses were haemolytic-uremic syndrome (3), Evans syndrome (2), immune thrombocytopenic purpura (1), disseminated intravascular coagulation (1), glomerulonephritis (1), hepatitis (1), and pregnancy related haemolytic crisis (1). Twenty-four reported cases with 4143_4144insA mutation were identified in the literature, eleven of which were homozygous (from nine families). There were limited clinical data on ten patients, and no strict definitions on disease severity.

Summary: Overall, patients homozygous for *ADAMTS13* mutation 4143_4144insA tend to have a relatively mild phenotype, despite symptoms since early childhood in most. However, we cannot rule out that we in this retrospective analysis have selected milder cases that survive long enough to get a molecular diagnosis. Misdiagnosis was usual at first presentation. Due to lacking definitions on disease severity it was difficult to compare our material with previously published cases. We suggest evidence of end-organ damage and dependency on prophylactic plasma infusions may be used to assess disease severity in congenital TTP.

AS 41 – Natural Anticoagulants

AS 41.1

Protease-activated receptor 3 (PAR3) tethered-ligand peptides derived from non-canonical cleavage at Arg41 by activated protein C provide vascular barrier protective effects *in vitro* and *in vivo*

Burnier L and Mosnier LO
The Scripps Research Institute, La Jolla, CA, USA

Background: Activated protein C (APC) conveys cytoprotective effects on cells and in various murine disease models that generally require the endothelial protein C receptor (EPCR) and protease-activated receptor 1 (PAR1). In contrast, thrombin signaling via PAR1 is proinflammatory, thus it is unclear how PAR1 can mediate both cytoprotective APC signaling as well as proinflammatory thrombin signaling. Neuro- and nephro-protective activities of APC that required PAR3 suggested involvement of PAR3. We found that cleavage of PAR3 by APC is EPCR dependent and proportional to the expression of EPCR on cells. Remarkably, APC and thrombin cleaved the *N*-terminal domain of PAR3 at different sites, with proteolysis of PAR3 by thrombin at K38 and cleavage by APC at R41.
Aim: We hypothesize that the specific cleavage site of PAR3 by APC creates a non-canonical tethered-ligand that, in contrast to the canonical PAR3 tethered-ligand generated by thrombin, will convey APC-like cytoprotective activities and improve vascular barrier function *in vitro* and *in vivo*.
Methods: PAR3 peptides of different length, either starting at T39 (P3K) or G42 (P3R) were tested for vascular barrier function *in vitro* on EA.hy926 endothelial cells. Vascular permeability *in vivo* was determined in immune-competent hairless mice by analyzing VEGF-induced Evans blue leakage in the skin and quantification by infrared fluorescent imagery.
Results: Induction of endothelial barrier disruptive effects by thrombin requires PAR1 but blocking antibodies against PAR3 revealed PAR3 contributions, indicating that PAR3 could modulate endothelial barrier function. PAR3 tethered-ligand peptides (13- and 24-mer P3R peptides) derived from APC cleavage at Arg41, but not 6-mer P3R peptides, prevented endothelial barrier disruptive effects induced by either thrombin or histones similar to APC. In contrast, P3K peptides (either 6-, 13- or 24-mer) did not prevent disruptive effect by thrombin or histones. Since PAR3 cannot signal on its own, but was shown to modulate PAR1 signaling, assays were performed in spontaneously leaky endothelial cells that do not rely on PAR1 to induce permeability. P3R peptides decreased spontaneous leakage but the barrier protective effects of P3R were abolished by a PAR1 antagonist (SCH79797), indicating that the barrier protective effects of non-canonical PAR3 tethered-ligand peptides required PAR1. *In vivo*, intravenous injection of 24-mer P3R peptides 60 min before injection of VEGF decreased vascular leakage by 38% ($P < 0.05$, $n = 8$ mice). In contrast, P3K had no effect and neither P3R nor P3K peptides affected vascular leakage in the absence of VEGF. Remarkably, injection of P3R peptides 5 min before VEGF was not vascular protective, indicating that P3R-mediated vascular protection is not an acute event.
Conclusions: Collectively, these results demonstrate that peptides (13-mer or longer) derived from PAR3 cleavage by APC at R41 act as APC-mimetics, reflecting the broad vascular barrier protective effects of APC *in vitro* and *in vivo*. The protective effect required PAR1, suggesting that the P3R peptides may act as allosteric modulators of PAR1 signaling. We propose a novel biochemical mechanism for APC-induced cell signaling via PAR3 and the generation of a novel non-canonical *N*-terminal tethered ligand that initiates APC-mimetic vascular protective signaling.

AS 41.2

Direct inhibition of factor VIIa by TFPI and TFPI constructs

Peraramelli S[1], Thomassen S[1], Heinzmann A[1], Rosing J[1], Hackeng TM[1], Hartmann R[2], Scheiflinger F[2] and Dockal M[2]
[1]*University of Maastricht, Maastricht, the Netherlands;* [2]*Baxter Innovations GmbH, Vienna, Austria*

Background: TFPI is a multi-Kunitz domain protease inhibitor that down-regulates the extrinsic coagulation pathway by inhibiting FXa and FVIIa. TFPI inhibits FXa via a slow-tight binding mechanism and inhibits TF-FVIIa in a direct FXa-independent manner (formation of a TFPI-TF-FVIIa complex) and FXa-dependent manner (formation of a quaternary TFPI-FXa-TF-FVIIa complex).
Aims: To investigate the role of the three Kunitz domains (KD) of TFPI in FVIIa inhibition using full length TFPI (TFPI-fl) and truncated TFPI constructs.
Methods: Recombinant full length TFPI (TFPI-fl) and TFPI constructs (KD1, KD1-KD2, TFPI1-150) were purified from bacterial expression systems. Inhibition of FVIIa with/without relipidated tissue factor (TF) or soluble TF (sTF) by TFPI-fl/TFPI constructs was quantified with a FVIIa-specific chromogenic substrate.
Results: TFPI-fl inhibited TF-FVIIa via a monophasic reaction that was rather slow at low TFPI-fl concentrations ($t_{½}$~5 min at 2 nM TFPI) and had a K_i of 4.6 nM. In the presence of sTF and without TF, TFPI-fl was a poor FVIIa inhibitor with K_i values of 122 and 1118 nM, respectively. TFPI constructs without KD3-*C*-terminus (TFPI1-150 and KD1-KD2) were 7–10-fold less effective than TFPI-fl in inhibiting TF-FVIIa and sTF-FVIIa. Compared to KD1-KD2, KD1 was a poor TF-FVIIa inhibitor (K_i = 434 nM). Protein S, which is a co-factor of TFPI-fl in FXa inhibition, also stimulated TF-FVIIa inhibition by TFPI-fl and decreased K_i ~7-fold (K_i = 0.7 nM). Protein S required phospholipids and the KD3-*C*-terminus of TFPI to express TFPI cofactor activity. In presence of FXa, a tight quaternary TF-FVIIa-TFPI-FXa complex was formed with TFPI-fl, TFPI1-150 and KD1-KD2 with K_i values < 0.15, 0.5 and 0.8 nM, respectively. Phospholipids and the Gla-domain of FXa were required for quaternary complex formation.
Summary and Conclusions: Our study shows that TFPI-fl is a direct TF-FVIIa inhibitor with protein S as co-factor, which decreases the Ki value close to the plasma TFPI-fl concentration (0.25–0.5 nM). Truncated forms of TFPI were much less active than TFPI-fl indicating that the KD3-*C*-terminus significantly contributes to direct inhibition of FVIIa by TFPI. Although it is generally accepted that KD1 binds to and inhibits FVIIa, KD1-KD2 was much more effective in FVIIa inhibition than KD1. This indicates that the KD2 domain of TFPI, which actually targets FXa, also contributes to FVIIa inhibition. Phospholipids and TF significantly enhance direct TF-FVIIa inhibition by TFPI-fl. In presence of FXa, TFPI-fl and truncated TFPI constructs efficiently formed a quaternary complex indicating that the KD3-*C*-terminus is not a prerequisite for quaternary complex formation.
Considering the TFPI-fl concentration in plasma (0.25–0.5 nM), one may question whether direct inhibition of TF-FVIIa by TFPI in the absence of FXa but in the presence of phospholipids and protein S (Ki~0.7 nM) is physiologically important. In this respect it should be emphasized that at the site of a growing thrombus the local TFPI concentration may be significantly higher due to release of TFPI from platelets. At such conditions, direct inhibition of TF-FVIIa by TFPI may contribute to the down-regulation of thrombin formation.

AS 41.3

Protective effects of non-anticoagulant activated protein C variant (D36A/L38D/A39V) in a murine model of ischaemic stroke

Crawley JTB, Efthymiou M, Yu Y, Watts H, Noormohamed H, Ma D, Lane DA and Andreou AP

Imperial College London, London, UK

Background: Ischaemic stroke is caused by occlusive thrombi in the cerebral vasculature that lead to ischaemia/tissue damage. Patients treated within 4.5 h of onset of symptoms can receive tissue-plasminogen activator (tPA) as thrombolytic therapy, which however has some major limitations including blood brain barrier disruption and increased risk of bleeding. Treatments that prevent/limit such deleterious side-effects could be of clinical importance. Activated protein C (APC) regulates thrombin generation through the protein S-dependent inactivation of FVa and FVIIIa. APC also exhibits cytoprotective cell signalling mediated through activation of protease-activated receptor 1. In murine models of stroke, APC in conjunction with tPA can limit the deleterious effects of tPA, however, APC in this setting can further elevate the risk of bleeding. Thus, APC variants with reduced anticoagulant, but normal cytoprotective function represent potential therapeutic agents.

Aims: Three APC variants with reduced anticoagulant, but normal cytoprotective function have been engineered; 1) APC KKK191-193AAA/R229A-R230A – APC(5A) 2) APC D222C-R237C – APC (Ca-ins), and 3) APC D36A/L38D/A39V – APC(36–39) – the latter which abolishes the ability of APC to be enhanced by its cofactor, protein S. We aimed to compare the relative anticoagulant functions and rates of inactivation by protein C inhibitor (PCI) of these three APC variants, and to explore the therapeutic benefit of the APC(36–39) in a murine model of ischemic stroke.

Methods: Human wild type (wt) and variant protein C, and their murine counterparts, were expressed, purified, activated and quantified. The relative anticoagulant functions of these variants were assessed using thrombin generation assays (TGA). The rate of inactivation of human variants by PCI was assayed using the chromogenic substrate S2366. Using a murine middle cerebral artery occlusion (MCAo) model, we measured neurological scores, cerebral infarction, oedema and cerebral haemoglobin 24 h post-MCAo and the influence of administration of t-PA with and without co-administration of either murine wtAPC or APC(36–39).

Results: Human and murine wt protein C, protein C(36–39) were expressed and secreted normally. The protein C(Ca-ins) variants were secreted partly as disulphide-linked dimers. The protein C(5A) variants were secreted with lower efficiency. TGA suggested reductions in anticoagulant function of ~50-fold for APC(36–39), ~25-fold for APC (Ca-ins) and ~17-fold for APC(5A). In PCI inactivation assays, wtAPC, APC(36–39) and APC(Ca-ins) were all inhibited similarly ($t_{½}$ – 33 to 39 mins). APC(5A) was inactivated ~9-fold faster ($t_{½}$ – 4 mins). Using the murine MCAo ischaemia/reperfusion injury model, APC (36–39) in combination with tPA improved neurological scores, cerebral infarct area and oedema ratio as well as, or better than, wt APC. APC(36–39) alone also significantly reduced cerebral haemoglobin (a measurement of bleeding) induced by administration of tPA, whereas wt APC was unable to significantly improve cerebral bleeding.

Summary/Conclusions: APC(36–39) is a non-anticoagulant form of APC that is expressed and activated normally and inactivated by PCI with similar kinetics to wtAPC. APC(36–39) in conjunction with tPA can ameliorate ischaemia/reperfusion injury in mouse brains and reduce the deleterious effects of tPA. These attributes suggest that APC(36–39) is a potential therapeutic agent with possible advantages over other non-anticoagulant APC variants.

AS 41.4

Identification of a novel pathway for encryption of the endothelial protein C receptor (EPCR) by TNFa that results in loss of activated protein C (APC) binding and induction of cellular APC resistance

Bouwens EAM and Mosnier LO

The Scripps Research Institute, La Jolla, CA, USA

Activated protein C (APC) provides antithrombotic and cytoprotective beneficial effects that require the endothelial protein C receptor (EPCR). EPCR is a CD1-like endothelial receptor with a phospholipid embedded in its hydrophobic groove that is required for (A)PC binding. According to the current paradigm, cytokine-induced EPCR shedding is responsible for EPCR inactivation on cells. However, upon incubation of EA.hy926 endothelial cells or blood outgrowth endothelial cells (BOECs) with TNFα, a disproportional loss of APC binding compared to EPCR surface expression was observed, inconsistent with EPCR shedding. Using a novel on-cell Western approach, we found that TNFα decreased EPCR-dependent APC binding on EA.hy926 cells to 25% of normal, whereas surface EPCR remained unchanged. In contrast, induction of EPCR shedding with PMA decreased APC binding and released abundant soluble (s)EPCR, which was not observed with TNFα. Accordingly, inhibition of EPCR shedding prevented PMA but not TNFα-induced loss of APC binding to cells. Thus, shedding was not responsible for loss of EPCR-dependent APC binding induced by TNFα on endothelial cells. Another proposed mechanism for EPCR inactivation involved cleavage of the fatty-acid chain at the sn-2 position of the lipid embedded in the hydrophobic groove of EPCR by phospholipase A_2 (PLA_2). However, inhibitors of PLA_2 did not restore loss of APC binding to cells induced by TNFα. In contrast, inhibitors of PLA_2 did block the loss of EPCR-dependent APC binding to endothelial cells induced by serum derived from TNFα-incubated whole blood. Thus, lipid editing by PLA_2 is important for EPCR inactivation on cells but was not involved in TNFα-induced loss of APC binding to endothelial cells. No *N*- or *C*-terminal proteolysis of EPCR in cells treated with TNFα was observed. However, APC binding to purified EPCR derived from TNFα-treated EA.hy926 cells was defective, whereas EPCR purified from non-treated cells showed normal APC binding. Next, two distinct nodes involved in TNFα signaling, NFκB and p38 MAPK were targeted. Interestingly, inhibition of NFκB completely normalized APC binding to TNFα-treated cells while inhibition of p38 had no effect. Insights gleaned from lipid editing in CD1 molecules suggest the involvement of clathrin-mediated mechanisms. An inhibitor of clathrin-mediated transport prevented TNFα-induced EPCR encryption but not NFκB-dependent ICAM1 expression induced by TNFα, indicating that the inhibitor did not interfere with general NFκB-dependent TNFα signaling. In contrast, an inhibitor of dynamin-mediated transport prevented both TNFα-induced EPCR encryption and ICAM1 expression. Remarkably, neither inhibitors inhibited TNFα-induced EPCR internalization, suggesting that the clathrin inhibitor may have affected endocytic sorting pathways rather than internalization of EPCR.

In summary, our results conceptualize a novel EPCR encryption mechanism that is responsible for TNFα-induced loss of EPCR-dependent binding of APC to endothelial cells. The EPCR encryption mechanism seemed partially homologous to lipid editing in CD1 molecules, and involved NFκB and clathrin-mediated effects. Insight into the molecular mechanisms for EPCR encryption may help to protect EPCR function on cells, improve efficacy of EPCR-dependent cytoprotective effects on cells and prevent inflammation-induced cellular APC resistance.

AS 42 – Diagnosis of Deep Vein Thrombosis and Pulmonary Embolism

AS 42.1

Age-adjusted D-Dimer for venous thromboembolism exclusion in the elderly: a systematic review and meta-analysis

Le Gal G[1], Carrier M[1], Keeling D[2], Penaloza A[3], Douma RA[4] and Righini M[5]

[1]*Ottawa Health Research Institute, Ottawa, ON, Canada;* [2]*Oxford Haemophilia and Thrombosis Centre, Churchill Hospital, Oxford, UK;* [3]*Cliniques Universitaires Saint Luc, Université Catholique de Louvain, Brussels, Belgium;* [4]*Amsterdam Medical Center, Amsterdam, the Netherlands;* [5]*Geneva University Hospital, Geneva, Switzerland*

Background: In combination with clinical probability assessment, a negative D-Dimer test allows to safely rule out the diagnosis of venous thromboembolism (VTE) in approximately one-third of patients, without any imaging test. D-Dimer levels increase with age. As a result, the proportion of patients in whom VTE could be ruled out on the basis of negative D-Dimer decreases with age. After 80 years of age, only 5% of patients will benefit from D-Dimer test. Recently, an age-adjusted cut-off was derived (age-adjusted cut-off = patient's age × 10, in μg/L), that might rule out VTE in a higher proportion than the conventional 500 μg/L cut-off without compromising diagnostic exclusion safety. Several retrospective external validation studies were published, but the limited number of patients included in these studies didn't allow to draw firm conclusions.

Aims: To assess the usefulness and safety of the age-adjusted cut-off for VTE exclusion in elderly patients.

Methods: A systematic literature search was conducted to identify potential studies on Medline and Embase, as well as on proceedings of recent American Society of Hematology and International Society of Thrombosis and Hemostasis meetings. From each retrieved study, we extracted the total number of patients, the number of patients with a low/intermediate or unlikely clinical probability of DVT or PE, the number of patients with negative D-Dimer test using the conventional and the age-adjusted cut-off, respectively, and the number of false-negative tests. We computed the pool proportions and 95% confidence intervals using inverse variance-weighted proportions, with a focus on the proportion of false-negative patients in those with a D-Dimer level above the conventional but below the age-adjusted cut-off. Subgroup analyses were performed on patients aged > 80 years.

Results: We identified 12 studies, gathering 22 537 patients with suspected VTE. Overall, 40% (95% CI 34–46%) of low/intermediate or unlikely probability of VTE had a negative D-Dimer at the conventional cut-off, with a false-negative rate of 0.5% (0.2–0.9%). Using the age-adjusted cut-off, 45% (39–51%) would have had a negative D-Dimer, with a false-negative rate of 0.7% (0.4–1.19%). Among the 1399 patients aged > 80 years, only 13% (9–18%) had a negative D-Dimer at the conventional cut-off, but this proportion increased to 33% (26–40%) when using the age-adjusted cut-off. The false-negative rates for the conventional and the age-adjusted cut-off were 0.3% (0.1–0.6%) and 2.3% (1.1–4.1%), respectively. The false-negative rate among the 240 patients aged > 80 years with a D-Dimer level > 500 μg/L but below their age-adjusted cut-off was 3.3% (95% CI 1.5–5.9%).

Summary/Conclusions: Age-adjusted cut-off allows to significantly increase the proportion of elderly patients in whom VTE could be excluded on the basis of D-Dimer test in combination with clinical probability assessment. However, the false-negative rate appears to be higher and might raise concerns about the safety of this strategy in elderly patients. The results of an ongoing prospective management outcome study are needed to formally assess the safety of the age-adjusted D-Dimer cut-off.

AS 42.2

Safety and feasibility of a diagnostic algorithm combining clinical probability, D-dimer and ultrasonography in suspected upper extremity deep vein thrombosis: a prospective management study

Kleinjan A[1], Di Nisio M[2], Beyer-Westendorf J[3], Cosmi B[4], Camporese G[5], Ghirarduzzi A[6], Kamphuisen PW[7], Otten HM[8], Porreca E[2] and Büller HR[1]

[1]*Academic Medical Center, Amsterdam, the Netherlands;* [2]*G.D'Annunzio University, Chieti, Italy;* [3]*University Hospital Dresden, Dresden, Germany;* [4]*University Hospital Bologna, Bologna;* [5]*University Hospital of Padova, Padova;* [6]*Hospital Santa Maria Nuova, Reggio Emilia, Italy;* [7]*University Medical Center Groningen, Groningen;* [8]*Slotervaart Hospital, Amsterdam, the Netherlands*

Background: Traditionally, the focus of the diagnosis of venous thromboembolism (VTE) is on deep vein thrombosis (DVT) of the leg and pulmonary embolism. Until recently, upper extremity DVT (UEDVT) was regarded as an uncommon presentation of VTE; however, the more widespread use of central venous catheters has caused a significant increase in its incidence. Therefore, effective and safe diagnostic strategies are needed.

Aims: This diagnostic management study assessed the safety and feasibility of a new diagnostic algorithm in patients with clinically suspected UEDVT.

Methods: In- and outpatients with suspected UEDVT were recruited from January 2010 until July 2012 in 16 hospitals in Europe and the United States, after approval of the protocol by the institutional review boards. Main exclusion criteria were previous UEDVT and the use of therapeutic doses of anticoagulants. Informed consent was obtained from all participants. The algorithm consisted of the sequential application of the Constans' clinical decision score[1] (score), D-dimer testing and compression ultrasonography. Patients were first categorized as UEDVT likely or unlikely by the score. In patients with an unlikely score and a normal D-dimer, UEDVT was considered excluded and no further testing was done. All other patients underwent ultrasonography, which first assessed the presence of UEDVT and then superficial vein thrombosis (SVT). The primary outcome was the 3-month incidence of symptomatic UEDVT and pulmonary embolism in patients with a diagnostic work-up excluding both UEDVT and SVT. To confirm an acceptable failure rate of excluding UEDVT (upper 95% confidence interval below 3%), approximately 400 patients needed to be included.

Results: The study population comprised of 406 consecutive patients with suspected UEDVT. The algorithm was feasible and could be completed in 96%. Of the 406 patients, 203 had an unlikely probability score and D-dimer was measured, except in three cases. In 87 patients (22%) an unlikely score was combined with a normal D-dimer, and therefore UEDVT was excluded. All these patients had an uneventful 3 month follow up. The remaining 113 patients with an unlikely and 203 patients with a likely probability score underwent ultrasonography. Ultrasonography was repeated if indicated according to protocol; seven times (1.7%) because of an indeterminate ultrasonography result and in 45 of the 51 patients (13%) with the combination of a likely score, abnormal D-dimer and normal ultrasonography. To summarize, of the 406 included patients, 103 patients had UEDVT (25%), 55 had SVT (14%) and in 249 patients the algorithm excluded UEDVT and SVT. Of these, one patient developed UEDVT during follow-up, hence, an overall failure rate of 0.40% (95% CI: 0.0–2.2%).

Summary/Conclusions: A new diagnostic algorithm which combines a clinical decision score, D-dimer and ultrasonography can safely and effectively exclude venous thrombosis of the upper extremity. This approach is attractive as it is simple, quick and non-invasive, and very similar to the well established algorithm for suspected DVT of the leg which could facilitate its implementation in clinical practice.

AS 42.3

Combined pretest probability assessment for acute coronary syndrome and pulmonary embolism in emergency department patients with chest pain and shortness of breath

Kline JA[1], Shapiro N[2], Jones AE[3], Hernandez J[4], Hogg M[4] and Troyer JI[5]

[1]Indiana University, Indianapolis, IN, USA; [2]Harvard School of Medicine, Boston, MA, USA; [3]University of Mississippi, Jackson, MI, USA; [4]Carolinas Medical Center; [5]University of North Carolina, Charlotte, NC, USA

Background: In the United States, large registries show that most emergency department patients with chest pain and shortness of breath undergo at least one diagnostic test for both acute coronary syndrome (ACS) and pulmonary embolism (PE). Most of these patients have neither PE nor ACS. We hypothesize that quantitative pretest probability (PTP) can reduce unnecessary cost and radiation exposure in emergency department (ED) patients with symptoms of acute coronary syndrome (ACS) and pulmonary embolism (PE). In this study, we examine the scope of the problem and potential role for quantitative pretest probability to reduce testing and radiation exposure.

Methods: Study design was a prospective, four center, non-interventional study of diagnostic accuracy. Patients were adults with non-diagnostic electrocardiograms and no obvious diagnosis. The clinician in charge of care provided inputs into a web-based computer program that provides quantitative pretest probability estimates for both ACS and PE using the method of attribute matching. Patients were followed for 90 days. The sample size was estimated with the assumption that 25% of patients would have PTP estimates for both ACS and PE below the predefined test threshold (< 2.5% for both), and that the outcome rate of ACS and PE would be at or near zero in this very low risk group, and that $n = 850$ would narrow the top limit 95% CI for the actual outcome rate of ACS or PE to < 2%.

Results: We enrolled 851 patients and excluded 11 because of screen failures. 840 patients had complete data. 23/840 (3%) had ACS and 15 (2%) had PE and 60 (7%) had another significant cardiopulmonary diagnosis within 90 days. Diagnosis was delayed in four patients with ACS and one with PE and all five had PTPs > 2.5%. Both the ACS and PE PTP estimates were below the predefined test threshold of 2.5% in 227 patients (27%, 95% CI 24–30%). None of these 227 very low risk patients had ACS or PE diagnosed within 90 days (0%, 0–1.6%) Of these with very low PTPs, 7 (3%, 1.5–6.2%) had another serious cardiopulmonary diagnosis, including four with pneumonia, two with pneumothorax, one with heart failure and none with aortic dissection. Only the patient with heart failure had a delay in diagnosis. The median chest radiation exposure per patient in the very low risk group was 0.06 mSv (1st–3rd quartiles 0.06–1.53) including 46 (21%, 95% CI: 16–26%) receiving > 5 mSv radiation to the chest as part of their evaluation which yielded no significant diagnosis. The median cost of care in this very low risk group was $653/patient ($454-$1863, $US).

Conclusion: These data show the safety and large opportunity for combined quantitative PTP for ACS and PE to reduce unnecessary testing and radiation exposure in ED patients with chest pain and shortness of breath.

AS 42.4

Validity of the primary care rule for risk stratification in patients with suspected DVT in auckland new zealand

Hyder SJ[1], Ockelford PA[2], Tagelagi M[3], Jackson SR[4] and Young LK[2]

[1]Primary Options for Acute Care; [2]Auckland City Hospital; [3]Health New Lynn; [4]Counties Manukau, Auckland, New Zealand

Background: The majority of patients who present with symptoms of deep vein thrombosis (DVT) do not have the disease. Clinical decision rules aim to identify those who require diagnostic ultrasound while safely excluding those who do not. The "Wells Rule"has been widely validated in the secondary care setting however its performance in primary care appears to be less accurate. The Primary Care Rule was reported in the Netherlands to be safe and accurate in the general practice environment. The rule includes points based on clinical risk factors and a whole blood (WB) point of care (POC) D-dimer which reduces the waiting time for test results and contributes significantly to the clinical probability score.

Aims: To validate the Primary Care Rule in Auckland, New Zealand using the same POC D-dimer (*Clearview Simplify*) and reduce unnecessary community ultrasonography through use of a decision rule.

Methods: A prospective study of consecutive patients with suspected DVT presenting to one of 100 primary care medical centres within the Auckland metro region (Pathway group). Each patient was assessed using the primary care rule incorporating POC WB D-dimer and followed up at 3 months. Staff received training in the POC methodology. Subsequently a separate comparative analysis of the POC D-dimer was undertaken in 200 consecutive patients in whom risk scores were initially evaluated using a laboratory quantitative D-dimer (Innovance) to compare the performance of the POC D-Dimer when undertaken by laboratory staff. Where required, whole leg ultrasonography (USS) was used to confirm or exclude DVT in both groups.

Results: Pathway group: DVT was identified in 17% (5/29) of the POC D-dimer negative (low risk) group. Sensitivity was 0.61 (95% confidence interval (CI) 0.32–0.84), specificity was 0.27 (CI: 0.18–0.37). Negative Predictive Value (NPV) was 0.82. DVT was confirmed in 11% (8/72) of the POC D-dimer positive (high risk) group. All five of the DVTs in the low risk group were identified early in the 3 month follow up period due to ongoing clinical suspicion.

Comparative analysis: There were concerns over the Pathway performance so 200 subsequent patients were evaluated for possible DVT using the laboratory D-Dimer. Parallel POC D-dimers were negative in 132 of these patients and in this group DVT was confirmed (positive laboratory D-dimer and ultrasound) in 2% (3/132). For the POC D-dimer performed in the laboratory, sensitivity was 0.8 (CI 0.51–0.94), specificity 0.69 (CI: 0.62–0.7), NPV of 0.97. DVT was confirmed in 18% (12/68) with positive POC D-dimer.

Conclusions: The POC D-dimer performed to the manufacturers' specifications when tested by experienced laboratory staff. Although training was given to clinical staff at each medical centre, sensitivity was poor in their hands and the Primary Care Rule did not adequately distinguish high and low risk patients. The pathway validation was stopped due to the high DVT incidence in patients stratified as low risk. The primary objective of reducing the number of USS was not met in the first 100 patients with adequate safety. The choice of clinical decision rule in primary care requires further study.

AS 43 – Non-Inherited Risk Factors for Venous Thrombosis

AS 43.1

Impaired glucose metabolism, assessed by HbA1c, and future risk of venous thromboembolism – The Tromsø study

Lerstad G[1], Brodin E[1], Enga KF[1], Brækkan SK[1], Jorde R[2], Njølstad I[3], Svartberg J[2] and Hansen JB[1]

[1]Hematological Research Group; [2]Endocrine Research Group; [3]Department of Community Medicine, University of Tromsø, Tromsø, Norway

Background: Experimental studies have suggested that hyperglycemia facilitate thrombosis development, but previous cohort studies on the impact of diabetes mellitus (DM) on risk of venous thromboembolism (VTE) have reported diverging results. Glycated hemoglobin (HbA1c), a marker of average plasma glucose during the last 8–12 weeks, is associated with future risk of cardiovascular disease (CVD) and all-cause mortality. However, no study has so far investigated the impact of HbA1c on risk of VTE.

Aims: The purpose of the present study was to examine the association between impaired glucose metabolism, assessed by HbA1c, and future risk of VTE in a prospective cohort recruited from a general population.

Methods: HbA1c was measured in 16 156 unique subjects, aged 25–87 years, who participated in one or more surveys of the Tromsø study, starting in 1994–95 (Tromsø 4; 1994–95, Tromsø 5; 2001–2, and Tromsø 6; 2007–8). Incident events of VTE were recorded to the end of follow-up, December 31, 2010. Cox's proportional hazard regression models were used to estimate crude and multivariable-adjusted hazard ratios with 95% confidence intervals. The analyses were adjusted for age, sex, body mass index, smoking, physical activity and CVD. HbA1c was analyzed in predefined categories (< 5.7%; normal, 5.7–6.4%; impaired glucose metabolism (IGM), and ≥ 6.5%; DM) and as a continuous variable. Moreover, to minimize regression dilution effects, Cox-regression was performed in subjects with at least two recordings of HbA1c during follow-up, allowing for time-dependency of the exposure variable and important co-variates. The study was approved by the regional committee for research ethics, and all participants gave their informed written consent to participate.

Results: There were 333 validated first VTE events (2.91 per 1000 person years), of which 137 were unprovoked, during a mean of 7.1 years of follow-up. HbA1c was not associated with future risk of VTE in analysis treating HbA1c as a continuous variable, or in categorized analyses. The risk of VTE increased by 5% per 1 SD (0.7%) increase in HbA1c (Multivariable-adjusted HR 1.05; 95% CI 0.97–1.14), and subjects with HbA1c ≥ 6.5% had 27% increased risk compared to those with HbA1c below 5.7% (Multivariable-adjusted HR 1.27; 95% CI 0.72–2.26). There was no significant trend for increased risk of VTE across categories of HbA1c ($P = 0.27$). Only minor changes in risk estimates were observed in time-dependent analyses.

Conclusion: In our study, levels of HbA1c were not associated with future risk of VTE in multivariable analysis. Our findings suggest that impaired glucose metabolism does not play an important role in the pathogenesis of VTE.

AS 43.2

Insulin resistance is not independently associated with unprovoked venous thromboembolism: results from the EDITH case-control study

Delluc A[1], Kerspern H[2], Le Moigne E[3], Tromeur C[4], Mottier D[5], Carré J-L[2], Le Gal G[5] and Lacut K[5]

[1]EA 3878 GETBO; [2]Department of Biochemistry and Pharmacology, CHU Brest, Hôpital Cavale Blanche; [3]Département de Médecine Interne et Pneumologie, CHRU Brest; [4]Université de Bretagne Occidentale; [5]Inserm, Brest, France

Background: Shared risk factors help explain the association between venous thromboembolism (VTE) and atherothrombosis. Insulin resistance is an independent risk factor for the development of metabolic syndrome and diabetes, and thus, leads to an increased risk of cardiovascular diseases. The homeostasis model assessment of insulin resistance (HOMA-IR) is an accurate and precise method to measure insulin resistance. To date, the potential association between insulin resistance and VTE has been poorly evaluated.

Aims: To assess the association between insulin resistance and VTE in the EDITH hospital-based case-control study.

Methods: Between May 2000 and December 2004, 677 patients with unprovoked VTE and their age and sex-matched controls were included. Fasting glycemia and insulinemia were measured and insulin resistance was estimated with the HOMA-IR equation (glucose [mM] × insulin [mUI/L]/22.5). Conditional logistic regression taking into account the matching factors was carried out to estimate odds ratios (OR) and 95% confidence intervals (CI) for VTE risk associated with HOMA-IR index in non-diabetic patients. The association between HOMA-IR and VTE was determined in a quintile-based analysis.

The protocol was approved by our hospital's Ethics Committee. After complete description of the study to the subjects, written informed consent was obtained from all patients.

Results: A total of 590 non-diabetic cases (median age 73.0 years, 255 men) and 581 non-diabetic controls (median age 72.0 years, 247 men) were analyzed. There was a trend for a higher median level of HOMA-IR index in cases than in controls (1.21 [interquartile range 0.84–2.10] vs. 1.19 [interquartile range 0.72–2.02], $P = 0.08$). The unadjusted analysis showed an increased risk of unprovoked VTE associated with increasing HOMA-IR (OR 1.53; 95% CI 1.00–2.34 for the highest quintile of HOMA-IR compared with the first quintile). Body mass index and fibrates use were also associated with unprovoked VTE in the unadjusted analysis (OR 1.07; 95% CI 1.05–1.10 per each standard deviation increase and OR 2.08; 95% CI 1.34–3.23 respectively), whereas aspirin use was associated with a decreased risk of VTE (OR 0.58; 95% CI 0.42–0.80), and statins use with a non-significant decreased risk of VTE (OR 0.72; 95% 95% CI 0.47–1.08). Adjustment for lipid lowering drugs and antiplatelets agents use (potential markers of insulin resistance) slightly modified the association between increasing HOMA-IR and VTE (OR 1.51; 95% CI 0.97–2.34 for the highest quintile of HOMA-IR compared with the first quintile). When body mass index was added in the adjusted model, HOMA-IR was no longer associated with VTE (OR 1.08; 95% CI 0.67–1.73 for the highest quintile of HOMA-IR compared with the first quintile).

Conclusions: Our study showed that insulin resistance assessed by the HOMA-IR index was not an independent risk factor for VTE. Our results highlight the key role of body mass index in the association between traditional cardiovascular risk factors and VTE. Changing lifestyle in order to lose weight is likely to be beneficial for overweight and obese patients after a VTE event.

AS 43.3

Lower leg cast immobilisation and risk of venous thrombosis: results from the MEGA study

Van Adrichem RA, Debeij J, Nelissen GHH, Schipper IB, Rosendaal FR and Cannegieter SC

Leiden University Medical Center, Leiden, the Netherlands

Background: Guidelines and clinical practice vary considerably with respect to antithrombotic treatment during plaster cast immobilisation of the lower leg. Due to the heterogeneity of the evidence on the risk of venous thrombosis (VT) in patients with lower leg cast immobilisation, the exact risk remains unclear and it is uncertain whether the benefits of thromboprophylaxis outweigh the risks.

***Aims*:** To estimate the risk of venous thrombosis after cast immobilisation of the lower leg and to identify high risk groups by taking genetic and other acquired risk factors as well as the indication for immobilisation into account.

Methods: We used data from a large population based case-control study (MEGA-study) into the aetiology of venous thrombosis (4420 cases, 6151 controls, consent and ethical approval obtained). Odds ratios (OR) with 95% confidence intervals (CI95) were calculated as a measure of the relative risk and adjusted for age, sex, body mass index and regular exercise. We used varying exposure time risk windows for reasons of statistical precision. Analyses of joint effect all have those with none of the risk factors in the analysis as reference group. Absolute risks were estimated from the ORs, assuming an incidence of VT of 1–2 per 1000 person-years in the general population.

Results: Patients with cast immobilisation of the lower leg (134 cases, 23 controls) had an eight-fold increased risk of venous thrombosis in the subsequent year (OR 8.3 [CI95; 5.3–12.9]). Most thromboses were seen in the first 3 months after cast application, leading to a 56-fold increased risk (OR 56.3 [CI95; 17.9–177]) in this period. This corresponds to an incidence of VT of 1.4–2.8% over 3 months. Considering events during 1 year after cast application showed that traumatic indications (fractures, tendon and ligament ruptures and contusions) led to a higher risk of VT (OR 12.7 [CI95; 6.6–24.6]) than non-traumatic indications (overuse injuries, plantar fasciitis and joint complaints): OR 7.6 (CI95; 0.9–66.4). An even more pronounced risk was found for the combination of genetic and other acquired risk factors. The combination of a lower leg plaster cast and oral contraception use led to an OR of 18.2 (CI95; 6.2–53.4); with obesity (BMI > 30 kg/m^2) to an OR of 17.2 (CI95; 5.4–55.2); with carriership of the factor V Leiden mutation, prothrombin G20210A mutation or a non-O blood type to an OR of 23.0 (CI95; 11.5–46.0) (all during the 1 year following the cast application). No information was available on thromboprophylaxis, while a proportion of the patients most likely did receive this. However, this implies that our estimate most likely represents an underestimation of the true risk.

Conclusion: Cast immobilisation of the lower leg is associated with a high risk of venous thrombosis, particularly in the first 3 months after application. Patients with lower leg cast immobilisation in combination with well known genetic and other acquired risk factors are high-risk groups. Prophylactic treatment can be individualised and optimised when the indication of cast immobilisation and the presence of genetic and other acquired risk factors are taken into account.

AS 43.4

Acute infection, immobility and venous thromboembolism: an analysis from the RIETE Registry

Frasson S[1], Gussoni G[2], Di Micco P[3], La Regina M[4], Bascuñana J[5], Peris ML[6], Villalobos A[7], Merah A[8], Monreal M[9] and the F[10]

[1]Fondazione Fadoi, Milano; [2] Research Department, FADOI Foundation, Milan, Italy; [3]Hospital Fatebenefratelli, Naples; [4]Hospital Spezzino, La Spezia, Italy; [5]Hospital Infanta Leonor, Madrid; [6]Consorcio Hospitalario Provincial de Castellón, Castellón de la Plana, Valencia; [7]Hospital General Universitario Carlos Haya, Málaga, Spain; [8]Hôpital Nord – CHU St-Etienne, Saint-Etienne, France; [9]Germans Trias I Pujol Hospital, Badalona; [10]RIETE Investigators, Madrid, Spain

Background: The strong association between immobility and venous thromboembolism (VTE) is well established. Acute infection and sepsis are frequent cause of immobility, and several risk assessment models include them among the items to be considered for VTE prevention. However available real-world evidence for an association among acute infection, immobility and VTE is limited, as well as detailed information on the role of specific types of infection.

Aims: Aim of the present analysis was to evaluate clinical characteristics of VTE patients with acute infection leading to immobility, in general and according to type of infection.

Methods: The RIETE registry is an ongoing, worldwide, prospective cohort of consecutive patients presenting with symptomatic deep vein thrombosis (DVT) or pulmonary embolism (PE) confirmed by objective tests, and followed-up for at least 3 months. Patients' characteristics were analyzed by means of the χ^2 test or the Student's t test as appropriate. A P value < 0.05 was considered to be statistically significant.

Results: The overall population of patients included in the RIETE registry at January 2013 (n = 44 898) was considered for this analysis. Acute infection leading to immobility was reported in 889 patients (2%), being isolated DVT diagnosed in 47.8% and PE in 52.2% of patients. At 3-month follow-up, recurrent VTE occurred in 2.4% of patients, major bleeding in 2.7% and overall mortality in 15.0% (2.0% VTE-related). Among different types of infection, pneumonia was present in 23.1%, other respiratory infections in 29.1%, urinary tract infections in 10.7%, and sepsis in 5.2% of cases. Patients with respiratory infections/pneumonia had more frequently PE as initial presentation of VTE if compared with other types of infection (61.6% vs. 41.9%, P < 0.001). By comparing patients with pneumonia and those with other respiratory infections, the latter had more frequent concomitant chronic lung disease (36% vs. 28%, P < 0.05), while no significant differences were noted neither for other risk factors (heart failure, cancer, previous VTE), nor for duration of immobility. Significantly more patients with pneumonia had received thromboprophylaxis prior to VTE (51.7%, vs. 30.5% in patients with other respiratory infections, P < 0.001).

Summary/Conclusions: Acute infection, the associated inflammation and their clinical consequences may increase the risk of VTE due to one or more of the precipitants proposed by Virchow, and namely venous stasis. Data from the very large RIETE registry allowed us to better characterize real-world patients with acute infection leading to immobility, and developing VTE. Respiratory infections accounted for the majority of cases, and they more frequently had PE at presentation. One potential strength of our study is that, being VTE events objectively confirmed, we avoided possible diagnostic misclassification of PE in case of respiratory infection. Of interest, patients with pneumonia had a high percentage of ineffective prophylaxis; future clinical trials might evaluate the opportunity of a more systematic and aggressive approach in these patients.

AS 44 – Inflammation and Coagulation Axis

AS 44.1

Akt2 plays a critical role in regulating alphaMbeta2 integrin function and heterotypic platelet-neutrophil interactions during vascular inflammation.

Cho J, Li J, Kim K, Hahm E, Du X and Hay N
University of Illinois College of Medicine, Chicago, IL, USA

Background: Heterotypic interaction of activated platelets and neutrophils on the activated endothelium plays an important role in mediating pathological thrombosis and inflammation. Heterotypic cell-cell aggregation results from the interaction of specific receptors-counter receptors which are well identified. However, the regulatory mechanisms of receptor interactions between platelets and neutrophils in thrombo-inflammatory disease remain unknown.
Aims: To investigate the role of Akt in regulating heterotypic neutrophil-platelet aggregation in vascular inflammation.
Methods and results: Using real-time intravital microscopy of Akt knockout (KO) mice, we have demonstrated that Akt2, but not Akt1 and Akt3, plays a critical role in neutrophil adhesion to the activated endothelium during TNF-alpha-induced vascular inflammation. Further, heterotypic platelet-neutrophil interaction on the activated endothelium was markedly inhibited in Akt2 KO mice. Studies with chimeric mice generated from bone marrow transplants on wild-type (WT) and Akt2 KO mice revealed that hematopoietic cell but not endothelial cell Akt2 regulates neutrophil adhesion and platelet-neutrophil interaction during vascular inflammation. Using *in vitro* reconstituted systems in which platelets and/or neutrophils were treated with an Akt2 specific inhibitor or both cells were isolated from WT and Akt KO mice, we observed that both platelet and neutrophil Akt2 play a central role in platelet-neutrophil aggregation under shear conditions. Akt1, Akt2, or Akt3 KO platelets showed a partial defect of P-selectin exposure by 30–40% of WT platelets during thrombin activation, whereas surface expression of P-selectin glycoprotein ligand-1 – a counter receptor for P-selectin – was similar on WT and Akt KO neutrophils. Notably, surface expression of alphaMbeta2 integrin is enhanced on WT and Akt1 KO but not Akt2 KO neutrophils upon fMLF stimulation. Consistently, human neutrophils pre-treated with an Akt2 specific inhibitor significantly reduced cell adhesion to surfaces coated with fibrinogen or intercellular adhesion molecule-1 (ICAM-1) and diminished activation of alphaMbeta2 integrin – a key receptor for stable interaction of neutrophils with platelets and endothelial cells. Further, neutrophils lacking Akt2 exhibited decreased adhesion to ICAM-1, and the adhesion was further inhibited by a combination with a blocking anti-beta2 but not anti-alphaM antibody, suggesting that Akt2 regulates alphaMbeta2 integrin-mediated neutrophil adhesion. We observed that compared to WT neutrophils, Akt2 KO neutrophils show decreased complex formation of SNARE proteins which are important for exocytosis-mediated alphaMbeta2 translocation during neutrophil activation.
Conclusion: These results indicate that neutrophil Akt2 is a key regulator for the membrane translocation, activation, and adhesiveness of alphaMbeta2 integrin, thereby orchestrating heterotypic platelet-neutrophil interaction in thrombo-inflammatory disease.

AS 44.2

Shedding of protease activated receptor 1 (PAR1) by *Streptococcus pyogenes* pyrogenic exotoxin B (SpeB) – a novel mechanism to evade host immune system

Schuepbach RA, Ender M, Andreoni F, Tarnutzer A and Zinkernagel AS
University Hospital Zurich, Zurich, Switzerland

Background: Protease activated receptor (PAR)-1 allows cells to sense proteolytic activity and mediates pleiotropic actions affecting coagulation/hemostasis endothelial barrier function and inflammation. Few bacterial proteases have been shown to blunt PAR1 signaling through *N*-terminal shedding. *Streptococcus pyogenes*, a major human pathogen leading to superficial and life threatening infections such as necrotizing fasciitis and streptococcal toxic shock toxin syndrome, expresses a multitude of virulence factors including efficient proteases. We hypothesized that streptococcal proteases cleave PAR1 and contribute to *streptococcal* virulence.
Aims: We analyzed whether streptococcal proteases cleave PAR, what the neo *N*-termini generated are and whether cleavage of PAR1 by streptococcal protease causes biological effects.
Methods: *S. pyogenes* M1T1was grown overnight in mammalian tissue culture medium and diluted supernatant were incubated with endothelial cells natively expressing PAR1. *Streptococcal* proteases were identified by zymography, protease deficient mutant strains and recombinant *streptococcal* proteases served as controls. Removal of *N*-terminal PAR1 antigen on natively expressing EA.hy926 endothelial cells was quantified using anti-PAR1 recognizing epitopes around R41, R 46 and D53 by cell surface ELISA. Alkaline phosphatase tagged PAR1 cleavage reporter constructs carrying mutants and deletions were transiently overexpressed in 293T embryonic kidney cells to localize cleavage sites. Complementary, soluble peptides corresponding to PAR1's *N*-terminus were incubated with streptococcal proteases and cleavage products were identified by *N*-terminal sequencing. To test how streptococcal proteases affect endothelial cells, direct induction of ERK1/2 phosphorylation and desentization of thrombin mediated ERK1/2 induction was analyzed. As biological read out we tested whether streptococcal proteases modify platelet aggregation.
Results: In natively endothelial expressed PAR1 proteases of *streptococcal* supernatants removed *N*-terminal R41 and R46 but not D53 epitopes. Consistent with cleavage between R46 and D53 in overexpressed PAR1 reporter constructs carrying either alanine substitutes or deletions, the cleavage site could be mapped at or close to L44. *N*-terminal sequencing of a peptide corresponding to PAR1's *N*-terminus revealed a L44 cleavage product upon incubation with streptococcal supernatants. Reporter constructs of PAR2, 3 and 4 were not cleaved by streptococcal supernatants. Zymography and cysteine protease inhibitor E64 identify *streptococcal* pyrogenic exotoxin B (SpeB), a cysteine protease expressed in stationary growth phase, as candidate protease. This was further supported by low nanomolar concentrations of recombinant SpeB efficiently cleaving PAR1 at L44 and failure of SpeB deficient streptococcus in cleaving PAR1. SpeB via cleavage of PAR1 prevented thrombin mediated ERK 1/2 phosphorylation in endothelial cells and blunted platelet aggregation.
Conclusion: We provide novel evidence that PAR1 is a target of *streptococcal* SpeB, a major *streptotoccal* virulence factor. Cleavage at the novel L44 abolishes responsiveness of endothelial cells as well as aggregation of platelets which are important for bacterial entrapping and pathogen clearance.

AS 44.3

CXCL7 (platelet basic protein) and CXCL4 (platelet factor 4) contribute to the pathogenesis of acute lung injury

Kowalska MA[1], Bdeir K[2], Mei J[1], Stasiak M[3], Zhao G[1], Kenawy D[2], Cierniewski CS[4], Cines DB[2], Poncz M[1] and Kowalska MA[1]

[1]The Children's Hospital of Philadelphia; [2]University of Pennsylvania, Philadelphia, PA, USA; [3]Medical University of Lodz; [4]Department of Medical Biology, Polish Academy of Sciences, Lodz, Poland

Background: Acute lung injury (ALI) is characterized by abnormally enhanced coagulation, microvascular barrier dysfunction and tissue necrosis. Platelets are known as primary effector cells of hemostasis and thrombosis, but a growing body of evidence also supports an important role for platelets in inflammatory response, including leukocyte recruitment. Activated platelets release chemokines and other proteins stored in their alpha-granules, including its two most abundant proteins, CXCL4 and CXCL7. CXCL4 role in thrombosis, atherosclerosis and megakaryopoiesis, and in the pathogenesis of heparin-induced thrombocytopenia has been well established in part due to studies using mouse (m) CXCL4 knockout (mCXCL4-KO) and mice overexpressing human (h) CXCL4 specifically in platelets ($hCXCL4^+$). CXCL7 belongs to the same family of chemokines as CXCL4, but has an *N*-terminal Glu-Leu-Arg (ELR) motif after *N*-terminal truncation to the 70 amino acid neutrophil activating peptide-2 (CXCL7-NAP-2). This ELR motif is key for CXCL7-NAP-2's binding to the chemokine receptor CXCR2, which mediates leukocyte (PMN) migration.
Aim: Since migration of PMNs into the lungs is a crucial element in lung injury, the aim of this study was to establish the role of platelet-released CXCL7 in acid-induced mouse model of ALI. We first determined if mouse (m) PBP can be processed to yield biologically active degradation product that bind CXCR2 and induces PMN chemotaxis and then studied over and under CXCL7-expressing mice in a model of lung injury. Similar studies were done for CXCL4.
Methods: Purified recombinant (r) mPBP and mNAP-2 was cleaved by cathepsin G and products were evaluated by mass spectrometry and Western blot. Created by us, CXCL7 knockout (mCXCL7-KO) and overexpressing human (h) CXCL7 specifically in platelets ($hCXCL7^+$) mice were used in a mouse model of severe lung injury and evaluated by *ALI score*, presence of neutrophils and protein in bronchoalveolar lavage fluid (BALF), and vascular permeability measured by extravasation of FITC-dextran from systemic circulation into the lung.
Results: We examined full-length recombinant mPBP and native mPBP released from mouse platelets and found that both are *N*-terminally processed by cathepsin G to yield a biologically active mNAP-2 version that like its human counterpart, increased PMN chemotaxis.
We found that mCXCL7-KO mice are protected from severe lung injury. In contrast, $hCXCL7^+$/mCXCL7-KO mice develop lung injury comparable to WT animals. We have also found that $hCXCL4^+$ mice had more severe injury as compared to mCXCL4-deficient mice.
Summary/Conclusions: Both platelet-released CXCL7 and CXCL4 contribute to ALI severity. As CXCL4 is not a ligand for CXCR2, the mechanism of CXCL4 effect may be different, possibly involving lipoprotein receptor-related protein-1, which has been implicated to help maintain the integrity of the capillary-alveolar barrier. These studies show a clear mechanism by which platelets may influence the degree of ALI and provide important new insights into the pathogenesis of ALI. They may also lead to novel therapeutic strategies to modify the severity of this challenging disorder.

AS 44.4

The P2X1 receptor plays a key role in LPS-induced lethal endotoxemia

Hechler B[1], Maitre B[1], Magnenat S[1], Heim V[1], Ravanat C[1], Evans RJ[2] and Gachet C[1]

[1]UMR_S949, Inserm, Université de Strasbourg, EFS-Alsace, Strasbourg, France; [2]University of Leicester, Leicester, UK

Background: The $P2X_1$ receptor, an ATP-gated cation channel, is expressed in platelets and in cells of the immune system (neutrophils, macrophages) which all contribute to acute systemic inflammation. The $P2X_1$ receptor has been reported to play a role in neutrophils migration.
Aims: Our aim was to evaluate the role of the $P2X_1$ receptor in LPS-induced lethal endotoxemia.
Methods: Wild-type (WT) mice and mice deficient for the $P2X_1$ receptor ($P2X_1^{-/-}$ mice) were studied in an experimental model of lethal endotoxemia, induced by intraperitoneal injection of lipopolysaccharide (LPS, 10 mg/kg). Mortality was recorded over 5 days. Blood samples were collected to measure cytokines production and lung histology was examined. The migration capacity of neutrophils was evaluated in the dorsal air pouch mouse model of inflammation.
Results: Within 5 days after LPS injection, 70% of WT mice died whereas only 15% of $P2X_1^{-/-}$ mice died (***$P = 0.0003$, $n = 20$). Histopathologic alterations associated with endotoxemia, such as lung injury with alveolar wall thickening and airspace collapse, were much less pronounced in $P2X_1^{-/-}$ mice as compared to WT mice. Neutrophil accumulation into the lung, assessed by immunostaining of lung sections with an anti-neutrophil antibody, was reduced in $P2X_1^{-/-}$ mice ($429 \times 10^3 \pm 41 \times 10^3$ pixels) as compared to WT mice ($660 \times 10^3 \pm 57 \times 10^3$ pixels, **$P = 0.0017$), indicating reduced inflammation. Inflammatory cytokines (TNFα, IL6) and chemokines (MIP1α, MIP1β, RANTES) reached significantly lower levels in the plasma of LPS-challenged $P2X_1^{-/-}$ mice as compared to the WT. In addition, the neutrophil recruitment was significantly reduced in the dorsal skin air pouch of LPS injected $P2X_1^{-/-}$ mice as compared to the WT, confirming *in vivo* the role of the $P2X_1$ receptor in neutrophil migration. As endotoxemia is accompanied by intravascular coagulation, thrombin-antithrombin (TAT) complexes were measured and found to reach lower levels in LPS-challenged $P2X_1^{-/-}$ mice (29.4 ± 3.2 ng/mL) as compared to WT mice (57.9 ± 5.2 ng/mL, $n = 5$, **$P = 0.0016$). Accordingly, platelet sequestration in the lung microvasculature, as evaluated by immunostaining of lung sections with an anti-platelet antibody, was reduced in $P2X_1^{-/-}$ mice ($125 \times 10^3 \pm 25 \times 10^3$ pixels) as compared to WT mice ($292 \times 10^3 \pm 33 \times 10^3$ pixels, ***$P = 0.0002$).
Conclusion: Our data indicate an important role for the $P2X_1$ receptor in LPS-induced lethal endotoxemia through a major contribution of migrating neutrophils. The respective contributions of the other blood cells or tissues which express the $P2X_1$ receptor remain to be delineated. In any case, selective antagonists of the $P2X_1$ receptor might be promising pharmacological means to limit the damages caused by acute systemic endotoxemia.

AS 45 – Innovative Treatments of Haemophilia A and B

AS 45

Alternative strategies for haemophilia treatment

Mast A

Blood Center of Wisconsin, Milwaukee, WI, USA

Current therapy for hemophilia A and B is replacement of the missing coagulation factor VIII (fVIII) or IX (fIX). This requires i.v. infusions several times per week to prevent spontaneous bleeding in patients with severe disease and carries risk for development of inhibitory anti-

bodies that block activity of the transfused clotting factor. Alternative non-i.v. therapies administered less frequently would be of great benefit for patients, many of whom are very young. One strategy that has shown promise in several animal models is to block the function of Tissue Factor Pathway Inhibitor (TFPI), an anticoagulant protein present within plasma and platelets and on the endothelium surface. TFPI exerts anticoagulant activity by inhibiting tissue factor/fVIIa (TF-fVIIa) and fXa. Under physiological conditions TFPI "forces"TF-initiated coagulation to proceed through activation of fIX. Therapeutically blocking TFPI inhibitory activity, or "inhibiting the inhibitor", allows for TF-initiated coagulation to proceed directly through activation of fX, bypassing the need for fVIII or fIX. TFPI is a multivalent Kunitz-type serine protease inhibitor with two primary alternatively spliced isoforms, TFPIα and TFPIβ. These isoforms both inhibit TF-fVIIa and fXa but differ in their *C*-terminal domains, where TFPIα has a third Kunitz domain and basic *C*-terminal region; and TFPIβ has a stretch of amino acids encoding a GPI-anchor attachment site. Thus, TFPIα is a soluble protein and TFPIβ is bound to the cell surface. Several recent advances defining the cellular expression and potentially unique functional activities of TFPIα and TFPIβ are important for understanding how pharmaceuticals targeted to different regions of TFPI may alter hemostasis in hemophilia patients. A key finding is that TFPIα and TFPIβ are distinctly expressed within the vasculature. TFPIα is the only isoform within platelets. TFPIα and TFPIβ are made by endothelial cells, but have distinct cellular expression with TFPIβ on the cell surface and TFPIα within an intracellular granule. Their distinct expression patterns suggest that TFPIα and TFPIβ have unique anticoagulant functions, which we have sought to define using cellular and murine model systems. Our current working hypotheses are that TFPIβ serves primarily to dampen the procoagulant potential of intravascular TF expressed in inflammatory conditions, while TFPIα released from platelets at the site of vascular injury actively regulates clot development and hemostasis. In this regard, mice lacking hematopoietic TFPI, which is primarily within platelets, have increased intravascular thrombus volume following large vessel injury. Interestingly, this is due to increased platelet accumulation within the clot rather than increased fibrin formation. Studies of fVIII deficient mice demonstrated that infusion of anti-TFPI antibody continued to decrease tail vein bleeding at concentrations beyond that necessary to totally inhibit plasma TFPI suggesting that platelet TFPIα released at the injury site promoted bleeding in this model. Consistent with notion, tail vein bleeding fVIII deficient mice lacking hematopoietic TFPI was significantly decreased compared to mice with hematopoietic TFPI, implicating platelet TFPIα as a primary physiological regulator of bleeding in hemophilia, which could be specifically targeted to restore hemostasis in hemophilia patients.

AS 45.1

A new class of coagulation factor VIII molecules that achieved four-fold longer half-life than recombinant FVIII in hemophilia A mice

Liu T[1], Seth Chhabra E[1], Kulman J[1], Zhu L[1], Patarroyo-White S[1], Drager D[1], Pape B[1], Moore N[1], Goodman A[1], Pierce GF[1], Schellenberger V[2], Mei B[1], Peters RT[1] and Jiang H[1]

[1]Biogen Idec Hemophilia, Waltham, MA; [2]Amunix, Mountain View, CA, USA

Background: The circulating half-life of coagulation factor VIII (FVIII) determines the frequency of injections required to maintain protective plasma levels of FVIII activity. Numerous approaches to extending half-life have been investigated, and molecules in late-stage development have achieved an approximately 1.6-fold half-life increase relative to currently marketed rFVIII. In order to achieve further improvement, the association between FVIII and von Willebrand factor (VWF) must be addressed. VWF couples the clearance rate of FVIII to its own due to the formation of a high affinity non-covalent complex between the two molecules in circulation. Engineering of FVIII molecules, disassociated with endogenous VWF, but containing elements sufficient to confer greater protection than that provided by VWF constitutes a promising strategy for further extending the half-life of FVIII molecules.

Aim: To increase the half-life of FVIII molecules by combining two approaches: 1) Fuse FVIII with the D'D3 region of VWF to preserve normal FVIII conformation but block its interaction with endogenous VWF; and 2) Insert XTEN at multiple locations within FVIII sequence to extend its circulating half-life.

Methods: The new class of FVIII molecules was designed to contain two polypeptides; one that consists of a single chain B-domain deleted (BDD) FVIII with XTEN inserted at one or more locations within the FVIII sequence, and one that is composed of the D'D3 region of VWF. Each polypeptide was also recombinantly fused to the Fc region of IgG1 to enable the D'D3 region to be correctly aligned to bind the FVIII moiety. The resulting FVIII variants were expressed in HEK 293 cells by transient transfection, and purified from the conditioned media. FVIII activity was evaluated by FVIII chromogenic assay and the pharmacokinetic properties were assessed in both FVIII knockout (HemA) and FVIII/VWF double knock-out (DKO) mice.

Results: Incorporating XTEN and D'D3 region of VWF into rFVIII led to the uncoupling of the clearance of the fusion proteins from endogenous VWF while extending their circulating half-life. FVIII in this fusion configuration is completely shielded from interacting with VWF, as measured by biolayer interferometry (Octet) analysis. Consistent with this, their pharmacokinetic profiles in HemA and DKO mice were found to be identical, indicating that their clearance rate in mice was effectively disconnected from VWF. Optimization of XTEN length and the locations for inserting XTEN identified a subset of the proteins that have exceeded the VWF limitation (16 h), reaching a circulating half-life of up to 30 h in HemA mice representing a four-fold improvement over BDD-FVIII. Importantly, these proteins maintained their functionality, as judged by FVIII chromogenic assay.

Conclusion: The VWF dependency has set a fundamental limitation for half-life of therapeutic FVIII. Uncoupling FVIII from VWF clearance pathways while extending half-life by the fusion of D'D3 region of VWF and XTEN has generated a novel FVIII molecule with a four-fold half-life extension. This is the first report of an engineered FVIII that has exceeded the half-life limitation observed through industry-wide efforts in development of long-lasting FVIII, representing a potentially significant advancement in prophylactic treatment of hemophilia A.

AS 45.2

IPSC-based strategy to correct the bleeding phenotype in haemophilia A

Talmon M[1], Ranaldo G[1], Grosso C[1], Cannizzo ES[1], Merlin S[1], Lombardo A[2], Raya A[3], Naldini L[2], Schinco P[4] and Follenzi A[1]

[1]University of Piemonte Orientale, Novara; [2]TIGET-HSR, Milan, Italy; [3]Institute for Bioengineering of Catalonia, Barcelona, Spain; [4]AO citta della Salute e della Scienza, Torino, Italy

Background: Hemophilia A (HA) is a X-linked bleeding disorder caused by mutations in the coagulation factor VIII (FVIII) gene. Existing therapy includes recombinant or plasma-derived FVIII infusion. Reprogramming of genetically corrected somatic cells can be used to generate high amount of autologous, disease-free induced Pluripotent Stem Cells (iPSCs), which can be differentiated into progenitor cells relevant for gene and cell therapy applications. In hemophilic patients, to harvest fibroblasts from skin biopsies is risky; thus, we utilized patient-derived peripheral blood cells as an easy-to-access source of cells to reprogram.

Aim: Development of a novel strategy for HA treatment, generating human B-domain-deleted FVIII (hBDD-FVIII)-corrected patient-specific iPSCs and differentiating them into functional endothelial cells (ECs), secreting FVIII in hemophilic mice after transplantation.

Methods: Mononuclear cells (MNC) were isolated from healthy and hemophilic donors by ficoll gradient. Cells were corrected by LV-hBDDFVIII transduction and reprogrammed with a cre-excisable polycistronic LV carrying OCT4, SOX2 and KLF4. MNC-derived iPSCs were characterized by Alkaline Phosphatase (AP), immunofluorescence stainings and RT-PCR of specific stem cell markers, telomers length and demethylation of Oct4 promoter. The IPSCs *in vitro* differentiation potential was analyzed by RT-PCR of three germ layers markers in embryoid bodies (EBs) and by adipogenic, osteogenic and condrogenic differentiation. IPSCs were differentiated in ECs using EB medium containing 50 ng/mL of hVEGF. Cells were evaluated for morphology, expression of endothelial markers and GFP-expression when transduced with LV carrying GFP under the control of endothelial-specific promoters: Flk-1 and Tie2. Two millions Flk1-GFP+ cells were transplanted by portal vein injection in MCT-treated NOD-SCID HA mice. Mice were killed 96 h later and cell engraftment analyzed by GFP-staining of liver sections.

Results: Reprogrammed MNC gave rise to iPSCs in about 45 days. iPSCs displayed embryonic stem cells (ESC)-like morphology: colonies were compact, uniform and with defined borders when grown on feeders. iPSCs were positive for AP staining and expressed specific stem cell markers at RNA and protein level, showing activation of the endogenous reprogramming factors. Moreover, iPSCs differentiated in osteogenic, condrogenic and adipose tissues. EB expressed markers of the three germ layers: alpha-fetoprotein, brachiury and nestin. Nevertheless, iPSCs showed demethylation at CpG islands at the core of Oct4 promoter, epigenetic marker of complete reprogramming to a pluripotent state. Additionally, telomeres length of original and reprogrammed cells did not show changes indicating telomerase reactivation. Furthermore, RT-PCR on HA-iPSCs showed the expression of hBDD-FVIII, confirming genetic correction of HA-MNC by LV transduction.

Importantly, iPSCs differentiated into ECs, acquiring a typical endothelial-like morphology with an increased expression of ECs markers, such as CD31, KDR, vWF and FVIII. Then, iPSC-derived ECs were transduced with LV-expressing GFP under the control of Flk-1 and Tie2. Flk-1-GFP+ cells were transplanted in NOD-SCID HA mice. GFP+ cells were detected in liver sections up to 1 week post transplantation.

Conclusion: Overall, these data will be instrumental to assess the engraftment, the proliferation and the levels of FVIII expression from differentiated, gene corrected and reprogramming factor free iPSCs to confirm the suitability of this approach for HA gene-cell-therapy.

AS 45.3

Platelet-specific expression of FIX induced by lentiviral gene delivery to hematopoietic stem cells restores hemostasis and induces immune tolerance in hemophilia B mice

Chen Y, Schroeder JA, Kuether L, Montgomery R and Shi Q
Medical College of Wisconsin, Blood Research Institute, Children's Research Inst, Milwaukee, WI, USA

Background: Gene therapy is an attractive approach for hemophilia treatment, however, immune responses to the transgene product or viral vector can occur during such approaches.

Objective: To develop a novel gene therapy approach that will not only provide therapeutic protein FIX, but also induce FIX-specific immune tolerance for hemophilia B.

Methods: Platelet- FIX (2bF9) expression, driven by the platelet-specific αIIb promoter, was introduced by lentivirus-mediated hematopoietic stem cell (HSC) transduction followed by syngeneic transplantation. Recipients were analyzed by PCR, flow cytometry, and FIX assays to assess 2bF9 expression and then challenged with recombinant human FIX (rhF9) to investigate whether immune tolerance was induced after platelet gene therapy.

Results: The 2bF9 transgene was detected by PCR in all transduced recipients. Flow cytometry showed that there were 20.8 ± 12.1% (n = 7) and 14.8 ± 10.7% (n = 6) 2bF9-transduced platelets respectively in the recipients preconditioned with 1100 cGy or 660 cGy. The antigen levels of FIX were 2.89 ± 1.75 mU/10^8 platelets (n = 9) in the recipients preconditioned with 1100 cGy and 1.87 ± 1.30 mU/10^8 platelets (n = 7) in the 660 cGy group. There was a small amount of FIX detected in recipient plasma with the average levels of 2.22 mU/mL in the 1100 cGy group and 1.44 mU/mL in the 660 cGy group. To analyze the distribution of the FIX between platelets and plasma, we normalized FIX levels to total whole blood FIX content. The results demonstrated that 90–95% of whole blood FIX was stored in platelets. The tail clip survival test demonstrated that 15 of 16 mice that received 2bF9-transduced HSCs survived the tail clipping, while only two of 10 FIX^{null} control mice survived under the same challenge. Nine months after transplantation, sequential transplantation was performed on some of the primary recipients. Platelet-FIX expression in the secondary recipients was sustained, leading to phenotypic correction and confirming that long-term engrafting HSCs were successfully transduced with 2bF9 LV. Notably, none of the transduced recipients developed anti-FIX antibodies after platelet gene therapy. To investigate whether immune tolerance was induced in 2bF9-transduced recipients, we challenged the recipients with rhF9 in the presence of adjuvant. Only one of nine 2bF9-transduced recipients developed a low titer of inhibitory antibodies (1.6 BU/mL) as measured by a modified Bethesda assay. In contrast, all of the FIX^{null} controls developed inhibitors ranging from 17 to 37 BU/mL after the same challenge (n = 5). To ensure that the immune system was not defective in the 2bF9-transduced recipients and that the tolerance induction is FIX antigen-specific, we further challenged the animals with ovalbumin (OVA) absorbed on Alum. Both the 2bF9-transduced and FIX^{null} control mice developed high-titer anti-OVA antibodies. The levels of anti-OVA antibodies in the 2bF9-transduced recipients were not significantly different from FIX^{null} mice after the OVA immunization, confirming that tolerance induction in 2bF9 LV-transduced mice is FIX-specific.

Conclusion: Our data suggest that platelet gene therapy can not only provide sustained phenotypic correction, but also induce immune tolerance in hemophilia B mice, indicating that this approach may be a promising strategy for gene therapy of hemophilia B in humans.

AS 45.4

A novel mutation that alters an ubiquitination site on adeno-associated virus serotype (AAV) – 8 capsid improves hepatic coagulation factor IX expression *in vivo*

Sen D, Vijay R, Nair S, Srivastava A and Jayandharan GR
Christian Medical College, Vellore, India

Background: Recombinant adeno-associated virus vectors based on serotype (AAV)-8 have shown significant promise for hepatic gene therapy of hemophilia B. However, in a recent clinical trial, patients who received the highest dose (2×10^{12} vg/kg) of the self-complementary AAV8 vector developed transaminitis and capsid specific T cells that was attenuated by glucocorticoid therapy. To circumvent this vector dose dependent immunotoxicity, it is important to develop better AAV8 vectors that provide enhanced gene expression at significantly less vector doses.

Aims: We hypothesized that AAV8 vectors during intracellular trafficking, are targeted for destruction in the cytoplasm by the host-cellular kinase/ubiquitination/proteasomal degradation machinery and modification of specific serine/threonine kinase or ubiquitination targets on AAV8 capsid may improve its transduction efficiency.

Methods/Results: To test this, point mutations at specific serine (S)/threonine (T) à alanine (A) or lysine (K) àarginine (R) residues were generated on AAV8 capsid. Using a reporter transgene construct

(p.CB-EGFP), we have identified that one of the mutant vector (K137R), had increased liver directed gene expression (46-fold) and higher vector DNA copy numbers (22-fold) when compared to WT-AAV8 administered animals. The K137R-AAV8 vector also showed significantly decreased ubiquitination of the viral capsid as measured by immunoblotting experiments. Furthermore, the K137R vector demonstrated reduced activation of markers of innate immune response (IL-6, IL-12, TNF- α, Kupffer cells and toll like receptor-9) or decreased (two-fold) levels of cross-neutralizing antibody formation compared to animals that received WT-AAV8 vector. To further study the utility of the novel AAV8-K137R mutant in therapeutic gene transfer, we delivered human coagulation factor IX (h.FIX) under the control of liver specific promoters (LP1 or hAAT) at two different doses ($2.5 \times 10e^{10}$ and $1 \times 10e^{11}$ vgs per mouse) in 8–12 weeks old male C57BL/6 mice. Mice were bled retro-orbitally 2, 4 and 8 weeks post vector administration and the antigenic activity (hFIX:Ag) was measured (Asserachrom, Stago). The circulating levels of h.FIX:Ag were higher in all the K137R-AAV8 treated groups as compared to the WT-AAV8 treated groups either at 2 weeks (62% vs. 37% for hAAT constructs and 47% vs. 21% for LP1 constructs) 4 weeks (78% vs. 56% for hAAT constructs and 64% vs. 30% for LP1 constructs) or 8 weeks (90% vs. 74% for hAAT constructs and 77% vs. 31% for LP1 constructs) post hepatic gene transfer.

Conclusions: These studies demonstrate the feasibility of the use of this novel AAV8 vector for potential gene therapy of hemophilia B.

AS 46 – Tissue Factor, Cancer and Thrombosis

AS 46

Tissue factor in brain cancer

Rak J

Montreal Children's Hospital, Montreal, QC, Canada

Brain tumours emerge and progress within a unique tissue microenvironment, which they modulate in ways that depend on the underlying oncogenic defects. The highly specialized brain vasculature that responds to, and actively participates in the malignant process in ways that are still poorly understood. In this regard glioblastoma multiforme (GBM), an incurable, infiltrative, high grade astrocytic tumour is exhibits an extensive and diagnostically important vascular involvement, including hyperproliferaitve endothelial cells, presence of myeloid cells, intravascular microthrombosis coupled with occlusion and hypoxia as well as high risk for peripheral venous thromboembolism (VTE). While pathomechanisms involved in these changes remain to be fully elucidated, recent studies revealed that GBM cells express several coagulation proteins including ectopic factor VII, tissue factor (TF) and several effectors of the coagulation-related signalling circuitry, notably protease activated receptors 1 and 2 (PAR-1/2). This expression is driven, at least to some extent, by overexpression (amplification) in GBM cells of the epidermal growth factor receptor (EGFR) and its constitutively active mutant (EGFRvIII). Oncogenic EGFR stimulates vesiculation of GBM cells, including emission of TF-containing extracellular vesicles (EVs, microparticles) and EVs containing EGFRvIII (oncosomes). Mesenchymal transition of EGFR-expressing cancer cells also leads to a shift in TF emission resulting in shedding of procoagulant exosomes. The link between EGFR and TF is observed not only in engineered GBM cell lines but also in the clinical material. Thus, our analysis of coagulation-related transcripts (coagulome) of GBM specimens reveals a close correlation between levels of EGFR and TF in the classical subtype of GBM. In contrast, molecular GBM subtypes not known to be driven by oncogenic EGFR (mesenchymal, proneural, neural) exhibit lesser or no TF upregulation. Indeed several coagulation related genes are expressed (often ectopically) in GBM, medulloblastoma (MB) in a manner that corresponds to molecular subtypes of these (and other) malignances. TF plays different roles at different stages of GBM progression in that growth of advanced experimental tumours can be partially attenuated by suppression of TF activity in cancer cells. Notably, TF-negative indolent human GBM cells fail to initiate tumour growth and remain viable but dormant in mice for nearly a year. Expression of TF in these cells leads to cessation of dormancy and the onset of tumour growth after 4–6 week long latency, a process related to the onset of angiogenesis and inflammatory infiltration. Thus, TF involvement in the pathogenesis of brain tumours is notable but also complex, and extends beyond thrombosis. The diagnostic and therapeutic implications of this pathway in brain tumours may depend on the type, stage of the disease as well as the configuration of oncogenic mutations and molecular subtype.

AS 46.1

Neuronal cell tissue factor contributes to microvascular thrombosis in the brain after injury

Sparkenbaugh EM[1], Russell J[2], Tencati M[3], Mackman N[1], Granger DN[2] and Pawlinski R[1]

[1]*University of North Carolina at Chapel Hill, Chapel Hill, NC;* [2]*Louisiana State University, Shreveport, LA;* [3]*University of Illinois at Urbana-Champaign, Urbana-Champagne, IL, USA*

Tissue factor (TF), the major cellular initiator of the coagulation cascades, is highly expressed within the central nervous system (CNS). Astrocytes are the main source of TF in the brain. Astrocyte endfeet form the glia limitans interna which surrounds the microvasculature within the brain. Therefore, it has been proposed that astrocyte TF forms the hemostatic envelope within the brain vasculature. However, this hypothesis has never been tested and the role of TF in the brain remains largely unknown. To study the role of TF in the brain we generated mice lacking TF gene in all neuronal cells, including astrocytes, by crossing $TF^{flox/flox}$ mice with mice expressing Cre recombinase under control of a nestin promoter ($TF^{flox/flox}$/nestin Cre). These mice were viable and were born at the expected frequency from crosses between $TF^{flox/flox}$ and $TF^{flox/+}$/nestin Cre mice. First, we determined the level of TF expression in the brains of $TF^{flox/flox}$/nestin Cre mice and $TF^{flox/flox}$ control littermates. We observed a 99.5% reduction of TF mRNA expression in in the brain of $TF^{flox/flox}$/nestin Cre ($n = 4$) mice compared to $TF^{flox/flox}$ ($n = 4$) mice ($P < 0.0001$). Consistent with the mRNA data, total procoagulant activity of the brain tissue extract was reduced by 98.7% ($P < 0.01$). Mice lacking TF in the CNS exhibited normal survival without any evidence of spontaneous bleeding. Next, we determined the effect of TF deficiency in all neuronal cells on microvascular thrombosis using a photoactivation model. After craniotomy, visualization of individual vessels and thrombosis was performed using a 40× water-immersion objective attached to an Axioskop 2 FS Plus research microscope. 5% FITC dextran (10 mg/kg) was injected intravenously and allowed to circulate for 10 min before photoactivation (Gavins FN et al, Blood 2011, PMID:21304105). Thrombus formation, assessed as time for complete cessation of microvascular blood flow after light/dye injury, was quantified using intravital fluorescence microscopy in WT ($n = 6$), $TF^{flox/flox}$ ($n = 8$) $TF^{flox/flox}$/nestin Cre ($n = 9$) male mice within arterioles, venules and capillaries. The average diameter of these three vessel types was the same in all groups of mice. We hypothesized that deletion of TF from all neuronal cell would significantly affect thrombosis within the capillaries, because of direct contact of astrocyte endfeet with the basal membrane under the endothelium. Consistent with this notion, a significant prolongation in flow-cessation time was observed in capillaries of $TF^{flox/flox}$/nestin Cre mice (11.8 ± 1.6 min) compared with flow-cessation time recorded for $TF^{flox/flox}$ (8.5 ± 0.9 min, $P = 0.02$) and WT mice (7.52 ± 0.7, $P = 0.04$). Interestingly, deletion of TF from all neuronal cells had no effect on the flow-cessation time in arterioles or venules. Our results indicate that TF expression by astrocytes plays an important role in brain hemostasis at the capillary level, and likely

contributes to microvascular brain thrombosis upon damage to this vascular bed. Studies investigating the other roles of neuronal TF in the pathophysiology of the CNS are currently ongoing in our laboratories.

AS 46.2

Transient phosphorylation of the cytoplasmic domain of tissue factor at serine 253 promotes its interaction with filamin-A and is prerequisite for tissue factor release into microparticles

Collier MEW, Maraveyas A and Ettelaie C
University of Hull, Hull, UK

Background: The release of tissue factor (TF) into cell-derived microparticles (MPs) is positively regulated by the phosphorylation of serine 253 within the cytoplasmic domain of TF. However, the molecular basis for this phosphorylation-dependent release of TF into MPs is unknown. The cytoskeletal protein filamin-A has been shown to directly bind to the cytoplasmic domain of TF. Moreover, this interaction is enhanced by the phosphorylation of serine residues 253 and 258 within the cytoplasmic domain of TF.
Aims: This study examined the role of filamin-A in the release of TF into MPs and examined the importance of the phosphorylation of serine 253 for the interaction of TF with filamin-A prior to MP release.
Methods: Human dermal blood endothelial cells (HDBEC) and human coronary artery endothelial cells (HCAEC) were transfected with pCMV-XL5-TF to express wild-type TF. Alternatively, cells were transfected with mutant forms of this construct in order to express TF with alanine or aspartate substitutions of residue 253 in order to prevent phosphorylation or mimic phosphorylation of this residue, respectively. MDA-MB-231 cells were used as a cell line that constitutively expresses TF. MP release was induced by activating protease-activated receptor 2 (PAR2) with an agonist peptide or factor Xa. MPs were then isolated from the culture media by ultracentrifugation. The interaction between TF and filamin-A was examined using a proximity ligation assay and co-immunoprecipitation. The expression of filamin-A was suppressed using filamin-A specific siRNA. The TF antigen content of the MPs was measured using a TF-ELISA and confirmed by western blot analysis. TF activity of the MPs was determined using a thrombin-generation assay. Total numbers of released MPs and size distributions were determined using nanoparticle tracking analysis.
Results: The interaction between TF and filamin-A was transient and peaked in HDBEC at 45 min post-activation of PAR2, in HCAEC at 60 min post-activation, and in MDA-MB-231 cells at 10 min post-activation. Two *C*-terminal fragments of filamin-A of 35 and 40 kDa were shown to co-immunoprecipitate with TF. HDBEC transfected with a mutant form of TF with alanine substitution of serine 253 resulted in reduced interactions between TF and filamin-A compared to wild-type TF. Mutation of serine 253 to aspartate resulted in increased interactions between TF and filamin-A, even in the absence of PAR2 activation. Furthermore, the interaction between aspartate substituted-TF with filamin-A was also transient, indicating that decreases in interactions observed at later time-points is not the result of serine 253 de-phosphorylation. siRNA-mediated suppression of filamin-A expression resulted in reduced levels of TF in the released MPs, but had no effect on the expression of TF. In addition, knockdown of filamin-A expression did not significantly alter the total number or size distribution of the released MPs.
Conclusions: These data show that filamin-A interacts with TF prior to MP release and the presence of filamin-A is required for the release of TF into MPs. This study therefore provides an insight into the mechanism by which the phosphorylation of serine 253 within the cytoplasmic domain of TF promotes the release of TF-positive MPs.

AS 46.3

Alternatively spliced Tissue Factor fuels breast cancer growth by binding to a non-canonical site on beta1 integrins

Kocatürk B[1], Van den Berg YW[1], Tieken C[1], Kuppen PJK[1], Ruf W[2], Reitsma PH[1], Osanto S[1], Bogdanov VY[3] and Versteeg HH[1]
[1]*Leiden University Medical Center, Leiden, the Netherlands;* [2]*The Scripps Research Institute, La Jolla, CA;* [3]*University of Cincinnati College of Medicine, Cincinnati, OH, USA*

Full-length tissue factor (flTF), the coagulation initiator, is overexpressed in breast cancer (BrCa) and induces coagulation-independent tumor angiogenesis in murine orthotopic breast cancer models though activation of PAR2. Nevertheless, associations between flTF expression and clinical outcome remain controversial. Interestingly, TF can be alternatively spliced yielding the non-coagulant soluble protein alternatively spliced tissue factor (asTF), but it is currently unknown whether asTF is expressed in BrCa and/or impacts BrCa progression.
To study the impact of TF isoform expression on tumor progression, breast tumor specimens from 574 patients were stained with flTF and asTF specific antibodies and percentages of positive cells were correlated with clinical parameters. Using this approach, we found for the first time that asTF, but not flTF, strongly associates with both tumor size and grade. To study this mechanistically, we generated MCF7-based breast cancer cells selectively expressing flTF, asTF or no TF protein. asTF expression, but not flTF expression, in these cells showed strong proliferative effects, compared to control cells. These proliferative effects were dependent on asTF binding to a non-canonical site on b1 integrins. Furthermore, asTF expression in these cells promoted oncogenic gene expression, anchorage-independent growth and strongly upregulated tumor expansion in a orthotopic luminal BrCa model. Furthermore, we characterized *in vivo*-selected MDA-MB-231 and found that these more aggressive MDA-MB-231-mfp cells expressed similar amounts of flTF, but more asTF, compared to MDA-MB-231. Increased proliferation rates of these cells compared to MDA-MB-231 were again dependent on asTF expression and b1 integrin. *In vivo*, asTF-blockade using specific antibodies resulted in diminished tumor growth and proliferation, but not diminished angiogenesis.
We propose that asTF plays a critical role in BrCa progression acting as an autocrine factor fueling tumor growth, while flTF impacts tumor angiogenesis. Targeting asTF either alone, or in combination with flTF/PAR2 blockade, may comprise a novel therapeutic strategy in BrCa that stems tumor growth, yet does not impair normal hemostasis.

AS 46.4

Alternatively spliced tissue factor contributes to tumor spread and activation of coagulation in pancreatic ductal adenocarcinoma

Bogdanov VY[1], Srinivasan R[1], Turner K[1], Unruh D[1], Qi X[1], Aronow B[2], Ahmad S[1], Lucas FV[1] and Versteeg HH[3]
[1]*University of Cincinnati College of Medicine, Cincinnati;* [2]*Cincinnati Children's Hospital and Medical Center, Cincinnati, OH, USA;* [3]*Leiden University Medical Center, Leiden, the Netherlands*

Background: Alternatively spliced Tissue Factor (asTF) is a minimally coagulant TF form that promotes neovascularization and monocyte recruitment through integrin mediated mechanisms. While it has been shown that asTF is expressed in some pancreatic ductal adenocarcinoma (PDAC) cell lines and increased asTF expression potentiates PDAC growth in a subcutaneous model, the expression of asTF in human PDAC lesions and its potential role in the growth and/or spread of PDAC in a physiologically relevant setting are yet to be ascertained.

Aims: To assess the expression of asTF protein in bona fide human adenocarcinoma tissue; to evaluate the effect(s) of asTF overexpression in PDAC cells in an orthotopic model; to investigate the changes in the procoagulant potential of PDAC cells overexpressing asTF.
Methods: Tumor microarrays (PDAC, breast, urothelial, ovarian, and prostatic carcinomas) were evaluated for asTF expression and monocyte infiltration ($n = 9$). Primary PDAC tumors and regional lymph node metastases were then analyzed for asTF expression. PDAC cell lines expressing various levels of asTF were implanted in the pancreases of nude mice and subsequent in-vivo imaging studies were performed. PDAC cells were treated with recombinant asTF and the resultant changes in gene expression were assessed using microarrays. TF activity was measured in PDAC cell lines Capan-1, Pt45P1, and asTF overexpressing cells Pt45P1/asTF+ as well as the corresponding microparticles (MP) using fXa generation-based chromogenic assay; full-length TF (flTF) and phosphatidylserine (PS) levels were assessed using flow cytometry.
Results: asTF was detected in lesional and stromal compartments in all five studied types of carcinoma; PDAC tissue contained significantly higher levels of $CD68^+$ monocytes ($P < 0.05$). Analysis of 29 specimens of human PDAC revealed detectable asTF in > 90% of lesions with a range of staining intensities (low – 15%, moderate – 70%, high – 15%). Intense staining of asTF in perineurally invasive cancer glands and pancreatic intraductal neoplasia lesions was identified. Staining intensity for asTF in PDAC lesions positively correlated with the degree of monocyte infiltration. In nude mice, Pt45P1/asTF+ cells exhibited the most aggressive growth with metastases to distal lymph nodes, which stained positive for asTF. PDAC cells stimulated with recombinant asTF exhibited upregulation of genes involved in EGFR binding, epithelial branch elongation/development, and epithelial-mesenchymal signaling. Pt45P1/asTF+ cells and MP derived from these cells displayed higher TF activity compared to Pt45P1 cells and Pt45P1 derived MP ($P < 0.05$). While there were no significant differences between the levels of PS detectable on the surface of these two cell lines and/or cell derived MP, and the total MP levels remained unchanged, MP produced by Pt45P1/asTF+ cells carried more flTF compared to MP produced by Pt45P1 cells.
Conclusions: Our findings demonstrate that asTF is expressed in bona fide PDAC lesions and lymph node metastases, and potentiates PDAC spread *in vivo*. asTF elicits global changes in gene expression likely involved in tumor progression and metastatic dissemination, and it also enhances the procoagulant potential of PDAC cells and cell derived MP. Thus, asTF may comprise a novel therapeutic target to treat PDAC.

Antidote for new oral anticoagulants: mechanism of action and binding specificity of PER977

Laulicht B[1], Bakhru S[1], Jiang X[1], Chen L[1], Pan D[1], Grosso M[2], Morishima Y[3], Brown K[2], Masumoto H[2], Costin J[1] and Steiner S[1]
[1]Perosphere Inc., Bedford, New York, NY; [2]Daiichi Sankyo, Inc., Edison, NJ, USA; [3]Daiichi Sankyo Co., Ltd., Tokyo, Japan

The new oral anticoagulants (NOACs) offer significant advantages over the heparins and warfarin therapies with regards to route of administration, drug interactions and predictability of bioactivity. Currently NOACs lack a specific reversal agent and concern over the need for rapid reversal for emergency procedures, serious bleeding or potential over dosage is heightened. As such we rationally designed, synthesized, and characterized a synthetic small molecule anticoagulant antidote (PER977).
In silico modeling data predicted the locations of non-covalent hydrogen bonding between PER977 and NOACs and heparins. *In vitro* dynamic light scattering (DLS) data reversal data correlate the *in silico* predicted non-covalent binding specificity of PER977 directly to NOACs and heparins (e.g. enoxaparin). Dynamic light scattering (DLS) of mixtures of PER977 and enoxaparin evidence the formation of molecular complexes formed at 1:1 and increasing in size at 10:1 ratios, indicating a strong physical, non-covalent association between PER977 and enoxaparin that accounts for the enoxaparin reversal activity of PER977.
Pre-clinical *in vivo* anticoagulant (rat-tail transection bleeding) assays demonstrate full reversal of all NOACs, with edoxaban requiring the lowest dose for full reversal of edoxaban by PER977. Importantly, PER977 exhibits no binding to any human plasma coagulation factors or albumin. Thromboelastography (TEG) measurements also demonstrate that PER977 returns edoxaban anti-coagulated rats to their naïve coagulation state. TEG reaction time (TEG-R) measurements demonstrate a statistically significant decrease ($P < 0.05$) back to normal TEG-R levels in edoxaban anticoagulated rats administered PER977 within 30 min of administration, as compared to rats receiving edoxaban followed by a saline sham.
In vivo and *in vitro* toxicology and safety studies have been completed and a first-in-human clinical trial to demonstrate safety and efficacy in healthy human volunteers with PER977 and edoxaban will follow. PER977 has also shown no pro-coagulant properties as measured in human blood. In conclusion, PER977 directly and specifically binds NOACs and heparins reversing their anticoagulant properties.

AS 47.2

A case of thrombotic thrombocytopenic purpura and two novel mutations on complement system genes: a new etiology of disease?

Peyvandi F[1], Rossio R[2], Lotta LA[3], Pontiggia S[2], Ghiringhelli Borsa N[4], Pizzuti M[5], Donadelli R[6] and Noris M[7]
[1]Fondazione IRCCS Maggiore Hospital Foundation; [2]Fondazione IRCCS Ca' Granda – Ospedale Maggiore Policlinico; [3]Angelo Bianchi Bonomi Hemophilia and Thrombosis Center; [4]Fondazione IRCCS Ca' Granda - Ospedale Maggiore Policlinico, Milano; [5]Unito of Ematology, San Carlo Hospital, Potenza; [6]Mario Negri Institute for Pharmacological Research, Ranica, Bergamo; [7]Clinical Research Center for Rare Diseases, Ranica, BG, Italy

Background: The differential diagnosis between thrombocytopenic purpura (TTP) and atypical hemolytic uremic syndrome (HUS), is challenging due to the overlapping clinical signs and symptoms. Severe deficiency of ADAMTS13 (A Disintegrin And Metalloprotease with ThromboSpondin 1 repeats) is a well-recognized cause of TTP, whereas HUS is caused either by enterohemorrhagic *E. coli* infection (typical HUS) or by mutations in genes encoding complement system proteins (atypical HUS). As the therapeutic approach to the different forms of TMA diverges, it becomes increasingly important to establish the underlying etiology. We report a case that redefines the boundaries between TTP and aHUS, which may have major future consequences for the treatment of patients with TTP.
Aims: To investigate etiology in a TTP patient without renal involvement and normal ADAMTS13 activity at presentation.
Methods: ADAMTS13 antigen (by ELISA), activity (by fluorescence resonance energy transfer), VWF:Ag, multimers and complement system-related plasmatic parameters were measured. Mutational analysis in six complement-regulator genes (*CFH, CFI, CD46, CFB,* thrombomodulin (*THBD*) and *C3* were performed by PCR and Sanger sequencing. The role of a new mutation on *CFI* was studied by the concentration of complement factor I (*CFI*) in plasma with an ELISA. *THBD* variation was investigated by stable *in vitro* expression studies in HEK293 cells followed by functional characterization of TAFIa production in the presence of thrombin in both wild type (WT) and mutant (p.P368L) THBDs.

Results: A 49-year-old woman with fever, abdominal pain, vomiting and confusion, platelet counts of 46×10^9/L; and microangiopathic hemolytic anemia (hemoglobin: 8.3 g/dL, negative Coombs test) was diagnosed with idiopathic TTP. There was no renal impairment (creatinine 52.8 μM; normal values: 53–106 μM), urinary sediment was normal and 24-h proteinuria was negative. Remission was achieved after six daily plasma exchange procedures. ADAMTS13 activity and antigen were normal, but there was an increase in VWF antigen, with the presence of ultra-large VWF multimers. The alternative complement system pathway was activated, as documented by very low residual activity of AP50 (5%, normal value 30–113). Sequencing revealed the presence of two novel missense mutations in *CFI* (c.805G>A, p.G269S) and in *THBD* (c.1103C>T, p.P368L), for both of which she was heterozygous. Plasmatic complement factor I concentration was normal 58 mg/L (normal value: 40–80 mg/L). The mutant THBD (p.P368L) recombinant form was less effective than wild-type in the generation of TAFIa (50% reduction vs WT).

Summary/conclusions: We report a classical case of TTP, without renal impairment but with normal ADAMTS13 activity, who has two mutations in complement regulation genes CFI (c.805G>A, p.G269S) and in THBD (c.1103C>T, p.P368L). *In vitro* expression studies showed a reduced generation of TAFIa caused by p.P368L mutation on *THBD* leading probably to endothelial activation by increasing circulating anaphylatoxins (C3a, C4a). This alteration associated with an impaired complement regulation caused by p.G269S mutation on *CFI* (increased C3 and C5 cleavage to C3a/C3b and C5a/C5b, thus creating a positive feedback loop of inflammation) may be a hitherto unknown pathophysiologic mechanism in patients affected with TTP and might open a new therapeutic horizon in these patients.

AS 47.3

Complement is not activated in nonhuman primates during development of hemolytic uremic syndrome and thrombotic microangiopathy induced by *E. coli* Shiga toxins

Lee BC, Mayer CL, Leibowitz CS, Stearns-Kurosawa DJ and Kurosawa S

Department of Pathology and Laboratory Medicine, Boston University School of Med, Boston, MA, USA

Background: Enterohemorrhagic *Escherichia coli* (EHEC) produce ribosome inactivating Shiga toxins (Stx1, Stx2) responsible for endothelial injury, development of hemolytic uremic syndrome (HUS) and acute kidney injury (AKI). Some patients show evidence of complement activation during EHEC infection, raising the possibility of therapeutic targeting of complement for relief. *In vitro* and murine Stx2 + LPS studies indicate that Stxs induce activation of the alternative complement pathway causing glomerular injury and microvascular thrombosis. However, these models do not recapitulate Stx-induced HUS, but the coagulopathy of disseminated intravascular coagulation (DIC). Our non-human primate (*Papio*) models of endotoxin-free Stx challenge exhibit full spectrum HUS including thrombocytopenia, hemolytic anemia, and AKI with glomerular thrombotic microangiopathy.

Aim: We examined whether complement was activated in Stx-challenged non-human primates during the development of HUS and AKI. In addition, we quantified D-dimer as a marker for fibrinolysis and the damage associated molecular patterns (DAMPs) HMGB1 and histone as markers of cell injury.

Methods: Plasma terminal complement complex (TCC), D-dimer, plasma/urine HMGB1 and histones were measured by ELISA in timed samples from juvenile baboons challenged i.v. with 100 ng/kg Stx1 or 50 ng/kg Stx2. Plasma from septic, bacteremic baboons with DIC after i.v. challenge with sub-lethal 5E + 09 CFU/kg *E. coli* B7 O86a:K61or lethal 3E + 09 CFU/kg attenuated *Bacillus anthracis* were used as positive controls.

Results: There were no significant increases in TCC levels in animals challenged with Stx1 ($n = 6$) or Stx2 ($n = 5$) in timed plasma samples from T0 to euthanasia at 49.5–128 h post-challenge. TCC levels in bacteremic animals with DIC peaked ≤ 48 h at 399.15 mAU/mL (O86a:K61) and 2204.99 mAU/mL (*B. anthracis*). D dimer consistently increased from 4 h, peaking at 48 h (Stx1, 736.89 ± 175.44 ng/mL) or 96 h (Stx2, 1009.75 ± 192.95 ng/mL). Plasma and urine HMGB1 was detectable by 8–24 h, rising earlier and higher after Stx1 compared with Stx2. Histones increased, but were variable between animals.

Conclusions: Complement is not activated in this pre-clinical HUS model, despite clear coagulopathy and cellular injury. This suggests complement activation is not required for the development of thrombotic microangiopathy and HUS induced by EHEC Shiga-like toxins. This was unexpected given the close links between coagulation, complement and endothelial injury. Instead, other bacterial and/or host factors must contribute. Complement is an important defense mechanism and benefits or risks of therapeutic inhibition should be studied further for this infection.

The interaction between complement factor H and von Willebrand factor increases factor H cofactor activity and regulates von Willebrand factor prothrombotic status

Rayes J[1], Roumenina RT[1], Dimitrov JD[2], Repessé Y[3], Ing M[1], Christophe OD[4], Sakari Jokiranta T[3], Halbwachs-Mecarelli L[1], Borel-Derlon A[5], Kaveri SV[6], Frémeaux-Bacchi V[1] and Lacroix-Desmazes S[6]

[1]Inserm 770, UMRS 872; [2]Inserm U872, Paris; [3]France; [4]Inserm U770, Le Kremlin Bicêtre; [5]Hemophilia Center, Caen; [6]Inserm UMRS 872, Paris, France

Background: Vascular endothelial cells are an important interface between primary hemostasis, coagulation and complement activation. EC synthesize both the clotting-initiator von Willebrand factor (VWF) and the complement regulator factor H (CFH). VWF is stored in EC Weibel-Palade bodies (WPB), but the intracellular location of CFH is not well defined.

Aim: Here, we address the question of the localization of CFH within endothelial cells and of the interaction of CFH with VWF.

Methods: The localization of CFH and VWF within human umbilical endothelial cells (HUVEC) was assessed by fluorescent microscopy. The binding of CFH to VWF was analyzed by SPR, ELISA and immunoprecipitation. The functional consequences of the interaction were probed by a cofactor test of CFH for cleavage of C3b by factor I, by VWF:RCo and by ADAMTS13-mediated VWF proteolysis.

Results: CFH co-localized with VWF in the WPB of HUVEC. Moreover, FH bound directly to VWF in real time and under static conditions with a K_D of 200 ± 25 nM. CFH-VWF complexes were isolated from normal human plasma. VWF bound to the C-terminal fragment of CFH. Besides, CFH bound to the D'D3 fragment of VWF, an interaction that was inhibited by FVIII. The binding of VWF with CFH enhanced CFH cofactor activity toward factor I as well as VWF-mediated platelet aggregation, whereas it reduced the proteolysis of VWF by its specific protease ADAMTS13.

Conclusion: The simultaneous secretion of VWF and CFH by activated EC may promote adhesion of platelets to sites of endothelial injury to assure wound healing, simultaneously dampening the pro-inflammatory effect of complement in order to limit bystander tissue damage.

AS 47.5

Thrombin binds to human ceruloplasmin and proteolytically hinders its antioxidant activity

De Filippis V[1], Acquasaliente L[2], Sokolov A[2], Kostevich V[2], Zakharova E[2] and Vasilyev V[2]

[1]*University of Padova, Padova;* [2]*School of Medicine, University of Padua, Padua, Italy*

Background: Human ceruloplasmin (CP) is a component of alpha-2 globulin fraction of blood plasma, structurally homologous to coagulation factors V and VIII. CP is a member of the multi-copper oxidase family and plays a key role in iron metabolism. Purified CP preparations contain the intact protein form (132 kDa) and, depending on the pathophysiological state of the donor and storage time of the sample, variable amounts of nicked species produced by some yet unidentified protease. In addition to its involvement in iron metabolism, intact CP (the 132 kDa form) efficiently inhibits the peroxidase and chlorinating activity of leukocyte myeloperoxidase (MPO), thus functioning as an effective antioxidant in inflammatory diseases characterized by activation of leukocytes and release of MPO (sepsis and rheumatoid arthritis). Strikingly, the MPO inhibitory function of CP (but not its oxidase activity) is hindered in the nicked species (Sokolov et al., 2008), thus suggesting that the antioxidant activity and tissue protective effects of CP might be regulated proteolytically. Human thrombin is the final effector protease in the coagulation cascade and plays a pivotal role at the interface of coagulation, inflammation and cell proliferation. Interestingly, the concentrations of both thrombin and CP are significantly increased at inflammatory sites, such as the synovial fluid of patients with rheumatoid arthritis.

Aims: (i) Verify that thrombin cleaves CP *in vivo*; (ii) quantify the affinity of CP for thrombin; (iii) mapping the binding sites in thrombin-CP interaction.

Methods: CP was purified from human plasma by ion exchange and heparin affinity chromatography. Recombinant wild-type and mutant thrombins were expressed in *E. coli* and *in vitro* refolded. CP-thrombin interaction was studied by fluorescence and surface plasmon resonance (SPR). Cleavage sites in CP were identified by SDS-PAGE, Western-blotting, and Edman sequencing. Samples of synovial fluid from 24 patients were tested for CP, thrombin and MPO concentrations.

Results: SPR analyses were performed either by injecting the inactive thrombin mutant S195A over the chip-bound CP and, oppositely, by injecting CP over thrombin-bound sensor chip. In both cases a similar affinity was measured, with $K_d = 3.1 \pm 0.5$ mM and $K_d = 2.0 \pm 0.7$ mM. A comparable value was obtained from fluorescence binding measurements. Displacement experiments, carried out with specific binders of thrombin exosite-1 (hirugen and HD1 aptamer) or exosite-2 (fibrinogen γ′-peptide and HD22 aptamer) and with thrombin mutants (Arg73Ala and Arg101Ala), having one of the two exosites selectively compromised, indicate that both exosites are involved in CP binding. After treating purified, intact CP with thrombin, the fragmentation pattern of CP in SDS-PAGE was identical to that of the nicked CP species found in human plasma. The major fragmentation sites correspond to Lys887-Val888 and Arg481-Ser482 peptide bonds, both located in highly flexible loops in the 3D structure of CP. Cleavage is abolished in the presence of hirudin, a potent and selective thrombin inhibitor. Notably, proteolytic degradation of CP was more pronounced in samples of synovial fluids with higher titres of thrombin and increased MPO activity.

Conclusions: Thrombin cleaves CP and hinders the inhibitory effect that intact CP exerts on MPO function in inflammatory diseases.

AS 47.6

A novel gene identified at an erythrocyte quantitative trait locus has a profound effect on thrombocyte formation in zebrafish

Stephens JC[1], Cvejic A[1], Haer-Wigman L[2], Van der Harst P[3], Van der Schoot E[2], Albers CA[1] and Ouwehand WH[1]

[1]*University of Cambridge and NIHR Cambridge, Cambridge, UK;* [2]*Sanquin Research, Amsterdam and Landsteiner Laboratory, Academic Medical Centre, Amsterdam;* [3]*University of Groningen, University Medical Center, Groningen, The Netherlands*

Background: The bone marrow residing precursor cells of platelets and red cells share a common progenitor, named the megakaryocyte-erythroid progenitor. Therefore important regulatory genes that regulate events in myeloid maturation may exert an effect on the formation of both red cells and platelets.

Aims: As part of an immunogenomics study, we sought to resolve the underlying genetic basis of the clinically relevant red cell blood group Vel.

Methods: The Vel group was discovered 60 years ago but efforts to identify the underlying sequence variant have resisted repeated attempts. We sequenced by targeted pull-down the exome of five individuals lacking the Vel group. Variants observed in 1% or more samples were removed by using the results of the 1000 and the UK10K Genomes projects. A single candidate gene was identified and by computational biology and gene knockdown in zebrafish its function in the formation of red cells and thrombocytes was elucidated.

Results: We identified the putative 78 amino-acid transmembrane protein Smim1 as the carrier of the high incidence Vel blood group, most commonly through the homozygous presence of a low frequency 17 nucleotide frameshift deletion. RNA-sequencing blood cell progenitors and precursors revealed that *SMIM1* transcription is restricted to the myeloid lineage. A common expression-quantitative trait locus (eQTL) at rs1175550 with a minor allele frequency of 0.21, contributed to variable expression of the *SMIM1* transcript ($P = 10^{-250}$). This SNP also pinpointed *SMIM1* as the causal gene underlying a genome-wide association signal at $P = 8.6 \times 10^{-15}$ for the mean haemoglobin concentration of red blood cells. Knock down of the zebrafish ortholog *smim1* caused a mild reduction of the number of red cells and a complete abrogation of thrombocytes.

Conclusions: We have discovered the previously hypothetical gene *SMIM1*, encoding one of a novel class of small integral membrane proteins on myeloid cells and carrying the Vel group. Genome-wide typing of nearly 100,000 individuals showed that the SNP rs1175550 that regulates the *SMIM1* transcript level is causally correlated with the haemoglobin concentration of red cells. This association observation was corroborated by knock-down in zebrafish which showed that *smim1* not only regulates red cell formation but also thrombocytogenesis. Our discovery adds to an expanding list of novel genes that regulate red cells and thrombocyte formation in a model system, for further evaluation in humans.

FS 01 – Antithrombotics and Pregnancy

FS 01.1

The Thrombophilia in Pregnancy Prophylaxis Study (TIPPS): a multi-national randomized trial of dalteparin vs. no dalteparin to prevent pregnancy complications in pregnant thrombophilic women

Rodger M[1], Hague WM[2], Kingdom J[3], Kahn SR[4], Karovitch A[5], Wells PS[5], Sermer M[3], Clement AM[1], Chan WS[6] and The TIPPS Investigators[1]

[1]Ottawa Health Research Institute, Ottawa, ON, Canada; [2]University of Adelaide, Adelaide, Australia; [3]University of Toronto, Toronto, ON; [4]McGill University, Montreal, QC; [5]University of Ottawa, Ottawa, ON; [6]University of British Columbia, Vancouver, BC, Canada

Background: Placental thrombosis is a common pathophysiologic feature of placenta mediated pregnancy complications (pre-eclampsia (PET), birth of a small for gestional age child (SGA), pregnancy loss and/or placental abruption). Thrombophilias are common and are purported to increase the risk of placenta mediated pregnancy complications and pregnancy-associated venous thromboembolism (VTE).
Aim: We hypothesized that dalteparin would reduce placenta mediated pregnancy complications and venous thromboembolism (VTE) in pregnant thrombophilic women at increased risk of these complications.
Methods: In a multi-national 19 center study, we randomized consenting pregnant women with laboratory confirmed thrombophilia at increased risk of placenta mediated pregnancy complications or VTE to open label dalteparin (5000 units SC daily until 20 weeks gestation and then 5000 units twice daily until at least 37 weeks gestation) or no dalteparin in a 1:1 allocation. Women were excluded if they had an indication for anticoagulation, were ≥ 20 weeks gestation, geographically inaccessible for follow-up or had contraindications to dalteparin. Post-partum dalteparin 5000 units/day was administered to all participants. The primary composite outcome was independently adjudicated placenta mediated pregnancy complications (severe or early onset pre-eclampsia, birth of a small for gestational age child (< 10th percentile) and/or pregnancy loss) and/or major VTE up to 6 weeks post-partum.
Results: We present preliminary data analysis on 289 of 292 recruited women (three deliver in 03/2013). Final analysis on all participants will be presented in July. Between 02/2000 and 09/2012, we recruited 292 thrombophilic women at increased risk of placenta mediated pregnancy complications (46 with prior PET, 42 with prior SGA < 10th percentile, 43 with three or more pregnancy losses < 10 weeks, 25 with two or more losses > 10 weeks, 58 with one or more losses > 16 weeks) or increased risk of venous thrombosis (86 with a family history of VTE in a first degree relative and 35 with prior VTE). Mean maternal age was 31.8 years and mean gestational age at enrolment was 12.0 weeks. There were three post-randomization exclusions, leaving 144 assigned to dalteparin and 142 assigned to no dalteparin for this preliminary analysis. No women were lost to follow-up or withdrew consent but 26 women crossed over from their allocated group (12 from dalteparin to no dalteparin and 14 from no dalteparin to dalteparin). In intention to treat analysis, dalteparin did not reduce the incidence of the primary composite outcome (25/144, 17.4% [95% CI:11.2–23.6%]) compared with the no dalteparin group (27/142, 19.0%, (95% CI: 12.6–25.5%). In on treatment analysis, the results were similar (dalteparin 28/146, 19.2% (95% CI:12.8–25.6%) vs. no dalteparin 24/140, 17.1% [95% CI:10.9–23.4%]). In secondary outcome analysis, major bleeding was no different in the dalteparin (2/144, 1.4% [95% CI:0–3.3%]) compared with the no dalteparin group (2/142, 1.4% [95% CI: 0–3.4%]).
Summary/Conclusions: In a large randomized trial, ante-partum prophylactic dalteparin in thrombophilic women at increased risk of placenta mediated pregnancy complications and/or venous thrombosis did not reduce the incidence of these complications.

FS 01.2

RhuFVIIa reduces the rate of interventional second line therapies in severe primary postpartum haemorrhages resistant to uterotonics: a multicenter, randomised, open controlled trial

Lavigne-Lissalde G[1], Aya G[1], Mercier F[2], Chauleur C[3], Morau E[3], Ducloy-Bouthors AS[4], Mignon A[5], Boehlen F[6] and Gris J-C[1]

[1]Caremeau University Hospital, Nimes; [2]AP-HP Antoine Beclere, Paris; [3]University Hospital, St. Etienne; [4]Jeanne of Flandre University Hospital, Lille; [5]Cochin University Hospital, Paris, France; [6]University Hospital and Faculty of Medicine of Geneva, Geneva, Switzerland

Background: Postpartum haemorrhage (PPH) is the most common cause of obstetric haemorrhage. The early introduction of uterotonic agents is recommended as a first-line therapy, before specific interventional second-line therapies (uterine compression sutures, vascular ligations, embolisation, and hysterectomy). Recombinant human activated factor VII (RhuFVIIa, Novoseven®, Novonordisk A/S Baagsvaerd, Denmark) has been empirically administered as a last-ditch attempt to prevent hysterectomy but no randomised controlled trial (RCT) is currently available.
Aims: to conduct an open RCT testing a single rhuFVIIa infusion vs. standard care in women with PPH still ongoing after first-line therapies applied accordingly to French national guidelines, i.e. refractory to uterotonic agents.
Methods: This trial was conducted between February 2007 and November 2010 at eight University hospitals sites (Nimes, Montpellier, Nice, Saint- Etienne, Clamart, Paris-Cochin, Lille and Geneva) in two countries (France and Switzerland). After oxytocin then sulprostone failure, the patients underwent block randomisation according to site to receive an early single intravenous dose of rhuFVIIa 60 μg/kg (intervention arm), or no early rhuFVIIa (standard care arm). The sample size calculation was obtained to detect an absolute reduction of 30% in specific second line therapies. The clinical criteria which triggered the inclusion procedure was failure to control the bleeding 1 h after the onset/start of the sulprostone infusion. The primary efficacy outcome was the need of second line therapies. The primary safety outcome was a composite of any thrombotic events during the 5 days after rhuFVIIa infusion and death.
Results: Eighty-four parturient were enrolled. A second-line therapy was needed in 39 women from the standard care arm (92.9%) and in 22 women from the intervention arm (52.4%), RR 0.56 (0.42–0.77), $P < 0.0001$, mean number of women to avoid one-second-line therapy: 2.6. A significant decrease in uterine artery embolisation needs, alone ($P = 0.0082$) or associated with other second-line procedures ($P = 0.008$), was evidenced. The rate of final haemostatic hysterectomies was 19% in the standard care arm, with a trend for lower needs in the study drug group (7%, NNT 8.4, $P = 0.10$). After categorisation of the patients according to the mode of delivery, we observed similar rates of the primary efficacy outcome in both delivery categories. Safety concerns only occurred in the intervention arm: one ovarian vein thrombosis case (day 2) and one late pulmonary embolism case (PE; 5 days after a C-section delivery for placental abruption and stillbirth).
Summary/Conclusions: This first RCT on rhuFVIIa use in women with a severe PPH (refractory to uterotonics) evidenced an absolute 40.5% decrease in the need of interventional second-line therapies and a 2.4% risk of late PE. In severe PPH settings, thromboprophylaxis modalities being defined, future studies will have to investigate the saving potential of rhuFVIIa on end-line haemostatic hysterectomies.

FS 01.3

Polymorphisms in the Annexin A5 promoter, placental Annexin A5 gene expression and risk of preeclampsia

De Jong PG, Afink GB, Ris-Stalpers C, Fouchier SW, Meijers JC and Middeldorp S

Academic Medical Center Amsterdam, Amsterdam, the Netherlands

Background: Annexin A5 (ANXA5) is an anticoagulant protein in the placenta. Reduced ANXA5 protein expression may induce placenta-mediated pregnancy complications such as recurrent miscarriage and preeclampsia. The M2 haplotype, encompassing four SNPs (rs112782763, rs28717001, rs28651243 and rs113588187) in the ANXA5 gene, is reported to be associated with recurrent miscarriage and with reduced ANXA5 promoter activity (N. Bogdanova et al., Human Molecular Genetics, 2007 vol. 16). Whether the placental expression of ANXA5 mRNA is reduced in the presence of this haplotype is unknown. Previous studies report an association between pregnancy outcome and the maternal ANXA5 genotype. We hypothesize that a stronger association with the neonatal than the maternal genotype is more likely, as placental tissue is of fetal origin and the placenta is a prerequisite to develop pregnancy complications as preeclampsia.
Aims: The aim of this study was to evaluate whether maternal or neonatal SNPs or haplotypes in the ANXA5 gene are associated with reduced placental ANXA5 mRNA expression.
Methods: The ANXA5 promoter region was evaluated by direct sequencing of maternal and umbilical cord blood DNA from a cohort of 287 women who delivered between 2005 and 2009 (45 with pre-eclampsia), which was obtained with informed consent. ANXA5 gene expression in placental tissue was determined by RT-qPCR and normalized to PSMD4 expression. Association between SNPs and placental expression of ANXA5 was evaluated in Haploview (X^2 test) and in SPSS (ANOVA and student's t-test). Mean ANXA5 gene expression in preeclamptic vs. normotensive women was compared (student's t-test).
Results: We identified seven SNPs, including the four SNPs that encompass the previously described M2 haplotype. We did not detect any association between placental ANXA5 mRNA levels and M2 haplotype in mother ($P = 0.72$) or neonate ($P = 0.66$) but did observe that placental ANXA5 expression is significantly increased in the presence of the minor allele of one SNP (c.-390C>T, rs62319820). This association is more prominent in umbilical cord DNA samples ($P = 0.002$) than in maternal DNA samples ($P = 0.007$) homozygous for the T allele. A mean of 13.2 ANXA5 normalized copy numbers was measured (range 0.40–27.12). Mean ANXA5 gene expression did not differ between preeclamptic and normotensive pregnancies ($P = 0.85$) and no SNP in maternal or neonatal genotype was associated with preeclampsia.
Conclusion: The presence of c.-390C>T is associated with increased placental ANXA5 mRNA expression. Whether ANXA5 protein levels are correlated to genotype in a similar fashion is yet to be determined. No SNP was associated with preeclampsia. In our population, the previously described M2 haplotype is not associated with reduced placental ANXA5 mRNA levels.

FS 02 – Thrombosis and Haemostasis in Children

FS 02

New approaches to unravelling the mysteries of clotting in children

Monagle P

Royal Children's Hospital University of Melbourne, Melbourne, Vic., Australia

One can argue that clotting in children is a different pathophysiological entity to clotting in adults based on the observed age related differences in the coagulation system, the vastly different incidence of thrombosis in children compared to adults, and the epidemiology of disease presentation in patients with inherited thrombophilia. There is also increasing evidence that the differences in plasma proteins alter the interactions of anticoagulant drugs, significantly affecting efficacy and safety. However as yet we poorly understand the differences. While many differences have been recently described, the practical implications for clinical care of patients and robust strategies to improve patient outcomes remain to be elucidated. A variety of approaches are required to help unravel these mysteries, which are important not just to improve the management of children with abnormal clotting, but because they are likely to contribute to improved care of thrombosis in adults as well. This talk will focus on novel methods being used to increase our understanding of developmental haemostasis and the interactions of the clotting system with clinically important anticoagulants. Initial studies of developmental haemostasis focussed on functional assays used in current clinical practice. However, more sophisticated quantitative and qualitative assessments of relevant proteins and specific measures of their binding activities with anticoagulant drugs, as well as other plasma proteins, (and diagnostic reagents) are now being used. Proteomics and metabolomics are increasingly relevant, including studies of the platelet binding and the platelet proteome, previously ignored aspects of the clotting pathway in children. In addition, new clinical studies are looking at the problems of thrombosis in children with a renewed focus. The traditional dogma of the necessity for RCTs may not be the most effective way to gather evidence at this point in time for many key questions that need to be answered. Large networks and alternative study designs are being implemented with good effect. Current ongoing studies in childhood stroke, post fontan surgery thrombosis prophylaxis, and central venous line associated thrombosis are excellent examples of differing study designs being utilised strategically with outstanding early results. Defining the natural history of the spectrum of thrombotic disease in children of different ages remains one of the most important pieces of the puzzle to be clarified. Only then, can true risk benefit analysis be performed. This presentation will describe a number of examples of the new approaches currently being used in pathophysiological research as well as clinical diagnostic and therapeutic research. For some, it is the case of the old becoming new again. The presentation will highlight the key areas that require further research and suggest approaches to tackling those questions.

FS 02.1

Significantly increased risk for venous thrombotic events in long-term pediatric, adolescent and young adult cancer survivors: a population-based study

Kulkarni K[1], Lorenzi M[2], Devji S[2], McBride M[2] and Lesley M[3]

[1]Stollery Children's Hospital, Edmonton, AB; [2]Cancer Control Research, BC Cancer Agency, Vancouver, BC; [3]University of Alberta, Stollery Children Hospital, Edmonton, AB, Canada

Background: With improving survival, longterm complications among pediatric and adolescent young adult (AYA) cancer survivors are being increasingly recognized. Venous thrombotic events (VTE) occurring during childhood and AYA cancers are well described and may place survivors at increased risk of recurrent VTE later in life. However, the incidence and risk factors for VTE in pediatric and AYA cancer survivors have not been studied.
Aim: To assess the incidence and risk factors for VTE among long-term childhood and AYA cancer survivors in comparison to control population.
Methods: A population-based cohort of long-term (≥ 5 years from diagnosis) cancer survivors identified through the provincial British Columbia (BC) Cancer Registry was used. All medically-necessary care is conducted within the public health system for BC residents and recorded in provincial registries and administrative databases. Hence,

the current study estimates are assumed to be an accurate approximation of the risk in an unselected total population of childhood and AYA survivors in post-treatment years.
For inclusion, a survivor had to be (i) diagnosed with cancer in childhood (age 0–14 years) or adolescence/young adulthood (age 15–24 years) between 1981 and 1999 (ii) alive on or after 1/1/1986 and (iii) linked to the BC health insurance plan registry in at least 1 year post-survivorship. Comparators consisted of 5-year birth cohort and gender-matched controls (10 per case) from the BC health insurance plan registry. Individuals were considered to have a VTE diagnosis if their physician-visit or hospitalization records indicated a VTE diagnosis (as coded by International Classification of Diseases Versions 9 or 10). Follow up (median 9 years, range 0–21 years) and outcome information was obtained from provincial health administrative files.
Results: 2857 survivors (1397 diagnosed in childhood) and 28,570 controls were assessed. The incidence of VTE was significantly increased in both childhood and AYA cancer survivors as compared to the controls: childhood 5.7% vs. 2.8% (Hazard Ratio (HR) 2.71, 95% CI 2.02–3.66) and AYA 7.0% vs. 4.9% (HR 1.92, 95% CI 1.46–2.5).
Several risk factors for VTE in survivors were identified. Survivors who experienced relapsed disease had a significantly increased risk (HR 3.26, 95% CI 1.79–5.92). Survivors who received chemotherapy, radiation, and surgery were nearly three times as likely to have a VTE than those with surgery alone (HR 2.91, 95% CI 1.16–7.30). Among childhood cancer survivors VTE risk was significantly increased in females (HR 1.61, 95% CI 1.02–2.52). Among AYA patients, carcinoma survivors ($n = 253$) had an increased risk of VTE as compared to lymphoma survivors (HR 2.26, 95% CI 1.06–4.83).
Summary: In this large study, we made a novel observation that VTE is an important complication in childhood and AYA long-term cancer survivors. The plausible hypothesis is that VTE (both symptomatic and asymptomatic) that develop during the treatment of cancer in these patients place them at an increased risk of recurrence. These observations underscore (i) the importance of developing strategies for early recognition, diagnosis and treatment of VTE in childhood cancer survivors and (ii) for primary prevention of VTE during cancer therapy.

FS 02.2
'Blood and bone thinning' in children on long-term oral anticoagulation: what a bone-scan can tell you

Avila M[1], Gupta S[2], Castle D[1], Kahr WHA[1], Williams S[1] and Brandao LR[1]
[1]The Hospital for Sick Children; [2]University of Toronto, Toronto, ON, Canada

Background and Aim: Chronic pediatric conditions may be complicated by low bone mass, measured by bone mineral density scans (BMD; i.e. *z*-score). Furthermore, children with chronic diseases are also at increased risk of developing thrombosis, requiring long-term anticoagulation (AC) with warfarin. Since warfarin may further jeopardize bone-health of a population already at risk for bone fragility, we wished to investigate bone-health outcomes in a cohort of such patients.
Methods: Our institutional protocol indicates children receiving warfarin for > 1 year undergo an initial BMD after the age of 5 years. Further management depends on the first results: group (G) 1 ($2.0 \leq z\text{-score} \leq -2.0$): bi-annual BMD; G2 ($-2.1 \leq z\text{-score} \leq -2.5$): annual BMD + biomarkers (Ca^{++}/Ph^{-}/PTH/1,25-vit.D); or G3 (z-scores < −2.5): annual BMD + biomarkers + spinal x-ray. For our analysis, patients on G2 and G3 were categorized as high-risk and G1, as low-risk. z-score s were deemed abnormal if < −2.0. Descriptive statistics and survival analysis were utilized. To minimize the influence of the per-protocol delay of younger patients to undergo a BMD scan, only patients commencing AC > 3 years (48/74) were included in survival analysis. The study was approved by the Institutional Ethics Review Board. Informed consent was waived.
Results: Seventy-four patients median age: 4.1 years (interquartile range [IQR] 2.0–10.1 at the time of starting long-term AC, M:F ratio 1.5:1), were followed-up at Sickkids, Toronto, between Jan/2003 and Dec/2011 and had at least one initial BMD scan, at a median of 3.6 years (IQR 1.5–7.5) from the time warfarin was started. Underlying conditions were: cardiac (85%), endocrine (8%), other reasons (7%), including rheumatic/renal diseases. The median AC duration was 7.8 years (IQR 5.2–12.4). 27/74 (36%) patients had additional LMWH therapy (median: 7.1 months [IQR 3.0–14.6]).
57/74 (77%) and 17/74 (23%) patients were categorized as low and high-risk groups, respectively. No statistical differences were found for age, sex, AC duration, dosing, previous LMWH, and time to 1st BMD. Only underlying condition was significant: whereas 80% of cardiac and 80% of other underlying conditions belonged to the low-risk group, 80% of endocrine patients were high-risk group ($P = 0.01$). Further investigation confirmed that the overall average z-score was −1.1, and −1.2 for cardiac and other conditions, and −3.9 for endocrine patients. Correlation between risk-group and condition was fair ($r = 0.4$).
Twenty-five patients (14 low vs. 11 high-risk) had an x-ray done. 7/25 (29%) suffered fractures; survival analysis revealed a significant difference in the time from AC-start to fracture between high and low-risk group (5.1 vs. > 15 years, log-rank $P = 0.032$).
13/48 (32%) patients reached an abnormal z-score at a median time from AC-start of 9.0 years (IQR: $3.5 \geq 15$ years). Log-rank test revealed no significant difference for sex ($P = 0.41$), preceding LMWH ($P = 0.27$), warfarin dose ($P = 0.94$), biomarkers abnormalities ($P = 0.41$), or underlying condition ($P = 0.06$). There was a statistically significant difference in the time from AC-start to abnormal z-score according to risk-group at presentation (high vs. low; 3.6 vs. > 15 years, $P < 0.0001$).
Conclusion: Children receiving long-term warfarin benefit from repeated bone health monitoring. Low-risk patients, defined as per their first BMD, appear to be stable over time. The first BMD also helps detecting children at higher risk of spontaneous bone fractures.

FS 02.3
Risk factors for the development of venous thromboembolism in childhood acute lymphoblastic leukaemia

Zuurbier CM[1], Stokhuijzen E[1], Van Den Bos C[2], Schouten-van Meeteren AYN[2] and Van Ommen CH[2]
[1]University of Amsterdam; [2]Emma Children's Hospital AMC, Amsterdam, the Netherlands

Background: Venous thromboembolism (VTE) frequently occurs during asparaginase (ASP) treatment in paediatric patients treated for acute lymphoblastic leukaemia (ALL). This complication causes significant morbidity. Identification of a susceptible population is crucial for effective thromboprophylaxis. However, risk factors for ALL-associated VTE have not been fully clarified.
Aims: The aim of this study was to investigate the incidence of VTE and to identify risk factors for the development of VTE in paediatric ALL patients treated according to the Dutch Childhood Oncology Group (DCOG) ALL IX or ALL X protocols.
Methods: A retrospective observational cohort study was performed for VTE among children (1–18 years), with newly diagnosed ALL receiving chemotherapy according to the ALL IX or ALL X protocol between February 1997 and January 2012. In the ALL IX protocol, patients were stratified into two risk groups: non-high risk (NHR) and high risk (HR). In the ALL X protocol, minimal residual disease was an important tool to stratify into three risk groups: standard risk (SR), medium risk (MR) and HR. All patients received central venous catheters: Broviac® or PAC®. Induction treatment included in the ALL IX protocol, day 0–49, dexamethasone and four doses of 6000 IU/m^2 ASP intravenously over a period of 2 weeks (day 29–40). The induc-

tion phase of the ALL X protocol, day 0–64, included prednisone and eight doses of 5000 IU/m^2 ASP intravenously over 3 weeks (day 12–33). Medical records were reviewed and all VTE were recorded. Furthermore, details of ALL diagnosis, treatment protocols, laboratory values of fibrinogen and antithrombin, and risk factors were recorded.
Results: Two hundred and five children (♂,n = 123; ♀, n = 82) treated according to the two different DCOG ALL protocols (ALL IX, n = 112; ALL X, n = 93) were included. The median age was 4.8 years (range 1–18 years). Totally, 19 children (9.3%; 95% CI: 5.3–13.3%) developed VTE; 9 (4.4%) during the induction phase and 10 (4.9%) during later treatment phases. In the induction phase, four VTE occurred in the central nervous system (45%) and five VTE were catheter-related (55%). During later treatment phases, two deep vein thromboses and eight catheter-related trombi occurred. During induction, univariate analysis showed that VTE was significantly more likely in children > 10 years of age (P = 0.031), in children treated according to the ALL X protocol (P = 0.012) and in children in MR or HR groups (P = 0.041). After induction, only MR and HR groups were associated with VTE (P = 0.005). Gender, body mass index, ALL-immunophenotype, type of catheter, antithrombin and fibrinogen levels, the presence of two or more of the following metabolic abnormalities: hyperuricemia, hyperkalemia and hyperphosphatemia, and infections appeared not to be associated with VTE. In the multiple regression analysis, after stepwise elimination, type of protocol (P < 0.0001) and risk group (P = 0.006) remained significantly associated with VTE during the induction phase.
Conclusion: VTE developed in about 9% of ALL paediatric patients. Protocol type including lower doses of ASP over a longer period and prednisone and the ALL protocol risk group were significant risk factors for the development of VTE.

Registry of congenital atypical HUS in Japan

Fujimura Y[1], Yoshida Y[1], Fan X[2] and Miyata T[2]
[1]Nara Medical University, Kashihara, Nara; [2]National Cerebral and Cardiovascular Center, Suita, Osaka, Japan

Thrombotic microangiopathies (TMAs) are pathological conditions characterized by microangiopathic hemolytic anemia, destructive thrombocytopenia, and renal dysfunction (organ failure). Two typical phenotypes of TMAs are thrombotic thrombocytopenic purpura (TTP) and hemolytic anemia (HUS), both of which are either caused by congenital or acquired form. Now it is well established that most of TTP patients have deficient activity of ADAMTS13, a von Willebrand factor-cleaving protease, due to its gene mutations or acquired autoantibodies to this enzyme. On the other hand, a major population of HUS patients develops in association with hemorrhagic enterocolitis by Shigatoxin-producing *E. coli* infection. However, a minor population of HUS patients, who usually do not accompany with diarrhea and therefore referred to atypical (a) HUS, is caused by uncontrolled complement activation due to gene mutations involved in the alternative pathway, such as complement factor H (CFH), complement factor I (CFI), membrane cofactor protein (MCP), thrombomodulin (THBD), complement component 3 (C3), and complement factor B (CFB). In addition, CFH auto-antibodies with or without gene mutations of CFH related proteins (CFHRs 1~5) have also been reported to be the cause of aHUS. Diagnostic criteria for congenital aHUS used in Japan is almost comparable to that of US and Western countries, and consisted of the abovementioned clinical features of TMA and the exclusion criteria of more than 5% of normal for ADAMTS13 activity. Since 1998, Nara Medical University (NMU) has been functioning as a nation-wide referral center for TMA in Japan through the protein-based analyses including ADAMTS13 and hemolytic assays, in collaboration with National Cerebral & Cardiovascular Center (NCVC), which takes charge of the gene analyses responsible for TMAs. Through this cohort study, we made a large registry of 1149 TMA patients until the end of 2012, in which 49 were the patients with congenital TTP (Upshaw-Schulman syndrome) and 55 were congenital aHUS. Among the 55 aHUS patients, a set of complement regulatory gene analyses was performed on 29 patients (23 at NCVC and nine at other institutions including foreign countries). As consequence, the gene mutations responsible for aHUS were identified in 22 patients (22/29, 76%), but were not identified in the remaining seven patients (7/29, 24%). The number of gene analysis on aHUS patients is still small in our registry, but the presence of two rare and consistent mutations of C3 (I1157T) and CFH (R1215Q) have been presented.

FS 03.3

SMTP-7, a novel thrombolytic with an anti-inflammatory potential, improves primate thrombotic stroke with reduced hemorrhage risk: a role of soluble epoxide hydrolase inhibition

Suzuki E[1], Matsumoto N[1], Sawada H[2], Nishimura N[2], Hasegawa K[2] and Hasumi K[1]
[1]Tokyo University of Agriculture and Technology; [2]TMS Co., Ltd., Tokyo, Japan

Background: There is increasing evidence showing a close correlation between inflammation and neuronal damage/hemorrhagic transformation after acute ischemic stroke, thereby development of novel stroke therapy, hopefully with a drug having cerebroprotective/anti-inflammatory potential, is urgently needed. The thrombolytic SMTP-7, a small molecule that promotes plasminogen activation through relaxation of plasminogen conformation, has excellent therapeutic activities in cerebral infarction in several rodent models. Unexpectedly, unlike the standard thrombolytic stroke drug t-PA, SMTP-7 has much wider therapeutic time window and even suppresses cerebral hemorrhage, possibly by triggering anti-inflammatory responses. In the course of our study, soluble epoxide hydrolase (sEH), which plays a major role in the regulation of the inflammatory response, was identified as a target molecule of SMTP-7. We further demonstrated its unique mechanisms of action against intrinsic sEH, which can account for anti-inflammatory and cerebroprotective efficacy *in vivo*.
Aims: Our study aims at (i) evaluating SMTP-7 efficacy in several animal models, and (ii) investigating precise molecular mechanism of sEH inhibition by SMTP-7.
Methods: A monkey photochemical-induced thrombotic middle cerebral artery (MCA) occlusion model, as well as several other rodent models, was utilized to evaluate therapeutic potentials of SMTP-7. LC-MS analysis was performed to measure total dihydroxyeicosatrienoic acid (DHET) level; a fatty acid dioxide converted from the anti-inflammatory fatty acid epoxyeicosatrienoic acid by sEH in HepG2 cells in culture and mouse liver *in vivo*.
Results: In the monkey MCA occlusion model, SMTP-7 (10 mg/kg, i.v. infusion) increased post-infusion MCA recanalization rate (32.5-fold, P = 0.043) and ameliorated post 24 h neurological deficit (by 29%, P = 0.02), cerebral infarct (by 48%, P = 0.025), and even cerebral hemorrhage (by 51%, P = 0.013) as compared with saline-treated control. In normal monkeys, SMTP-7 did not affect general physiological and hemostatic variables including coagulation and platelet parameters. SMTP-7 inhibited sEH in a cell-free enzyme assay as well as in HepG2 cells. The IC_{50} value of 1.7 μM in HepG2 cells is well below the level of pharmacological plasma concentration of SMTP-7 (3–30 μM), suggesting that SMTP-7 inhibits sEH *in vivo*. Inhibitory effect on sEH by SMTP-7 (10 mg/kg, i.v.) was also observed in the liver (by 53% P = 0.033) derived from normal mice after 30â˜60 min post treatment. The findings observed in our rodent models suggested an importance of the drug's cerebroprotective/anti-inflammatory properties via the inhibition of intrinsic sEH function, as well as its

regulated profibrinolytic action, serving as a physiological on-demand system coping with thrombotic events.
Conclusions: SMTP-7 is effective in treating thrombotic MCA occlusion stroke in monkeys, which can be due, at least in part, to the thrombolytic activity as well as anti-inflammatory efficacy via the suppression of intrinsic sEH function, thereby resulting in amelioration of neurological deficits, infarct size, and even hemorrhagic transformation.

FS 03.4
ACTN1 mutations cause congenital macrothrombocytopenia

Kunishima S[1], Okuno Y[2], Sanada M[2], Miyazaki K[3], Sakai M[4], Iguchi A[5], Miyano S[2], Saito H[1], Kojima S[6] and Ogawa S[2]
[1]Nagoya Medical Center, Nagoya; [2]The University of Tokyo, Tokyo; [3]Kitasato University School of Medicine, Kanagawa; [4]University of Occupational and Environmental Health, Kitakyushu; [5]Hokkaido University Graduate School of Medicine, Sapporo; [6]Nagoya University Graduate School of Medicine, Nagoya, Japan

Background: Congenital macrothrombocytopenia (CMTP) is a heterogeneous group of rare platelet disorders, characterized by a congenital reduction of platelet counts and abnormally large platelets, for which the causative genes are known only in approximately half the cases.
Aims: This study aims to identify novel causative genes for CMTP by next-generation sequencing.
Methods: We performed whole exome sequencing and targeted Sanger sequencing in CMTP cases in which a dominant mode of transmission had been suspected but no known responsible mutations had been documented.
Results: In 13 Japanese CMTP pedigrees, we identified six pedigrees (46%) with *ACTN1* variants, which co-segregated with CMTP. *ACTN1* encodes α-actinin-1, a member of the actin-crosslinking protein superfamily that participates in the organization of the actin-based cytoskeleton. Patients with variant *ACTN1* presented moderate macrothrombocytopenia with anisocytosis, but were either asymptomatic or associated with only a modest bleeding tendency. *In vitro* transfection experiments in Chinese hamster ovary cells demonstrated that mutant α-actinin-1 disrupted the normal actin-based cytoskeletal structure. Moreover, transduction of mouse fetal liver-derived megakaryocytes with patient-derived *ACTN1*-variants caused a disorganized actin-based cytoskeleton in megakaryocytes, resulting in the production of abnormally large proplatelet tips, which were reduced in number. In the entire cohort, *ACTN1* variants accounted for 5.5% of the dominant forms of CMTP cases and represent the fourth most common causative gene in Japanese individuals.
Summary/Conclusion: Our findings provide a novel insight of actin-based cytoskeleton in the pathogenesis of CMTP.

FS 03.5
Impaired haemostasis in Reelin-deficient mouse: a potential role of plasma Reelin in thrombin generation and fibrin clot formation

Tseng W-L[1], H C, Huang[2], Chen TH[1], Huang YH[1], Cheng J-Ch[3] and Tseng CP[1]
[1]Chang Gung University; [2]Graduate Institute of Medical Biotechnology and Laboratory Science, Tao-Yuan County; [3]Department of Medical Laboratory Science and Biotechnology, Taichung city, Taiwan

Background: Haemostasis prevents excessive bleeding during vessel wall injury and is properly controlled by a balance between platelets, coagulation factors, and endothelial cells. Assembly of factor Xa/Va on activated platelet results in the burst of thrombin generation that plays an important role in converting fibrinogen to fibrin. Reelin is an extracellular glycoprotein that was first identified in mice with the characteristic of reeling gait. In addition to the central nervous system, Reelin is present in the plasma and interacts with platelets, facilitates platelet lamellipodia formation and F-actin bundling and enhances full spreading of platelets on fibrinogen. Nevertheless, whether plasma Reelin has any functional link with haemostasis *in vivo* has not yet been elucidated.
Aims: In the present study, the *reeler* ($Reln^{-/-}$) mouse was used as the model to explore the potential role of Reelin on haemostasis.
Methods: Heterozygous *reeler* ($Reln^{+/-}$) mice were interbred to generate wild type ($Reln^{+/+}$), and homozygous ($Reln^{-/-}$) *reeler* mice. Thrombelastography (TEG) and calibrated automatic thrombogram (CAT) assays were used to analyze the integrity of coagulation system. Prothrombin time (PT) and activated partial thromboplastin time (aPTT) were used to confirm the functional impact of Reelin deficiency on haemostasis.
Results: $Reln^{-/-}$ mice displayed a normal platelet number and size with a prolonged tail-bleeding time and an increase in rebleeding rate. TEG analysis revealed that $Reln^{-/-}$ mice was impaired in blood coagulation. Of the five TEG analytical parameters, R, K, and a-angle were similar for $Reln^{-/-}$ and control mice. In contrast, $Reln^{-/-}$ mice displayed a significant decrease in MA and CI which measures the strength of a clot and overall assessment of coagulability, respectively. In accordance with these findings, $Reln^{-/-}$ mice displayed a slight decrease in coagulation time when compared to the $Reln^{+/+}$ and $Reln^{+/-}$ mice in PT assays. The dH value that measured scattered light intensity change for $Reln^{-/-}$ mice was significantly decreased when compared to the $Reln^{+/+}$ and $Reln^{+/-}$ mice. For aPTT assays, $Reln^{-/-}$ mice displayed a five-fold increase in the coagulation time when compared to the $Reln^{+/+}$ and $Reln^{-/-}$ mice. The average dH for $Reln^{-/-}$ mice was significantly lower than the dH for $Reln^{+/+}$ and $Reln^{+/-}$ mice. A loosen fibrin clot structure was observed for the blood clot obtained from the $Reln^{-/-}$ mice as revealed by scanning electron microscopy. CAT analysis further indicated that Reelin deficiency resulted in a decrease in thrombin generation. Of the six CAT analytical parameters, the lag time and time to peak (ttpeak) were similar for $Reln^{+/+}$, $Reln^{+/-}$ and $Reln^{-/-}$ mice. Notably, $Reln^{-/-}$ mice displayed a significant decrease in the rate of thrombin generation, peak thrombin concentration, start tail (indicator of anticoagulant activity) and ETP (indicator for the total amount of thrombin generation). Impaired thrombin generation thereby contributes to the formation of fibrin clots with reduced strength for the Reelin-deficiency plasma.
Conclusions: This study represents the first report to define a novel function of plasma Reelin in thrombin generation and fibrin clot formation. Reelin is therefore suggested to be a key component in the regulation of coagulation cascade and haemostasis.

FS 04.4
Education in the developing world

Meireles Rezende S
Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil

Thrombosis and haemostasis (T&H) is clearly emerging as a well-defined and growing subspeciality area. Although most of the professionals are specialists in Hematology, the field attracts a smaller number of professionals when compared to other subspecialties such as Oncohematology, Bone Marrow Transplant and Blood Transfusion. Furthermore, Thrombosis and Haemostasis is a complex field of Medicine, which requires education on clinical and laboratory training. This subspecialty is highly dependent on appropriate laboratory diagnosis, which can be expensive. This issue, in addition to few experts available and a lack of specialized centers makes the education on T&H in developing countries particularly challenging. An adequate

educational program in T&H should start at undergraduate levels of Medicine and related areas such as Pharmacy, Biochemistry, Biology and Biomedical Sciences. This strategy would attract young professionals to the field early on their carriers. Furthermore, training such as medical residency in Hematology, Internal Medicine and Clinical Pathology should address topics related to T&H with the aim of educating professionals with competence on diagnosis, treatment and research in the field. Indeed, in some countries (especially those located in Europe), a curriculum for T&H has been proposed and a role for a T&H specialist has been suggested. In the field of bleeding disorders, some countries have implemented training to educate medical professionals as hemophilia doctors. In the developing countries, these initiatives are still incipient and, therefore, a major effort is needed to implement education in T&H. In some countries, there is no Society of T&H, but of Hematology and its interest is, particularly, directed to the other fields of Hematology. In most of the cases, there is no T&H curriculum available during the medical residency in Hematology, Internal Medicine or Clinical Pathology. Lastly, the implementation of "state of art"diagnosis and treatment as well as research in T&H involves high costs which need public funding, not easily available. Some developing countries, however, have been capable of building good programs in T&H. In conclusion, education in T&H in developing countries is a major challenge. An appropriate approach needs training at early levels of education in the related fields with incentives, creation of a national curriculum for T&H, involvement of the related societies and close partnership with governmental bodies.

Adherence to prescribed treatment regimen is related to chronic pain among adolescent and young adults with moderate or severe hemophilia: Early results from the IMPACT QoL survey

Witkop ML[1], McLaughlin JM[2], Lambing A[3], Munn JE[4], Anderson LT[2] and Tortella B[2]

[1]Munson Medical Center, Traverse City, MI, USA; [2]Pfizer Specialty Care, Medicines Development Group, Collegeville, PA; [3]Henry Ford Adult Hemophilia & Thrombosis Treatment Center, Detroit; [4]University of Michigan Hemophilia Treatment Center, Ann Arbor, MI, USA

Background/Aim: Little data exist, especially for adolescents and young adults, about the relationship between adherence to prescribed hemophilia treatment regimens and chronic pain. We examined this relationship among moderate and severe hemophiliacs aged 13–25.

Methods: A convenience sample of hemophiliacs aged 13–25 completed an IRB-approved, cross-sectional, online survey that assessed, among other factors, regimen-specific adherence and chronic pain. Recruitment occurred at major hemophilia meetings, hemophilia treatment centers, and through social media from April through December of 2012. Adherence was assessed using the VERITAS-Pro and VERITAS-PRN for prophylactic and on-demand participants, respectively. VERITAS scores range from 24 (most adherent) to 120 (least adherent). Chronic pain was measured using the revised Faces Pain Scale (FPS-R). For purpose of analysis, chronic pain was dichotomized as *high* for those who reported their pain as 'moderate,' 'severe,' 'very severe,' or 'worst pain possible' (i.e. ≥ 4) and *low* for 'mild pain' or 'no pain' (i.e. < 4). Multivariable, parsimonious logistic regression models were constructed to assess factors associated with having high (vs. low) levels of chronic pain. Separate models were constructed to evaluate i) a combined VERITAS score among prophylactic and on-demand patients and ii) the VERITAS-Pro score among prophylactic patients only. Small sample size prevented analysis for on-demand (only) participants.

Results: Ninety-three adolescents and young adults with hemophilia completed the survey. Mild patients ($n = 13$) were excluded. Of the 80 participants (79 male) included in the final analysis, most had severe disease (91%), infused prophylactically (86%), and had Hemophilia A (91%). Fifty-one percent were aged 13–17 and most were white (76%), non-Hispanic (88%), and never married (93%). The majority (94%) had some type of health insurance, with the highest proportion having only commercial insurance (45%), only Medicaid (28%), or both (9%).

Mean VERITAS-Pro ($n = 69$) and PRN ($n = 11$) scores were 49.6 ± 12.9 (range 25–78) and 51.0 ± 11.6 (range 35–74), respectively. Chronic pain was reported as *high* for 35% of respondents (36% for prophylactic vs. 27% for on-demand, $P = 0.74$). Mean VERITAS-Pro scores for those with high and low chronic pain were 53.6 ± 12.3 vs. 47.4 ± 12.9, $P = 0.05$. VERITAS-PRN scores were similar across chronic pain status. Logistic regression analysis revealed that for each 10-point reduction (i.e. increase in adherence) in the combined VERITAS score (Pro and PRN) there was a 35% (OR = 0.65; 95% CI = 0.44, 0.96; $P = 0.03$) reduction in the odds of having high chronic pain. Among prophylactic respondents only, for each 10-point reduction in the VERITAS-Pro score there was a 39% (OR = 0.61; 95% CI = 0.39, 0.96; $P = 0.03$) reduction in the odds of having high chronic pain. Among prophylactic participants, the model also revealed that, compared to whites, non-whites were 4.42 (95% CI: 1.21, 16.1; $P = 0.02$) times as likely to report high chronic pain.

Summary/Conclusion: This study provides evidence that among adolescent and young adults with severe hemophilia, better adherence to prescribed treatment regimens (either prophylactic or on-demand) is associated with a significantly lower likelihood of having debilitating levels of chronic pain. Moreover, among prophylactic infusers, non-whites were > 4 times as likely as whites to report high levels of chronic pain.

NS 01.2

Effectiveness of patient education in VTE prevention: a nurse led collaborative local service improvement project

Brown R and Law C

NNMN, Berkhamsted, UK

Background: The National Institute for Health and Clinical Excellence (NICE) Quality Standard for venous thromboembolism (VTE) prevention (2010) states that all adult hospital in-patients and carers should receive both verbal and written information regarding VTE prevention on admission and discharge. Whilst much focus has been placed on VTE risk assessment and appropriate prophylaxis, it is widely acknowledged that nurses play a key role in patient education and this is central to delivering successful outcomes. The National Nursing and Midwifery Network (NNMN) for VTE prevention surveyed the current provision of educational information to evaluate its effectiveness.

Aims: To initiate a nurse-led collaborative local service improvement project across VTE Exemplar Centres to review and enhance the effectiveness of patient education for the prevention of VTE.

Methods: All VTE Exemplar Centres were invited to participate by contributing generic findings from a minimum of 10 patients interviewed at discharge from hospital. Patients were asked if they had received written and verbal information, along with 10 key questions relating to their level of understanding. Each participating hospital used its own standard literature. The Education Workstream Lead for the NNMN collated the findings.

Results: Thirteen centres collected data on 563 patients.

The median number of returns was 20 with a range of 10–226.

Content analysis identified 5 key themes relating to;

1) Provision of information:-patients who received leaflets didn't always read them, or found the leaflets too long or complex.

Patients that were given both written and verbal information had a better understanding of VTE prevention compared with either method alone.
2) Route of admission:-elective surgical patients were better informed than emergency surgical patients or medical patients.
3) Reducing risk of VTE:-patients had good understanding of how to reduce risks of VTE but had some significant misconceptions.
4) Appreciation of signs and symptoms of VTE:-patients more aware of those for DVT than PE.
5) Discharge information:-some patients were unsure of the duration of extended thromboprophylaxis and some were unsure who they should contact if they developed a problem after discharge.

Summary/Conclusions: The key themes identified from the collaborative work of 13 VTE Exemplar Centres across England highlight specific areas where efforts can be focused to improve the quality of patient education on VTE prevention. Whilst service improvement strategies will be implemented locally, the implications of these findings are useful for a wider audience and will be disseminated by the NNMN. This includes the promotion of;

combined provision of verbal and written information

reviewing the level and content of patient information for maximum effectiveness

strategies to empower nurses to lead service improvement through service evaluation, change management and re-evaluation

development of an aid memoire of key learning points to support the effective delivery of patient literature in alignment with the work of the National VTE Prevention Programme Board.

NS 01.3

An audit of the use of novel anticoagulants: Dabiagtran and Rivaroxaban for stroke prevention in AF

Rhodes S, Bond SK, Bailey J, Curtis K, McMullon A, Mowbray M and Percival M

Great Western Hospital, Wiltshire, UK

In June 2012 our Acute Trust adopted the NICE TA for both Dabigatran and Rivaroxaban as an alternative for the treatment of non-valvular AF in stroke prevention. Funding was agreed with the local PCT and both drugs were added to the formulary. Prior to this all oral anticoagulation initiation was performed in the secondary care led anticoagulant service and had been for the past 15 years. We had an agreement with both the Trust and local PCT that the anticoagulant service would continue to provide counselling for patients who were commenced on either of the two novel anticoagulants and then further care would be overseen by the general practitioner. As part of our care we added these patients to our existing database and also drew up a proforma for monitoring these patients.

The decision which oral anticoagulant to prescribe is made by the referring clinician and anticoagulant staff use a decision aid to ensure the suitability of the proposed anticoagulant. This takes into account NICE criteria, patient age, baseline bloods including renal function, FBC and LFT's, concurrent medications, history of previous dyspepsia or gastric ulcer. To date we have 26 patients on Rivaroxaban (24/26 on 20 mg and 2/26 on 15 mg) and 17 on Dabigatran (11/17 on 150 mg BD and 6/17 on 110 mg BD).

After a 3 month period we contact all patients by telephone to establish whether the patient has had any problems taking the current medication. This includes: any problems with bleeding (if yes then date of episode, whether hospitalisation was required and any intervention needed), any renal problems (including checking that any relevant up-to date screening has been checked) and for patients taking Dabigatran if they have had any episodes of dyspepsia.

We are also recording if any of the patients have been cardioverted whilst on either of the novel anticoagulants.

23/43 patients have had 3 month follow up.

Of these, 19 (83%) reported no adverse event or side effects that warranted discontinuation of the drug.

4/21 (17%) of patients taking Dabigatran discontinued the medication.

2/4 discontinued due to SOB and chest pain (thought to be cardiac in origin), 1 switching to warfarin and the other Rivaroxaban (also discontinued – patient preference).

2/4 discontinued due to dyspepsia (one despite taking a prescribed PPI). One switched to Rivaroxaban and the other is currently not taking any anticoagulation.

Conclusion: It is important to keep a database of these patients so we can monitor for any side effects and support both the patient and primary care colleagues.

One of the issues seen in secondary care is a lack of awareness that these are anticoagulants which has resulted in poor prescribing, where Dalteparin has been prescribed as well as Dabigatran or Rivaroxaban. No harm has come to the patient as the error has been picked up by the pharmacist but there needs to be extensive continuing education relating all novel anticoagulants until their use is more familiar.

Effective communication across all teams is essential to minimise the risk of prescribing errors.

Prolylcarboxypeptidase promotes angiogenesis and vascular repair

Adams GN[1], Merkulova A[2], Stavrou E[2], Fang C[2], Amer AM[2], Nakajima K[2], Simon DI[2], Jain MK[2] and Schmaier AH[2]

[1]*Cincinnati Children's Hospital Medical Center, Cincinnati;* [2]*Case Western Reserve University, Cleveland, OH, USA*

Background: Prolylcarboxypeptidase (PRCP) is a serine protease and endopeptidase on vasculature and kidney that degrades peptides with a Pro-X C-terminus (AngII, desArg9BK, $aMSH_{1-13}$). In kidney it is a major enzyme forming Ang-(1-7) (Am J Physiol Cell Physiol, In Press). PRCP hypomorphic mice (*PRCPgt/gt*) are lean, hypertensive, and prothrombotic (JCI 119:2130, 2009; Blood 117:3929, 2011). Although *PRCPgt/gt* are protected from metabolic insults (e.g. atherosclerosis), they have vascular inflammation. This injury is characterized by increased vessel ROS, reduced vasculo-protective transcription factors KLF2 and KLF4, reduced and uncoupled eNOS, reduced thrombomodulin with less protein C activation, and increased tissue factor and PAI-1.

Aims: Since PRCP levels influence vascular inflammation, we determined if PRCP also regulates vessel growth, migration, angiogenesis, and injury repair.

Methods: PRCP levels were manipulated in bovine aortic endothelial cells (BAEC) by siRNA and human PRCP cDNA (*hPRCP*) transfection. *hPRCP* was mutagenized at S179 and H455 (*hPRCPmut*). BAEC growth and proliferation were measured by counting and MTS color reaction. Cell ROS and apoptosis was assayed by dihydroethidium (DHE), HPLC, and annexin V. BAEC scratch assay assessed cell migration; aortic sprouts and matrigel plugs examined angiogenesis. Five mm punch biopsy wounds examined inflammation and repair angiogenesis. Femoral artery ligation examined ischemic injury repair angiogenesis. Femoral artery wire injury investigated vessel repair inflammation in $PRCP^{gt/gt}$ mice and $PRCP^{gt/gt}$ backcrossed in inflammation-protected MRP-$14^{-/-}$ mice.

Results: PRCP depletion by siRNA reduced BAEC growth, whereas transfection of *hPRCP* enhanced cellular proliferation. PRCP depletion is associated with increased ROS (by DHE and HPLC) and annexin V binding, and over-expression reduces ROS and apoptosis. Transfection of *hPRCP* or its active site mutant (*hPRCPmut*) rescued reduced cell growth after PRCP siRNA knockdown. These data indicate that PRCP levels directly affect cell growth, and this effect is not a function of its proteolytic activity. PRCP-depleted cells migrated less on scratch assay and murine $PRCP^{gt/gt}$ aortic segments had reduced sprout formation. Matrigel plugs in $PRCP^{gt/gt}$ mice had reduced hemoglobin content, less PECAM and NG2 staining, and a reduced NG2/PECAM ratio, indicating diminished angiogenesis. Skin wounds on $PRCP^{gt/gt}$ mice had delayed closure and reduced PECAM staining on day 7 but normal CD11b inflammatory response on day 2. $PRCP^{gt/gt}$ mice also had reduced reperfusion of the femoral artery after limb ischemia on days 7, 14 and 21 with decreased angiogenesis at day 28. After femoral artery wire injury, $PRCP^{gt/gt}$ mice had increased neointimal formation (neointima/media ratio) with increased CD45 leukocyte accumulation and Ki67 cellular proliferation. Mating $PRCP^{gt/gt}$ mice with MRP-$14^{-/-}$ mice reduced inflammation, cellular proliferation, and neointimal thickening after wire injury in the hypomorphic mice.

Summary: PRCP is known to regulate metabolism and vascular homeostasis. Deficiency of PRCP is associated with improved glucose tolerance and less insulin resistance but with sick blood vessels leading to hypertension and thrombosis. PRCP levels regulate endothelial cell growth, angiogenesis, and the response to vascular injury. This activity is not related to its protease function. This combined information suggests that PRCP is a unique regulator of vascular well-being and a target to promote vascular health.

OC 01.2

UPAR's domain 2 regulates single chain urokinase-mediated angiogenesis through beta-1-integrins and VEGFR2

Schmaier AH[1], Merkulova A[1], LaRusch GA[1], Mahdi F[2], Shariat-Madar Z[2], Sitrin RG[3] and Cines DB[4]

[1]*Case Western Reserve University, Cleveland, OH;* [2]*University of Mississippi, Oxford, MS;* [3]*University of Michigan, Ann Arbor, MI;* [4]*University of Pennsylvania, Philadelphia, PA, USA*

Background: The mechanism by which single chain urokinase (ScuPA) mediates angiogenesis is incompletely understood. Previous studies indicate that VEGF stimulation of VEGFR2 induces MMP-2 that activates ScuPA to tcuPA bound to uPAR to stimulate angiogenesis. Alternatively, soluble uPAR through its sequence $S^{88}RSRY^{92}$ stimulates angiogenesis through a protease-independent mechanism. CD146 stimulates angiogenesis through up-regulation of ScuPA, uPAR, VEGF and VEGFR2.

Aims: The purpose of this study is to map a ScuPA signaling pathway in endothelial cells that promotes angiogenesis and determine if it is similar to that described for factor XII (Blood 115:5111, 2010).

Methods: Cultured HUVEC (human umbilical vein EC), HMEC (human microvascular EC) and SIN$1^{-/-}$ MEFs treated with ScuPA, tcuPA, or APMSF-treated tcuPA were utilized for the signaling studies. Domain 2 (D2) of uPAR was modeled for the ScuPA and HK binding regions using Cn3D4.3 from NCBI. Peptides from uPAR's D2 and HK's domain 5 (D5) mapped ScuPA's binding region. MEK and PI3 kinase inhibitors characterized the mechanism for ScuPA-induced pERK1/2 and $pAktS^{473}$. Antibodies to beta-1-integrin, AG1478, and PP3 characterized the signaling pathways. siRNA to HER1-4 and VEGFR2 determined the communicating tyrosine kinase for ScuPA-induced signaling. ScuPA-induced cell proliferation and BrdU incorporation was determined. The pathway to ScuPA-induced *in vitro* sprouting and *in vivo* matrigel plug angiogenesis was determined.

Results: ScuPA (> 4 nM), APMSF-treated tcuPA or tcuPA induces pERK1/2 (MAPK44 and 42) and $pAktS^{473}$ in HUVEC or HMEC. ScuPA-induced activation of pERK1/2 is blocked by PD98059 or U0126 and $pAktS^{473}$ inhibited by Wortmannin or LY294002. ScuPA (32 nM) or protease-inhibited two-chain uPA stimulates pERK1/2 to the same extent, indicating that signaling is not dependent on enzymatic activity. ScuPA induces pERK1/2, but not $pAktS^{473}$, in SIN$1^{-/-}$ MEFs indicating that the two pathways are not identical and ScuPA interacts with uPAR independent of domain 1. Modeling of uPAR's crystal structure indicates that its domain 2 is on the surface and it does not interact with the ATF of ScuPA and uPAR's domain 1. Peptides from uPAR's D2 or HK's D5 or cleaved HK compete with ScuPA for induction of pERK1/2 and $pAktS^{473}$. A peptide to the integrin binding site on uPAR, a beta-1-integrin peptide that binds uPAR, antibody 6S6 to beta-1-integrin, the tyrosine kinase inhibitors AG1478 or PP3, and siRNA knockdown of VEGFR2, but not HER1-4, each block ScuPA-induced pERK1/2 and $pAktS^{473}$. ScuPA initiated cell proliferation is blocked by MEK and PI3 kinase inhibitors, antibody 6S6, and uPAR D2 and HK D5 peptides. ScuPA promotes aortic sprouts and matrigel plug angiogenesis in normal, but not uPAR deficient mouse aorta or mice, respectively, that is blocked by PD98059, LY294002, AG1478 or HKa.

Summary: These data suggest that ScuPA promotes endothelial cell proliferation and angiogenesis through a non-proteolytic signaling pathway, similar to factor XII, mediated by interactions involving uPAR's D2, beta-1-integrin, and VEGFR2. HKa's D5 peptides down regulate this pathway by, at least, blocking ScuPA binding to uPAR's D2. ScuPA, uPAR, VEGF, and VEGFR2 function in an autoregulatory and autocrine manner to promote angiogenesis.

OC 01.3

Junctional adhesion molecule-A modulates angiogenesis through transcriptional regulation of VEGF/VEGFR2 expression

Naik MU, Cooke VG, Chatterjee S and Naik UP
University of Delaware, Newark, DE, USA

Background: The process of angiogenesis is associated with a number of human pathologies. Vascular endothelial growth factor (VEGF) is a potent angiogenic growth factor. VEGF expression is upregulated during ischemia and tumor growth. VEGF expression and thus VEGF-dependent angiogenesis are normally suppressed in healthy adults. The mechanism of this suppression is not known.
Aim: To show that junctional adhesion molecule-A (JAM-A), a tight junction protein expressed on endothelial cells, is an endogenous suppressor of VEGF-induced angiogenesis.
Methods: Using gene-targeted Jam-A null mice, we performed *in vivo* tumor growth, and a variety of angiogenesis assays such as MatrigelÒ plug and aortic ring sprouting. Wild-type (WT) mice were used as controls. Vascular permeability was assessed by Miles assay using Evans blue dye. Real-time PCR and Western blot analysis were used to assess gene expression.
Results: We found that murine melanoma tumor growth and associated angiogenesis were significantly augmented ($P < 0.001$) in Jam-A null mice compared to WT mice. Additionally, Jam-A null mice showed significantly enhanced ($P < 0.004$) vascular permeability. Furthermore, VEGF-, but not FGF-2-dependent angiogenesis is significantly augmented ($P < 0.001$) in the absence of Jam-A. Vascular endothelial cells isolated from Jam-A null mouse aorta showed significantly enhanced ($P < 0.05$) cell migration and tube-like structure formation ($P < 0.05$) in response to VEGF. Additionally, we found the plasma levels of VEGF in Jam-A null mice to be significantly ($P < 0.000001$) and age-dependently increased compared to WT mice. Furthermore, both mRNA and protein levels of VEGF and its receptor VEGFR2 were significantly increased ($P < 0.001$) in Jam-A null endothelial cells, suggesting that the VEGF/VEGFR2 signaling axis is augmented in the absence of Jam-A. To further confirm this finding, we injected anti-VEGFR2 (DC101) into the Jam-A null mice inoculated with murine melanoma (B16F0) cells. Inhibition of VEGF/VEGFR2 signaling by DC101 significantly reduced ($P < 0.00003$) tumor growth and associated angiogenesis in Jam-A null mice. Additionally, vascular permeability observed in Jam-A null mice was completely abrogated upon DC101 treatment. When tested if the expression of soluble Flt (sFlt), which is known to trap VEGF, is downregulated in the absence of Jam-A, we found no significant difference in sFlt mRNA expression in Jam-A null endothelial cells compared to WT. In order to determine the mechanism of this upregulation of the VEGF signaling axis, we tested the expression of hypoxia inducible factor-1a (HIF-1a) and inhibitor of DNA binding 1 (Id1), two transcription factors known to upregulate VEGF and VEGFR2 gene expression respectively. Interestingly, mRNA and protein levels of both HIF-1a and Id1 were significantly augmented ($P < 0.02$) in endothelial cells lacking Jam-A. Consistent with this finding, the overexpression of JAM-A in HUVECs attenuated the levels of Id1.
Summary: The results presented here suggest that JAM-A suppresses VEGF/VEGFR2 expression in endothelial cells by attenuating HIF-1a and Id1 expression, thus suppressing adult angiogenesis. During pathological conditions such as ischemia and tumor growth, it is possible that JAM-A levels are downregulated, thus supporting pathological angiogenesis.

OC 01.4

The intestinal microbiota triggers tissue factor-dependent vascular remodelling in the small intestine via the angiopoietin-1/Tie-2 pathway

Reinhardt C[1], Bergentall M[2], Brandão I[1], Hörmann N[1], Walter U[1], Ruf W[3] and Bäckhed F[2]
[1]Center for Thrombosis and Hemostasis (CTH), Mainz, Germany; [2]The Wallenberg Laboratory for Cardiovascular Research at Sahlgrenska Academy, Gothenburg, Sweden; [3]The Scripps Research Institute, La Jolla, CA, USA

After birth the epithelial surfaces of the newborn are colonized by myriads of different bacteria that form one of the most densely colonized ecosystems on earth – the gut microbiota. We have used germ-free mouse technology to demonstrate that colonization with an intestinal microbiota promotes the formation of intricate capillary networks in the villi of the distal small intestine. The exact mechanisms that trigger mucosal vascular remodeling in the small intestine are largely unexplored.
We found that conventionally-raised (CONV-R) mice show wider villus structures and increased vascularization compared with germfree (GF) control mice. This is paralleled by increased angiopoietin-1 (Ang-1) mRNA levels and increased Tie-2 phosphorylation in the distal part of the small intestine. Furthermore, transcript levels of apelin (Apln), a regulator of vascular caliber size and cord hollowing that is regulated via the Ang-1/Tie-2 pathway are also increased in colonized mice. Isolated primary epithelial cells from CONV-R mice also showed increased Ang-1 mRNA levels. Since tissue factor (TF) has previously been implicated in angiogenesis and augments activation of protease-activated receptors (PARs) we blocked the intestinal TF function with an inhibitory antibody. Ex-germfree mice that were colonized with a gut microbiota (CONV-D) and treated with a functional inhibitory anti- TF antibody showed reduced vascularization and reduced Ang-1 mRNA levels compared to isotype-treated littermate controls. In line with this finding, decreased vascularization was observed in the small intestine of low TF mice that are expressing about 1% of human TF relative to mouse TF. The small intestinal epithelium is a major site of TF expression and both expression of fully N-glycosylated TF antigen and PAR1 expression was elevated in CONV-R mice compared with GF controls. TF expression could be induced by peptidoglycan treatment in the small intestinal epithelial cell line MODE-K. Increased TF procoagulant activity was also reflected by increased thrombin-antithrombin complex (TAT) levels and increased TF-dependent Factor Xa generation in CONV-R mice. Treatment of primary intestinal epithelial cells with thrombin resulted in increased phosphorylation of the TF cytoplasmic domain. In contrast, reduced TF cytoplasmic domain phosphorylation was noted upon inhibition of thrombin with hirudin in CONV-D mice and in CONV-D mice where TF was blocked with anti-TF suggesting that the TF cytoplasmatic domain could be involved in vascular remodeling in the small intestine. Indeed, we found small intestinal vascularization and expression of Ang-1 reduced in PAR1-deficient mice and in mice lacking the TF cytoplasmic domain. The functional importance of Ang-1 for vascular remodeling in the small intestine is further corroborated by inhibition of Ang-1 with the peptibody mL4-3, which resulted in inhibition of Tie-2 phosphorylation and in decreased villus vascularization.
Collectively, we revealed how the intestinal microbiota can activate vascular remodeling in the distal small intestine via the TF/PAR1/Ang-1 signaling axis. Apln could represent a novel factor involved in microbiota-induced intestinal vascular remodeling. Our findings exemplify how gut microbes can impact angiogenic signaling pathways to shape their habitat.

Tissue factor rich endothelial-microparticles induce angiogenesis and post-ischemic revascularization

Badimon L, Arderiu G and Peña E

Cardiovascular Research Center (CSIC-ICCC), IIBSantPau, Barcelona, Spain

Therapeutic angiogenesis may be a promising strategy for treating ischemia. However, the mechanisms of angiogenesis need to be further elucidated. Tissue Factor (TF) has shown to induce microvessel formation, but whether tissue factor-rich endothelial microparticles (TF+EMPs) released from activated endothelium induce angiogenesis has not been shown. Here we hypothesized that TF+EMPs trigger or facilitate angiogenesis by paracrine regulation. We used human dermal microvascular endothelial cells, human microvascular endothelial cells and human vascular smooth muscle cells. TF+EMPs shed from TF overexpressing migrating endothelial cells were used to perform *in vitro*, *ex vivo* and *in vivo* experiments. Endothelial cell activation and phenotype change, from quiescent to angiogenic, induces significant TF+EMPs release (0.8 ± 0.3 μg/μL vs 6.6 ± 0.5 μg/μL; $P < 0.001$). Released TF+EMPs showed autocrine and paracrine effects. TF+EMPs rapidly adhered to smooth muscle cells (SMC) in a β1-dependent fashion and increased SMC migration through β1-integrin, Rac1, and ERK1/2 activation independently of PAR2 signaling. Functionally, TF+EMPs up-regulated angiogenesis in aortic sprouting assays in a β1-integrin dependent pathway. Importantly, TF+EMPs induced angiogenesis in an *in vivo* model in which matrigel plugs containing TF+EMPs were implanted subcutaneously into nude mice. Finally, using a murine hindlimb ischemia, TF+EMPs enhanced collateral flow recovery and capillary formation in non-perfused adductor muscles ($N = 5$) in comparison to control buffer and EMPs without TF. The TF+EMPs -induced increase in *in vivo* angiogenesis operated through β1-integrin signaling via Rac1, and ERK1/2-dependent pathway. In conclusion, these experiments show that activated endothelial cells are able to further induce angiogenesis by releasing microparticles enriched in TF. These results suggest that TF-EMP could be a mechanism to overcome the consequences of arterial occlusion and tissue ischemia by promoting post-ischemic neo-vascularization and tissue reperfusion.

OC 01.6

Protease Nexin-1 regulates the retinal vascular development

Arocas V[1], Selbonne S[1], Boulaftali Y[2], Jandrot-Perrus M[1] and Bouton M-CH[1]

[1]Inserm, Paris, France; [2]The University of North Carolina, Chapel Hill, NC, USA

Angiogenesis is a process tightly controlled by a physiological balance between stimulatory and inhibitory signals for blood vessel growth, involved in reparative neovascularisation and in various ischemic and inflammatory diseases. Among the regulatory molecules, we recently identified serpinE2, or protease nexin-1 (PN-1), as an underestimated player of the angiogenic balance. PN-1 belongs to the serpin family of structurally related proteins that are present in the plasma or in tissues and play a central role in the regulation of protease activity. PN-1 is expressed by vascular cells, is secreted by platelets upon activation, and is often found overexpressed at sites of tissue injury. It is the most efficient tissue inhibitor of thrombin but also a powerful inhibitor of plasminogen activators, proteases largely involved in tissue remodelling.

We recently pointed out the anti-angiogenic activity of PN-1 *in vitro* on VEGF-induced HUVEC responses, *ex vivo* in the aortic ring assay and *in vivo* in the Matrigel plug assay, using PN-1 deficient mice. These effects are related to the interaction of PN-1 with endothelial cells glycosaminoglycans but do not require the anti-protease activity of the serpin. In this study, we used the well characterized postnatal vascular development of newborn mice retina, in which an organized bidimensional vascular architecture develops from the optic disk to the retina periphery, to further investigate the role of PN-1 in physiological angiogenesis and its mechanism of action. This vascular network can be observed by endothelial cell staining with markers such as isolectin B4. We observed that PN-1−/− retina display increased retinal vascularization in the postnatal period, with a rise in capillary thickness and density. Interestingly, the number of veins/arteries in the retina is increased in PN-1 deficient mice retina, from 4 to 5 in wild-type mice (WT), to 6–7 in PN-1−/− mice. Using transgenic (PN-1-lacZ) mice expressing X-Gal under the promoter of PN-1, we observed by X-Gal staining that PN-1 is expressed in the retinal vasculature. Retinal PN-1 expression, analyzed in WT whole retina lysates by immunoblotting, was elevated in the first postnatal days and progressively decreased to a very low level in adult retina. We did not observe any difference in the kinetics of retinal vasculature development, in VEGF expression, or in the overall retinal structure.

To go further in the mechanism of anti-angiogenic activity of PN-1, we performed antibody arrays on mice retina lysates, and PCR arrays on mice retina RNA. These studies identified angiogenesis-related factors that are differentially expressed in WT and PN-1-deficient newborn mice, in particular Midkine, Smad 5 and Sonic hedgehog, whose overexpression was confirmed by RT-PCR. We are now investigating how modification of expression of these factors could mediate the PN-1 anti-angiogenic effect.

Altogether, our results thus indicate that PN-1 limits physiological angiogenesis and has a real important anti-angiogenic potential. The characterization of its role in angiogenesis would not only increase our understanding in the functions of PN-1 in the development of diseases but may also provide important therapeutic strategies.

Antithrombotic treatment of splanchnic vein thrombosis in the ISTH international registry: results of 6-month follow-up

Riva N[1], Ageno W[1], Schulman S[2], Bang S-M[3], Sartori MT[4], Grandone E[5], Beyer-Westendorf J[6], Barillari G[7], Di Minno D[8], Duce R[9], Malato A[10], Santoro R[11], Poli D[12], Verhamme P[13] and Dentali F[1]

[1]Department of Clinical and Experimental Medicine, Insubria University, Varese, Italy; [2]McMaster University, Hamilton, ON, Canada; [3]Seoul National University, Seoul, South-Korea; [4]University of Padua, Padua; [5]IRCCS Casa Sollievo Della Sofferenza, S.Giovanni Rotondo, Italy; [6]Dresden University Clinic, Dresden, Germany; [7]Ospedale di Udine, Udine; [8]University of Naples, Naples; [9]Galliera Hospital, Genoa; [10]Cattedra ed UO di ematologia con trapianto, Palermo; [11]Azienda Ospedaliera Pugliese-Ciaccio, Catanzaro; [12]Careggi Hospital, Florence, Italy; [13]Leuven University, Leuven, Belgium

Background: Treatment of splanchnic vein thrombosis (SVT) is a clinical challenge due to heterogeneity of clinical presentations, increased bleeding risk and lack of evidences from clinical trials.

Aims: We carried out an international registry aimed to describe current treatment strategies and factors associated with therapeutic decisions in a large prospective cohort of SVT patients.

Methods: Between May 2008 and January 2012, consecutive SVT patients were enrolled in the registry and information on clinical presentation, risk factors, and therapeutic strategies was collected in an electronic database. Clinical outcomes during the first 6 months of treatment were documented. A two-year follow up is ongoing.

Results: Six hundred and thirteen patients from 12 countries were enrolled in the registry. Mean age was 53.1 (SD ± 14.8) years (range 16–85); 62.6% were males, 74.4% Caucasians. SVT occurred in the portal vein in 470 patients, in the mesenteric vein in266, in the splenic vein in 139, and in the supra-hepatic veins in 56; 38.8% of patients had multiple vein segments involved. In 29.8% of patients SVT diagnosis was incidental. Most common risk factors included cirrhosis (27.8%), solid cancer (22.3%), intra-abdominal inflammation/infection (11.5%), surgery (8.9%), and myeloproliferative neoplasm (MPN) (8.2%); in 27.6% of patients SVT was idiopathic.

During the acute phase, 471 (76.8%) patients were treated with anticoagulant drugs: unfractionated heparin (10.4%), low molecular weight heparin or fondaparinux (66.4%), vitamin K antagonists (VKA) (48.5%). Four patients received aspirin, 9 received thrombolysis. A total of 135 patients (22.0%) remained untreated. Of patients with incidentally diagnosed SVT, 61.1% received anticoagulant treatment.

Currently, information on treatment and clinical events occurred during the first 6 months of follow-up is available for 570 patients (96.1% of the population available for follow-up, since three centres participated in the baseline phase only). Baseline characteristics of patients with available follow-up were similar to those of patients with unavailable follow-up at the time of this analysis.

At 6 months, 79.2% of treated patients were still receiving anticoagulant treatment, while the remaining had stopped treatment earlier.

Venous thromboembolic events, including recurrent SVT and other site venous thromboembolism occurred in 26 patients (4.56%, 95% CI 3.06–6.70), 19 in treated patients (4.3%) and 7 in non-treated patients (5.5%). Major bleeding occurred in 18 patients (3.16%, 95% CI 1.94–5.04), 12 while on anticoagulant treatment (2.7%) and 6 in not-treated patients (4.7%). Death occurred in 55 patients (9.65%, 95% CI 7.41–12.45), 40 in treated patients (9.0%) and 15 in non-treated patients (11.8%).

Conclusions: The large majority of patients observed in our prospective cohort received anticoagulant treatment for their SVT, and 79.2% of them continued for at least 6 months. The incidence of both recurrent thrombosis and major bleeding events during this 6-month period is non-negligible, suggesting the need for a careful individual evaluation of the risks and benefits of anticoagulant treatment in SVT patients.

OC 02.2

What is the clinical impact of major bleedings with rivaroxaban? Results from the pooled EINSTEIN studies

Eerenberg ES, Middeldorp S, Levi M, Lensing AWA and Büller HR
[1]*Academic Medical Center, Amsterdam, the Netherlands*

Background and aims: Rivaroxaban is one of the new oral anticoagulants, a member of the class of factor Xa inhibitors, that can be prescribed in a fixed dose, making regularly monitoring and dose adjustments unnecessary. In the EINSTEIN studies, rivaroxaban proved to be safe and effective in comparison to standard of care with enoxaparin/vitamin K antagonists (VKA; target INR 2.0–3.0) in treating acute deep vein thrombosis and pulmonary embolism and versus placebo for the prolonged treatment of both diseases. Nevertheless, as any anticoagulant, it carries a risk of bleeding. There is little knowledge on how bleedings during treatment with new oral anticoagulants develop. Therefore, all major bleedings during therapy with rivaroxaban and standard of care from the EINSTEIN studies were blindly assessed for their clinical impact and the measures that were required.

Methods: Two investigators (SM, HRB) performed a descriptive subgroup analysis on major bleedings in patients treated with either rivaroxaban (15 mg twice daily for the first 3 weeks, followed by 20 mg once daily) or standard of care. In the classification for *clinical presentation*, events were assigned to category one if the presentation was without any clinical emergency. The second category was reserved for all bleedings that could not be classified to any of the other three categories. Category three was used for bleedings presenting with great medical emergency; e.g. hemodynamic instability; or severe disability. The fourth category was applied to all bleedings with an (almost) immediate fatal outcome. The first category of the classification for *clinical course* was assigned to bleedings for which only standard measures were applied to treat discomfort. Bleedings requiring standard measures such as transfusions of erythrocytes, and straight forward interventions were placed in category two. Bleedings from the third category were described as life threatening requiring immediate and elaborate measures to avoid death. Category four comprised all bleedings for which death was unavoidable, so that no life saving attempts were made.

Results: Rivaroxaban-associated major bleeding events had a milder presentation (82% presented as categories one and two, versus 65% for standard of care). In 80% of all major bleeding events associated with rivaroxaban, the clinical course was also mild (category one and two, 68% of standard of care associated bleeds acted likewise).

Conclusions: Rivaroxaban associated major bleeding events appear to have a milder presentation, and to take a milder course in comparison to major bleeding events with standard of care, in patients who were treated for venous thromboembolism in the EINSTEIN studies.

OC 02.3

Subgroup analysis of the FONDACAST study comparing fondaparinux to low-molecular-weight heparin for the prevention of venous thromboembolism after an isolated, non-surgical below-knee injury

Samama CM[1], Riou B[2], Roy P-M[3], Sautet A[4], Mismetti P[5] and Van Der Veen A[6]
[1]*Hôtel Dieu and Cochin University Hospitals;* [2]*La Pitié Salpêtrière University Hospital, Paris;* [3]*Angers University Hospital, Angers;* [4]*Saint Antoine University Hospital, Paris;* [5]*Saint-Etienne University Hospital, Saint-Etienne, France;* [6]*Catharina Hospital, Eindhoven, Netherlands*

Background: In a prospective, randomized, open-label study in 1349 patients requiring 21–45 days of immobilization (cast/brace), for below-knee, isolated, non-surgical injury, with at least one risk factor for venous thromboemboslism (VTE), once-daily s.c. fondaparinux 2.5 mg (1.5 mg if creatinine clearance 30–50 mL/min) was more effective than once-daily s.c. nadroparin 2850 aXa IU (0.3 mL) in preventing VTE, with no significant difference in terms of tolerability, both drugs being administered until mobilization (1).

Aims: To assess whether efficacy results were consistent across prespecified subgroups.

Methods: The incidence of the primary efficacy outcome up to complete mobilization plus 2 days, i.e. the composite of VTE [asymptomatic (ultrasonographically detected) or symptomatic deep-vein thrombosis (DVT) or symptomatic pulmonary embolism (PE)] or death was examined on the intent-to-treat population in pre-specified subgroups according to key demographic and below-knee injury characteristics, as well as potential risk factors for VTE. All events were blindly adjudicated by an independent committee. For each subgroup, treatments were compared using a Fisher's exact test. Odds ratio (OR) of fondaparinux/nadroparin and 95% confidence intervals (CI) were estimated using a univariate exact logistic regression model. The protocol was approved by independent Ethics Committees and written informed consent was obtained from all patients before inclusion.

Results: Overall, OR of fondaparinux/nadroparin in the subgroups examined were consistent with the overall study results on primary efficacy (OR: 0.30, 95% CI: 0.15–0.54, $n = 1170$). In each subgroup in which OR showed statistically significant difference between treatments in the risk of VTE or death, this risk was lower in fondaparinux-patients than in nadroparin-patients. OR were consistent according to age, gender, weight, body-mass index, or whether or not the patients have had previous VTE, a history of- or active cancer,

one, two or three risk factors for VTE, and whether or not they were receiving aspirin or antiplatelet agents at randomization. There were only 22 patients with a creatinine clearance < 50 mL/min, and no VTE events or death were reported in these patients. OR were also consistent irrespective of whether the patients had a bone fracture (n = 1041, OR: 0.31, 95% CI: 0.16–0.58) or not (n = 129, OR: 0.27, 95% CI: 0.00–2.51), the bone fracture was proximal (n = 60, OR: 0.60, 95% CI: 0.05–5.70) or distal (n = 981, OR: 0.29, 95% CI: 0.14–0.56), the injury was severe (n = 1066, OR: 0.31, 95% CI:0.16–0.57) or not (n = 104, OR: 0.42, 95% CI: 0.00–5.52), and the immobilization was rigid (n = 1050, OR=0.28, 95% CI: 0.14–0.52) or semi-rigid (n = 102, OR=1.04, 95% CI: 0.01–83.28).

Conclusions: In patients at risk of VTE immobilized following injury to the lower extremity, the statistically significant superior efficacy of fondaparinux 2.5 mg (1.5 mg if creatinine clearance 30–50 mL/min) *versus* nadroparin 2850 aXa IU (0.3 mL) in reducing the risk of VTE or death was consistent across all subgroups examined and with the overall study results.

OC 02.4

Effect of dabigatran etexilate on the risk of myocardial infarction and other cardiac events: a systematic review and updated dose-response meta-analysis of randomized controlled trials

Douxfils J[1], Buckinx F[2], Mullier F[3], Rabenda V[2], Reginster J-Y[2], Hainaut P[4], Bruyère O[2] and Dogné J-M[1]

[1]University of Namur, Namur; [2]University of Liège, Liège; [3]CHU UCL Mont-Godinne-Dinant, Yvoir; [4]UCL – Clinique Universitaire Saint-Luc, Bruxelles, Belgium

Background: Dabigatran etexilate (DE) is an oral direct thrombin inhibitor widely used for the prevention of venous thromboembolic events in major orthopedic surgery and in stroke prevention in patients with non-valvular atrial fibrillation. Early signals of an increased risk of myocardial infarction (MI) in clinical trials raised concerns about its use, particularly in patients with coronary disease.

Aims: We undertook an updated dose-response meta-analysis of randomized controlled trials (RCTs) to assess the possible association between the use of DE and the risk of MI or other cardiac events.

Methods: We conducted searches of the published literature, and a clinical-trials registry maintained by the drug manufacturer. Criteria for inclusion in our meta-analysis included all RCTs and the availability of outcome data for MI and cardiac events. Among the 318 unique references identified by all searches, there were 14 RCTs of which 13 fulfilled inclusion criteria. Three of them did not contribute to the analysis since there were no MI or other cardiac events reported. Stratification analyses by comparators (warfarin, placebo or enoxaparin) and doses of DE (150 mg *bid* and 110 mg *bid*) and sensitivity analyses were conducted. Statistical heterogeneity across trials was assessed with the Cochran Q-test and I^2 statistics.

Results: In the DE group, there were 292 MIs among the 23 839 exposed patients which represented an absolute risk of 1.23%. The overall odd ratio (OR) for MI was 1.32 (95% CI, 1.07–1.63; P = 0.010). When compared to warfarin, enoxaparin or placebo regimens, estimated OR for MI were 1.38 (95% CI: 1.08–1.77; P = 0.009), 0.96 (95% CI: 0.57–1.60; P = 0.869) and 1.70 (95% CI: 0.80–3.58; P = 0.165), respectively. In RCTs using the higher licensed DE dose (150 mg *bid*), the OR for MI was 1.45 (95% CI: 1.10–1.90; P = 0.008), and 1.41 (95% CI: 1.07–1.88; P = 0.016) when compared to any comparator or to warfarin, respectively. The sensitivity analyses preserved a significant increase of the MI associated with DE when compared with warfarin dropping one study at a time. The overall OR for MI was 1.33 (95% CI: 0.99–1.77; P = 0.057) for DE 110 mg *bid*. Additional analysis with a limited number of studies showed that there was no association between other cardiac events and DE based on 841 events. No publication bias was found and the observed heterogeneity was negligible.

Conclusions: This meta-analysis of RCTs provides robust evidence that DE is associated with a significantly increased risk of MI, especially at high dose (150 mg *bid*). No firm conclusion can be taken with the lower DE dose (110 mg *bid*) because of the limited number of studies included in this meta-analysis. Health care professionals and regulators should consider appropriate strategy to prevent such serious adverse drug reactions. The limitation of the use of DE in patients at high risk or suffering from coronary heart disease, the concomitant use of aspirin or switching to a FXa inhibitor should be carefully considered.

OC 02.5

Management of anticoagulation with vitamin k antagonists: can the time in therapeutic range (TTR) be used to optimize the interval between measurements?

Moreira CS[1], Leitão P[2], Gonçalves V[2], Morais S[3], Leite F[3], Campos M[3] and Cruz E[3]

[1]Serviço de Hematologia Clínica – Secção de Trombose e Hemostase; [2]Izasa Portugal, Werfen Group; [3]Centro Hospitalar do Porto – Hospital de Santo António, Porto, Portugal

Background: The efficacy and safety of vitamin K antagonists (VKA) for the prevention of thromboembolism are dependent on the time for which the International Normalized Ratio (INR) is in the therapeutic range. This requires regular monitoring and appropriate dose adjustment. It has been reported that anticoagulation clinics should aim for a time in therapeutic range (TTR) between 70–80% to optimize benefit and minimize hemorrhagic and thrombotic complications.

Aims: The goal of our study was to evaluate quality of anticoagulation monitoring with the objective to adopt the new recommendations of interval between measurements of 12 weeks (according to 2012 guidelines of American College of Chest Physicians), instead of the current 8 weeks, using TTR determined by Rosendaal method.

Methods: We retrospectively analysed data of the last 6 years (September 2006 to June 2012) including patients that are regularly followed up at the outpatient Anticoagulation Clinic of a central hospital under anticoagulation for at least 8 weeks. 61 988 appointments corresponding to 2087 patients were analyzed. Patients were divided according to target INR in three groups: Group 1 with target INR 2-3, including 1927 patients corresponding to 54 325 appointments with mean age 65 ± 15 years, majority (44%) with atrial fibrilation; Group 2 with target INR 2.5–3.5, including 120 patients corresponding to 5754 appointments with mean age 54 ± 8 years, majority (88%) with mechanical heart valves; Group 3 with target INR 3–4, including 40 patients corresponding to 1909 appointments with mean age 41 ± 16 years, majority (65%) with antiphospholipid syndrome.

Results: In general, patients in Group 1 had TTR of 83%, patients in Group 2 had TTR of 74% and patients in Group 3 had TTR of 54%. Analyses of patients with longer mean interval between appointments (4–8 weeks interval) showed that there was no decrease of monitoring quality: patients in Group 1 had TTR of 86%, patients in Group 2 had TTR of 78% and patients in Group 3 had TTR of 64% (n.s.). Analysis of patients by age, using only patients from Group 1, showed that there were no differences in TTR in patients with less or equal to 80 years-old comparing to patients with more than 80 years-old (TTR 83% vs 82%, n.s.), showing that age *per se* is not a factor affecting monitoring quality.

Conclusions: In conclusion, patients with target INR of 2–3 and 2.5–3.5 had TTR that can be considered effective. Therefore this can be an indirect indicative that it would be safe to increase time between measurements to 12 weeks, as recommended by the new guidelines. Age should not be a limitation for this increase, at least in patients with target INR 2–3, which are the older ones in the present study. In patients

with target INR 3–4 we obtained the lowest value of TTR, probably due to proximity between therapeutic and toxic doses that can complicate VKA management. Therefore, for patients with target INR of 3–4 there is not enough evidence to support the increase of the interval between measurements.

OC 02.6

Cost-effectiveness of rivaroxaban for the treatment of pulmonary embolism and secondary prevention of venous thromboembolism – a UK perspective

McLeod E[1], Guillermin A[2], Hudson R[2], Bamber L[3], Muston D[4] and Lensing AWA[3]

[1]IMS Health London; [2]IMS Health, London, UK; [3]Bayer HealthCare Pharmaceuticals, Wuppertal, Germany; [4]Bayer plc, Berkshire, UK

Background: The current standard of care for pulmonary embolism (PE) – initial treatment with low molecular weight heparin (LMWH) overlapping with, and followed by, a vitamin K antagonist (VKA) – suffers from limitations. Rivaroxaban, an oral, direct Factor Xa inhibitor, provides a single-drug approach that does not require LMWH bridging therapy, dose adjustment or routine laboratory monitoring. EINSTEIN PE compared rivaroxaban with LMWH/VKA for 3, 6 or 12 months of treatment post-PE. Rivaroxaban was shown to be non-inferior to LMWH/VKA therapy in the prevention of recurrent venous thromboembolism (VTE; hazard ratio 1.12, 95% confidence interval 0.75–1.68; $P = 0.003$) and resulted in a significant reduction in major bleeding (hazard ratio 0.49, 95% confidence interval 0.31–0.79; $P = 0.003$). These data indicate a potentially improved benefit-risk profile. On the basis of the EINSTEIN PE results, the European licence was extended to include treatment of haemodynamically stable patients with acute symptomatic PE.

Aim: To compare cost-effectiveness of oral rivaroxaban with standard of care for the treatment of PE and secondary prevention of VTE, from a UK payer perspective.

Methods: A Markov model was developed to explore cost-effectiveness over a patient's lifetime. Patients entering the model had experienced a PE and required 3, 6 or 12 months' treatment. A scenario evaluating high-risk patients requiring lifelong treatment was included.

Patients were exposed to treatment-specific risks of recurrent VTE and bleeding events. Associated mortality, post-thrombotic syndrome and chronic thromboembolic pulmonary hypertension were applied to both treatment arms. Inputs were derived from EINSTEIN PE and systematic literature reviews. To account for differences in patient risk profiles, rivaroxaban treatment effects were applied to the probability of events in patients treated with LMWH/VKA, according to intended treatment duration.

Economic inputs were based on costs from publicly available sources. An observational study provided resource use associated with routine laboratory monitoring. Consistent with EINSTEIN PE findings, a reduction in length of stay (LOS) was included for admitted patients treated with rivaroxaban. Quality-of-life (utility) inputs accounted for the impact of events and VKA treatment. Costs and benefits were discounted at 3.5% per annum. Extensive sensitivity analyses were undertaken.

Results: Rivaroxaban demonstrated per-patient cost savings of £396, £213 and £133 relative to LMWH/VKA therapy in patients treated with 3, 6 and 12 months' anticoagulation, respectively. Patients treated with rivaroxaban accrued more quality-adjusted life-years (QALYs; increases of 0.027, 0.013 and 0.019) compared with LMWH/VKA. Consequently, rivaroxaban dominated the comparator. Assuming a willingness-to-pay threshold of £20 000/QALY, rivaroxaban remained cost-effective in all sensitivity analyses. These included analyses in which no reduction in LOS or impairment to quality of life caused by warfarin administration was assumed. Probabilistic sensitivity analyses indicated that the likelihood of rivaroxaban being cost-effective was > 93% in all three groups. Rivaroxaban was cost-effective for patients requiring lifelong anticoagulation, with an incremental cost-effectiveness ratio of £7072/QALY.

Summary/Conclusions: The benefit-risk profile and single-drug approach of rivaroxaban improved QALY outcomes and reduced management costs. Rivaroxaban represents a cost-effective alternative to standard of care in the treatment of PE and secondary prevention of VTE from a UK payer perspective.

OC 03 – Clinical Issues in Haemophilia A

OC 03.1

Impact of sports on children with haemophilia in terms of their health status, health-related quality off life and physical performance

Von Mackensen S[1] and Khair K[2]

[1]University Medical Centre Hamburg-Eppendorf, Hamburg, Germany; [2]Great Ormond Street Hospital, London, UK

Introduction: Sport is nowadays perceived as beneficial for children with haemophilia, as good muscle strength supports joints and may reduce bleeding frequency; by contrast psychological benefits are less known yet. On the other hand, there are still several obstacles towards sport activities such as worries of the patient/family and school teachers as well as limited knowledge of potential benefits related to different sport types. This study introduces the impact of sport on health status, health-related quality of life (HRQoL) and physical performance in children with haemophilia.

Methods: A cross sectional, multi-site study of boys aged 6–17 years with haemophilia A or B of any severity, current or past inhibitor was undertaken in children and their parents from HTCs in the UK. One hundred and twenty haemophilia families were invited to complete a questionnaire at routine review clinics including the following assessments using age appropriate questionnaires: socio-demographic data, questions about haemophilia, health-related quality of life (KINDL, Haemo-QoL), subjective physical performance (HEP-TEST-Q) and questions about sports activities. Additionally clinical data were collected from patient records; the orthopaedic status was assessed with the Petrini Haemophilia Joint Score.

Results: Eighty-four haemophilia boys (23 mild, 19 moderate, 42 severe) with a mean age of 11.52 years (SD = 3.4) were enrolled from 2 haemophilia centres in the UK (70% response rate). 92.3% had haemophilia A, 51.9% were severely affected; 66.3% received prophylactic treatment and had a mean Petrini Score of $M = 1.55 \pm 3.6$. 28.4% were classified overweight/obese according to their BMI in the respective age group. 90.5% participated in regular sporting activity, the majority 2–3 times/week at least twice a week (79.9%), mainly with friends (80%) and at school (80%). HRQoL in children was generally good, with highest impairments in boys aged 8–12 years. Children of younger age groups reported high impairments in the dimension 'sports & school', while adolescents showed highest impairments in social dimension such as 'perceived support' and 'friends'. Boys aged 8–17 years reported good physical performance ($M = 80.0$, SD=16.0) with highest impairments in the dimensions 'endurance' and 'mobility'.

Sedentary lifestyle and doing sport had no impact on children's health status. By contrast, children with a more sedentary lifestyle (watching > 1–2 h TV/playing computer games per day) had more haemophilia-related days lost ($M = 9.40$, SD = 7.1) than those with a less sedentary life style ($M = 3$, SD = 3.2) ($P < 0.032$). Sport had no impact on the HRQoL of younger boys; on the other hand older boys not doing sport showed more impairments in the HRQoL dimensions 'feeling' ($P < 0.014$) and 'family' ($P < 0.013$). Children doing sport reported better physical performance in all domains of the HEP-Test-Q ($P < 0.0001$).

Conclusion: Boys doing sport had a significantly better physical performance and HRQoL than boys not doing sport. Sedentary life style had a negative impact on the subjective physical performance and number of days lost of children. Participating in sport did not increase the risk of bleeding or developing target joints. Encouraging haemophilia boys to participate in sport will have a direct impact on their overall HRQoL. There is a further need of interventional studies confirming our findings.

OC 03.2

Intracranial haemorrhage in children with haemophilia A and B – interim analysis of the retrospective part of a multicentre study

Gretenkort Andersson N and Ljung R

Lund University/Skåne University Hospital, Malmö, Sweden

Background: In children with haemophilia A and B, the discussion on choice of therapy is focused on joint outcomes, even though intracranial haemorrhage (ICH) is a significant cause of death and morbidity in such patients. The risk of getting an ICH is 20–50 times higher in patients with haemophilia and affects 3–10% of patients with haemophilia treated on-demand. There are no recent studies on the incidence, morbidity and mortality of ICH on a well-defined prophylactic regimen.

Aims and objectives: Does prophylactic treatment reduce the frequency of intracranial haemorrhages? If ICH occurs, is the risk of sequelae lower?

Methods: Study group: Children (goal $n = 1000$), age < 18 years, with severe haemophilia A or B (FVIII/IX < 1%), without inhibitors who are on prophylactic treatment (defined as > 20 U/kg, minimum twice/week or prophylaxis three or more times a week), other prophylactic treatment (at least once a week) or on-demand.

Methodology: The study is a 3-year prospective survey of the cohorts with a 5-year retrospective part. Thirty-one international centres from PedNet (the European Paediatric Network for Haemophilia Management) and INPH (the International Network of Pediatric Hemophilia) are taking part in this multicentre study. The questionnaire is online (www.ich-hemophilia.se). The main questions are: mode of treatment, ICH or ICH-free period, technique for ICH imaging, preceding trauma and sequelae after ICH.

Results: At present, 796 patients have been recruited (median age 11.2 years, [range 1.9–20.0 year]) with a total of 3596 patient years: 2838 are on regular prophylaxis, 244 are on once/week prophylaxis and 514 are taking on-demand therapy. The present evaluation represents the 5-year retrospective part of the study. Nineteen events of ICH occurred in 17 patients with haemophilia A and two with haemophilia B. Three patients out of the 19 with ICH were on regular prophylaxis (two as a second bleeding after neonatal intracranial haemorrhage and one after trauma). Two patients with ICH were on prophylaxis once a week. The remaining 14/19 with ICH were treated on-demand, in three patients the ICH occurred in the neonatal period, and in six in the first year of life. The incidence of ICH in the whole cohort is 1.06/200 patient years versus 1 ICH/200 patient years in recent studies. The incidence for children taking on-demand therapy is 5.4/200 patient years, for children on full prophylaxis 0.21/200 patient years and for children on prophylaxis once a week 1.6/200 patient years.

Conclusion: The incidence of ICH in children on regular (at least twice/week) prophylaxis in this interim analysis of the retrospective cohort is 0.21/200 patient years compared to 5.4/200 patient years for the on-demand group. This strengthens the hypothesis that ICH occurs less frequently in patients on prophylaxis. Nine out of 19 ICH events occurred in the first year of life at an age when patients do not usually receive prophylaxis. If those patients are deducted from the analysis, the incidence is 1.9/200 patient years in the on-demand group, i.e. nine times higher compared to children on prophylaxis.

OC 03.3

Clinical risk factors in the development of inhibitors in non-severe hemophilia A patients: the first results of the INSIGHT case–control study

Van Velzen AS[1], Eckhardt CL[1], Peters M[1], Peerlinck K[2], Oldenburg J[3], Hay CRM[4], Mancuso ME[5], Astermark J[6], Van Der Bom JG[7] and Fijnvandraat KJ[1]

[1]Emma Children's Hospital, Academic Medical Center, Amsterdam, the Netherlands; [2]University of Leuven, Leuven, Belgium; [3]University Hospital Bonn, Bonn, Germany; [4]Royal Infirmary Hospital, Manchester, UK; [5]IRCCS Maggiore Hospital Foundation and University of Milan, Milan, Italy; [6]Skåne University Hospital Malmö/Lund, Malmö, Sweden; [7]Leiden University Medical Center, Leiden, the Netherlands

Background: Inhibitor development is a major complication of treatment with factor VIII concentrates in non-severe hemophilia A and the etiology is only partly understood. It is important to identify clinical situations that elicit inhibitor development, as this enables the design of preventive strategies.

Aims: This case–control study investigates the association between clinical risk factors and inhibitor development in patients with non-severe hemophilia A.

Methods: From a source population of the INSIGHT study, including all 2711 non-severe hemophilia A patients (FVIII:C 2–40%) that were treated with FVIII concentrates in 33 European and 1 Australian center between January 1st 1980 and January 1st 2011, we selected 77 inhibitor patients (cases) and 230 control patients, matched for age and cumulative number of exposure days to FVIII concentrates. The reason for treatment (bleeding or surgery) and the intensity of treatment (1–2 exposure days (ED), 3–4 ED or ≥ 5 ED) were analyzed using a multivariate survival model with the exposure days to FVIII concentrates as time-variable.

Results: This first analysis of the INSIGHT case-control study includes 7793 exposure days in 307 patients, with a median age at first exposure of 22 years (inter quartile range (IQR) 6–44) and a median FVIII baseline level of 9 IU/dL (IQR 5–16). The 77 cases developed an inhibitor at a median age of 36 years (IQR 15–60) and after a median of 25 ED (IQR 12–40).

Neither intensity of treatment, nor surgery was independently associated with inhibitor occurrence. After adjustment for confounders (ethnicity, mild/moderate hemophilia A, family history and age) the adjusted odds ratios (aOR) for moderate bleed (3–4 ED) and major bleed (≥ 5 ED) compared to the reference of 1–2 ED, were 0.68 (95% confidence interval (CI) 0.08–5.85) and 0.66 (CI 0.24–1.79) and for moderate surgery (3–4 ED) and major surgery (≥ 5 ED) compared to ED in the absence of surgery were 4.25 (CI 0.74–24.47) and 1.04 (CI 0.38–2.83), respectively.

Factor VIII exposure at an older age showed a trend towards an increased risk of inhibitor development; aOR 1.82 (CI 0.79–4.17) in the age-group of > 60 years compared to patients who were exposed at younger ages (0–30 years).

Conclusions: In contrast to previous findings in patients with severe hemophilia, surgery was not independently associated with inhibitor development among patients with non-severe hemophilia A. This may reveal that exposure to therapeutic FVIII concentrates in patients with non-severe hemophilia always occurs in clinical situations with a certain threshold of tissue damage.

Factor VIII infusions at older ages seemed to convey a higher risk for inhibitors than infusion at younger ages. This may reflect that the immune system of older patients has been challenged relatively late in their life with therapeutic FVIII concentrates.

OC 03.4

Has the inhibitor incidence increased in severe hemophilia A from 1990 to 2009?

Van Den Berg HM[1] and Ljung R[2]

[1]University Hospital Utrecht, Utrecht, the Netherlands; [2]Department of Pediatrics Lund University, Malmo, Sweden

Background: About 25% of patients with severe hemophilia A develop inhibitory allo-antibodies (inhibitors) towards infused factor VIII products. The risk of patients developing inhibitors depends on several genetic and non-genetic risk factors. Over the last decades, higher inhibitor incidences have been reported. It is unclear whether this is caused by a real increase in prevalence or by higher awareness and more frequent and sensitive testing.

Aim: To objectivate the perceived increased incidence for inhibitors.

Methods: The CANAL study collected data from patients born 1990–2000 with severe hemophilia until 50 exposure days. Similar data were collected in the RODIN study (2000–2010). Primary outcome for both studies was clinically significant inhibitor development, defined as ≥ 2 positive inhibitor titers combined with decreased *in vivo* factor VIII recovery. The secondary outcome was high-titer inhibitor development, defined as the occurrence of clinically relevant inhibitors with peak titers of ≥ 5 Bethesda Units (BU)/mL. A positive inhibitor titer was defined according to the cut-off level of the used inhibitor assay in each center's laboratory.

To make direct comparison on inhibitor incidence in these two patient cohorts, we selected only patients with severe hemophilia A (FVIII < 0.01 IU/mL) and a follow-up of at least 50 exposure days.

Results: In total 892 patients were included (319 selected in 1990–2000, 573 in 2000–2009). Excluding 51 patients born in 2009 (as 65% of them had not yet reached 50 exposure days), 245/863 patients (28.4%) had inhibitors, 174 of them (20.2% high-titer inhibitors. To compare different time periods, patients were divided into four 5-year periods; 1: patients born 1990–1994; 2: patients born 1995–1999; 3: patients born 2000–2004; 4: patients born 2005–2009. Total inhibitor development was as follows: period 1: 28/144 patients (19.4%); period 2: 47/175 patients (26.9%); period 3: 96/309 patients (32.1%); period 4: 74/264 patients (30.2%). High-titer inhibitor development did not increase significantly between 1990 and 2009: period 1: 24/144 patients (16.7%); period 2: 37/175 patients (21.1%); period 3: 66/309 patients (22.1%); period 4: 47/264 patients (19.2%). So, 85.7%, 78.7%, 68.8% and 63.5% of all patients with inhibitors had high-titer inhibitors.

Conclusions: The overall increase of inhibitor incidence in the period 1990–2009 is caused by the detection of more low-titer inhibitors, increasing to > 30% of all inhibitors in period 3 + 4. This could be explained by more frequent and sensitive testing. The high-titer inhibitor incidence, however, did not change significantly in the same time period, which seems to imply that high-titer inhibitors will be detected also with less frequent testing.

OC 03.5

Validation of the Extended Magnetic Resonance Imaging Scale for evaluation of joint status in adult patients with severe hemophilia A

Raunig D[1], Hong W[2] and Lundin B[3]

[1]ICON Medical Imaging, Warrington, PA; [2]Bayer HealthCare, Montville, NJ, USA; [3]Lund University and Skåne University Hospital, Lund, Sweden

Background: Prophylactic replacement factor therapy reduces bleeding frequency and joint damage compared with on-demand treatment in patients with hemophilia. Because of varying treatment regimens used worldwide, adolescents with hemophilia enter adulthood with joint status ranging from little damage to severe deterioration. Most previous joint imaging scales for hemophilia have focused on earlier disease stages observed in younger patients. Adults with hemophilia, who may have more severe baseline joint damage, would benefit from an imaging scale with greater scale item detail that could evaluate a wide range of joint damage.

Aim: To demonstrate that the 45-point Extended Magnetic Resonance Imaging (eMRI) Scale, which scores soft-tissue changes, cartilage changes, and additive damage from all three bones in each joint (ie, ankles, elbows, knees), is a valid instrument for measuring joint status in adults with severe hemophilia A.

Methods: Six scale items (effusion hemarthrosis, synovial hypertrophy, hemosiderin, erosion, subchondral cysts, and cartilage loss) in two domains (soft tissue [range, 0–9 points] and osteochondral [range, 0–36 points]) were evaluated for each joint. eMRI scores were derived from baseline data from a randomized, controlled, parallel-group clinical trial (NCT00623480; SPINART). Scores were evaluated for linearity (through comparisons with the Colorado Adult Joint Assessment Scale [CAJAS] and the 17-point International Prophylaxis Study Group MRI scale) and reproducibility (through measurements of interreader variability and site variance). An item analysis assessed the internal reliability of items to consistently measure the health status of each joint.

Results: Patient eMRI scores correlated with age ($r = 0.58$), similar to the expected correlation of joint health with total lifetime bleeds ($r = 0.35$–0.68) for older scales and consistent with the expectation that all patients experience joint bleeds and older patients have more bleeds. eMRI scores demonstrated excellent between-reader agreement for the overall patient endpoint (intra-class correlation coefficient [ICC] = 0.88) and outstanding agreement for knee evaluations (ICC = 0.95). These agreement statistics are very close to those of older scales despite the increased complexity of the eMRI Scale and the increased burden to the reviewer. There was a strong linear relationship of the eMRI score with the CAJAS ($r = 0.7$). Internal reliability was good (overall Cronbach alpha, 0.75). There was minimal ceiling effect (5% maximum scores for all evaluated joints) compared with the 17-point MRI scale (20%). There was no apparent change in the ability of the eMRI Scale to evaluate joints regardless of the country where the image was acquired. Adding individual bone evaluations for each joint increased the sensitivity of the instrument to detect change at low scores.

Conclusions: Additive evaluation of bones articulating each joint and increased granularity of the extent of damage to joint cartilage increased sensitivity to change with the eMRI Scale compared with the 17-point MRI scale at low and high ends of the scale. Increased reviewer burden did not appear to add variability or affect the ability to discriminate between different levels of joint damage. Excellent to outstanding agreement between the two readers demonstrated reliability of the scale for use by different experienced radiologists.

OC 03.6

US retrospective database analysis on prevalence of cardiovascular comorbidities among hemophilia A patients

Pocoski J[1], Ma A[2], Kessler C[3], Boklage S[1] and Humphries J[1]

[1]Bayer HealthCare, Montville, NJ; [2]University of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Georgetown University Medical Center, Washington, DC, USA

Background: There is conflicting evidence in the published literature on whether patients with hemophilia in the United States have greater, reduced, or similar risks for cardiovascular disease compared with the general population.

Aims: To evaluate the prevalence of cardiovascular comorbidities among US male patients with hemophilia A relative to a general health-insured male population with similar patient characteristics.

Methods: Male patients with hemophilia A with continuous insurance coverage were identified by two International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) codes of

286.0 between January 1, 2007, and December 31, 2009 using the *MarketScan®* Commercial and Medicare Research Databases. Patients with hemophilia A were exact matched in a 1:3 ratio with males without a diagnosis of hemophilia A. Patients were matched by eligibility months in the study period, age, region, and plan type. The proportions of patients with evidence of cardiovascular comorbidities were determined for matched study cohorts using ICD-9-CM codes. Univariate descriptive statistics were used to describe demographics, clinical characteristics, and frequencies of comorbidities, with Student *t* tests and chi-square tests used to detect statistically significant differences in continuous and categorical variables, respectively.

Results: Of the study population, 2506 were grouped in the hemophilia A cohort and 7518 in the general cohort. The frequencies of hemorrhagic stroke (2.0% vs 0.5%; $P < 0.001$), ischemic stroke (1.9% vs 0.9%; $P < 0.001$), coronary artery disease (10.7% vs 5.8%; $P < 0.001$), myocardial infarction (0.8% vs 0.3%; $P = 0.001$), hypertension (22.6% vs 15.5%; $P < 0.001$), hyperlipidemia (16.2% vs 12.0%; $P < 0.001$), arterial thrombosis (12.2% vs 5.9%; $P < 0.001$), and venous thrombosis (4.3% vs 1.1%; $P < 0.001$) were significantly greater for the hemophilia A cohort compared with the general cohort. These results were consistent across most age groups.

Summary/Conclusions: This study is the first large, retrospective analysis to assess the prevalence of cardiovascular comorbidities among US patients with hemophilia A. These results, which contrast with other published data, indicate that among the US hemophilia population, cardiovascular comorbidities are more prevalent and appear earlier in life compared with the general male population, suggesting the need for enhanced screening for age-related comorbidities in the hemophilia community. Inherent limitations of claims database analyses include coding errors and inability to account for all disease- and treatment-related variables such as hemophilia severity, cardiovascular risk factors, and cardiovascular diagnostic and treatment variability. Despite the retrospective nature of these data, they may provide insight into specific risks associated with the frequent use of clotting factor replacement in otherwise hypocoagulable individuals; alternatively, the data may reflect the episodic hypercoagulability induced by infrequent replacement of large amounts of clotting factor protein, or they may indicate the necessity of implementing counterintuitive therapies to patients with hemophilia in certain scenarios (eg, antiplatelet therapy in those with high risk of atherosclerotic complications). Future studies are warranted to assess whether these databases and other registries reveal an accurate but worrisome trend toward increased cardiovascular and venous hypercoagulability in aging patients with hemophilia A.

OC 04 – Clinical Issues Related to Cancer and Haemostasis

OC 04.1

Type 1 plasminogen activator inhibitor (PAI-1) and risk of colorectal cancer in the european prospective investigation into cancer (EPIC)-Italy cohort

Iacoviello L[1], Agnoli C[2], De Curtis A[1], Giurdanella MC[3], Krogh V[2], Mattiello A[4], Matullo G[5], Panico S[4], Sacerdote C[6], Tumino R[3], Vineis P[7] and Donati MB[1]

[1]Catholic University, Campobasso; [2]National Cancer Institute, Milano; [3]Cancer Registry ASP, Ragusa; [4]Federico II University of Naples, Napoli; [5]Human Genetic Foundation HuGef, Torino; [6]Cancer Prevention Centre (CPO) Piemonte, Torino, Italy; [7]Imperial College, London, UK

Background: Experiments in KO and transgenic mice demonstrated that host-produced PAI is essential for cancer cell invasion and angiogenesis. High PAI-1 levels are predictive of poor survival for patients with different cancers. However, an involvement of circulating PAI-1 in the risk of cancer in human has never been demonstrated. We evaluated the association between PAI-1 and risk of colorectal cancer in 4 out of 5 of the (EPIC)-Italy cohort.

Materials and Method: We conducted a case-cohort study on 1028 (356 men; 672 women) participants in the EPIC-Italy cohort, by comparing subjects who developed colorectal cancer in a mean follow-up of 9.11 years.

Using a nested case-cohort design in the (EPIC)-Italy study ($n = 34\,148$), we identified a random subcohort ($n = 834$*) and incident colon cancer cases ($n = 194$ plus one case originated from the random subcohort*) occurring between baseline (1993–1997) and end of 2003 (Varese), of 2004 (Ragusa and Turin) or 2006 (Naples); PAI-1 levels were measured in citrated plasma collected at recruitment by ELISA (Hyphen Zymutest PAI-1, Intrumentation laboratories, Milan, Italy). The relative risk (RR) and 95% confidence interval (CI), adjusted by relevant confounders and stratified by center, were estimated by aCoxregression model using Prentice method.

Results: Individuals in the highest compared with the lowest quartile of PAI-1 had significantly increased risk of colorectal cancer (RR, 2.38; 95% CI, 1.45–3.90; *P* for trend < 0.001) after adjustment for sex, age and recruitment center. Additional adjustment for education, smoking status, BMI, physical activity did not modify the risk (RR, 2.45; 95% CI, 1.42–4.22; *P* for trend < 0.001). The risk of colorectal cancer increased by 33% for each increase in 1 standard deviation of PAI-1 levels.

Conclusions: Our data provide the first evidence for a link between high PAI-1 levels and an increased risk of colon cancer in the population.

OC 04.2

The risk of venous thrombosis in patients with malignancy is largely mediated through levels of factor VIII and von Willebrand factor

Timp J, Timp JF, Lijfering WM, Rosendaal FR, Versteeg HH and Cannegieter SC

Leiden University Medical Center, Leiden, the Netherlands

Background: Venous thrombosis is a common complication in patients with cancer, but the pathophysiology underlying this association is unclear.

Aim: To assess the role of factor VIII and von Willebrand factor in the relation between cancer and venous thrombosis, overall and for different cancer types.

Methods: From a large case–control study (MEGA study), 4765 patients with a first venous thrombosis and 6149 partner controls or random digit dialing controls were included. At least 3 months after the thrombotic event, after discontinuation of the anticoagulant therapy, patients and controls were interviewed, and a blood sample was taken. With unconditional logistic regression, age and sex adjusted odds ratios (OR) with 95% confidence intervals for venous thrombosis were calculated for malignancy versus no malignancy. Mean levels of factor VIII (activity (IU/dL) as well as antigen (IU/dL)) and von Willebrand factor antigen (IU/dL) are given for participants with and without venous thrombosis and with or without an active malignancy. In mediation analyses we assessed the role of these haemostatic factors in the relation between cancer and venous thrombosis. Consent and ethical approval were obtained for this study.

Results: Among 4765 patients with venous thrombosis 453 individuals were known with active cancer (9.5%) as opposed to 106 in 6149 control participants (1.7%). The presence of a malignancy increased the risk of venous thrombosis about six-fold (OR 5.7 (95%CI 4.6–7.1), after adjustment for age and sex. Mean levels of factor VIII and von Willebrand factor were increased in venous thrombosis patients and in participants with a malignancy, with the highest mean levels in participants with both conditions present. For control participants without and with cancer and for venous thrombosis patients without and with

cancer mean factor VIII activity levels were respectively (111.9; 122.2; 139.6 and 157.2). Similarly, mean factor VIII antigen levels were respectively (116.1; 128.7; 155.1 and 178.1) and mean von Willebrand factor levels were respectively (111.4; 120.9; 147.3 and 177.2). In mediation analyses in which we analysed the effect on thrombotic risk of a malignancy conditional on the concentration of the haemostatic factors we found both factor VIII and von Willebrand factor to be mediators of the effect, with reduced odds ratios for the relation between cancer and venous thrombosis (adjustment for factor VIII activity: OR 2.8 (95%CI 2.0–4.0); factor VIII antigen: OR 2.8 (95%CI 1.9–3.9) and von Willebrand factor: OR 2.8 (95%CI 2.0–4.0)). Correction for the factors combined did not result in an additionally reduced risk [OR 2.8 (95%CI 1.9–3.9)]. Results were consistent for most of the common cancer types (haematological cancer, breast and prostate cancer), except for gastrointestinal cancer.

Conclusion: The increased risk of venous thrombosis in the presence of active cancer is largely explained through levels of factor VIII and von Willebrand factor. Further study is needed to determine the role of haemostatic factors in the relation between cancer and venous thrombosis for different cancer types and for further elucidation of the mechanism.

OC 04.3

Platelet count measured prior to cancer development is a risk factor for venous thromboembolism in cancer patients – the Tromsø Study

Jensvoll H, Blix K, Brækkan SK and Hansen JB

Hematological Research Group, University of Tromsø, Tromsø, Norway

Background: Platelets are essential in hemostasis, thrombosis and cancer progression. The platelet count is determined by both inherited and environmental factors, but is not associated with venous thromboembolism (VTE) in the general population. However, an elevated platelet count in cancer patients before start of chemotherapy has been associated with increased risk of venous thromboembolism (VTE). It is not known whether the risk of VTE by platelet count in cancer patients is causal or merely a consequence of the malignant disease.

Aims: To investigate whether platelet count measured prior to cancer development was associated with risk of VTE in subjects who developed cancer during follow-up and in subjects who remained cancer-free.

Methods: Platelet count and other baseline characteristics were measured in 25 175 initially cancer-free subjects who participated in the Tromsø Study, a prospective population-based study, in 1994–1995. The study was approved by the regional committee of research ethics, and participants gave their informed written consent. Incident cancer and VTE events during follow-up were registered up to September 1st, 2007. Subjects who developed cancer (cancer cohort) and subjects who remained cancer free (cancer-free cohort) where analyzed separately. In the cancer cohort, platelet count was measured on average 7.1 years before cancer development. The mean observational time was 9.8 years in the cancer cohort and 11.0 years in the cancer-free cohort. Cox-regression models were used to calculate hazard ratios (HRs) for VTE by platelet count with 95% confidence interval (CI). Platelet count was analyzed as a categorized (< 40th, 40–80th, and > 80th percentile) and as a continuous variable. The analyses were adjusted for age, sex, body mass index, smoking, mean platelet volume and white blood cell count.

Results: Overall, 1784 subjects developed cancer during follow up. There were 403 incident VTE events, of which 119 (30%) occurred in the cancer cohort (6.8 per 1000 person-years) and 284 (70%) in the cancer-free cohort (1.1 per 1000 person-years). In cancer patients, pre-cancer platelet count above the 80th percentile ($\geq 295 \times 10^9$/L) was associated with a 2.2-fold higher risk of VTE (HR: 2.16, 95% CI: 1.29–3.61) compared to platelet count below the 40th percentile ($< 235 \times 10^9$/L). When platelet count was treated as a continuous variable, the VTE risk increased by 32% (HR 1.32; 95% CI 1.12–1.48) per one standard deviation increase (1 SD = 56×10^9/L). In cancer-free subjects, no association was found between platelet count and VTE in either continuous (HR per 1 SD: 0.95, 95% CI 0.80–1.12) or categorized analyses (HR: 0.99, 95% CI: 0.681.43 in upper versus lower platelet category).

Conclusions: Platelet count measured several years prior to cancer development was associated with increased risk of VTE in cancer patients, whereas no association was found between platelet count and VTE in subjects who remained cancer free. Our findings suggest that platelets may play a role in the pathogenesis of cancer-related VTE.

OC 04.4

Chemotherapy-induced hypercoagulability and biomarkers for prediction of thromboembolic events in patients with metastatic testicular cancer

Lubberts S, Boer H, Altena R, Meijer C, Lefrandt JD, Nuver J, Mulder AB, Lisman T, Kamphuisen PW and Gietema JA

University Medical Center Groningen, Groningen, the Netherlands

The majority of patients with disseminated testicular cancer can be cured with combination chemotherapy consisting of bleomycin, etoposide and cisplatin (BEP). Because of this success, focus shifts to adverse effects of this treatment. The incidences of venous and arterial thromboembolism (VTE and ATE) during and after chemotherapy are up to 15%.

Low molecular weight heparin (LMWH) reduces VTE in cancer patients, but the incidence is too low to justify prophylaxis in most patients starting with chemotherapy.

To investigate the influence of BEP-chemotherapy administered to testicular cancer patients on coagulation and to estimate the predictive value of plasma levels of hemostatic proteins and activation markers in prediction of VTE and ATE within 2 years after treatment.

Patients with newly diagnosed metastatic testicular were included in this prospective cohort study, which was approved by the local ethical committee. Informed consent was obtained from all participants. Patients received 3 or 4 BEP-courses during 9–12 weeks. Serial measurements were performed at baseline, at the last day of the third BEP-course (day 56) and directly after chemotherapy. We assessed the Khorana-score and measured levels of the following hemostatic proteins: von Willebrand factor (VWF), fibrinogen, tissue-type plasminogen activator (tPA), plasminogen activator inhibitor 1 (PAI-1), soluble P-selectin (sP-selectin), coagulation factor VIII (FVIII) and D-dimer. Outcome parameters were symptomatic VTE or ATE or asymptomatic VTE or ATE discovered on staging CT-scans.

We included 74 patients with a median age of 31 years at start of chemotherapy. Eight patients (10.8%) developed thrombosis during or after chemotherapy, 4 had pulmonary embolisms (PE), of which 3 asymptomatic, and 4 had ATE (3 ischemic stroke, 1 asymptomatic splenal infarction), during a median follow-up of 3.2 years. Median duration from start of chemotherapy until development of VTE was 82 days (range: 32–278) and for ATE 85 days (range: 69–435).

Median baseline biomarker levels were not elevated. VWF, fibrinogen, FVIII, D-dimer and PAI-1 levels clearly increased during chemotherapy. Levels normalized to baseline 1 month after treatment, except for FVIII and VWF levels, which remained increased. High FVIII levels (> 150%) at baseline had a positive predictive value (PPV) of 50% (95%CI: 14–86) and a negative predictive value (NPV) of 92.3% (95% CI: 82–97), with a hazard ratio (HR) for TE of 4.7 (95%CI: 1–22) adjusted for age at start of chemotherapy. The Khorana-score had a low predictive value. Furthermore, a large increase between baseline and day 56 in both VWF ($\Delta > 86.5\%$) and D-dimer ($\Delta > 935$ ng/mL) had a PPV of 44.4% (95%CI: 15–77), a NPV of 95.2% (95%CI:

86–99) and a HR of 7.0 (95% CI: 2–33) for TE occurring after day 56. Hemostatic markers correlated with tumor markers.
BEP-chemotherapy in metastatic testicular cancer patients is associated with a hypercoagulable state. Elevated FVIII before start of chemotherapy and large increases in D-dimer and VWF levels during chemotherapy are associated with an increased risk of developing ATE or VTE. This study suggests that baseline FVIII is a predictor for future TE in testicular cancer patients.

OC 04.5

Prevalence of pulmonary embolism in patients with oncogene addicted advanced lung adenocarcinoma

Verso M[1], Franco L[1], Mosca S[2], Fischer M[2], Chiari R[3], Marconi V[2], Paglialuca L[3] and Agnelli G[1]
[1]*Division of Internal and Cardiovascular Medicine-Stroke Unit;* [2]*Radiology Department, Santa Maria della Misericordia Hospital;* [3]*Division of Medical Oncology, Santa Maria della Misericordia Hospital, Perugia, Italy*

Background: Non-small cell adenocarcinoma (NSCLC) is associated with a higher risk of thromboembolic event in comparison with SCLC. Adenocarcinoma represent roughly 75% of NSCLC patients. Lung adenocarcinomas harboring EGFR and KRAS mutations as well as EML4/ALK rearrangements represent distinct subsets of this disease. EGFR or KRAS mutations and EML4/ALK rearrangements are predictors for response to therapy in patients with NSCLC, mainly adenocarcinoma. No data are available concerning the prevalence of pulmonary embolism in NSCLC patients with these mutations.
Aims: The aim of the study was to evaluate the prevalence of pulmonary embolism in patients with stage III B-IV NSCLC harboring EGFR and K RAS mutations as well as EML4/ALK rearrangements.
Method: Patients with stage IIIB or IV NSCLC referred to Division of Medical Oncology at the Perugia Hospital between 2008 and 2012 were included in the study. In these patients, contrast-enhanced CT scans of the chest were reviewed for the presence of pulmonary embolism by a panel composed by three radiologists. In the same patients, data on the oncogene mutations (EGFR, KRAS or EML4/ALK) were collected.
Results: A total of 209 patients with stage IIIB or IV NSCLC were included in the study. A histologic diagnosis of lung adenocarcinoma was done in 173 patients (82.7%). In 127 of these patients sequence analysis for know EGFR and K RAS mutation was performed. In this population 31/173 patients were EGFR mutated (17.9%), 27/173 were K RAS mutated (15.6%) and 17/173 were EML4/ALK rearrangements (9.8%). Forty-one patients with lung adenocarcinoma had a diagnosis of pulmonary embolism at CT scan (23.7%). Of these, 34.1% had no oncogene mutations in comparison with 28.8% of the patients without pulmonary embolism. Of the 41 patients with a diagnosis of pulmonary embolism 12.1% had an EGFR mutation and 12.1% a KRAS mutation, in comparison with 19.7% and 16.6% of patient without pulmonary embolism, respectively. In patients with lung adenocarcinoma, EML4/ALK rearrangements was observed in 19.5% among patients with pulmonary embolism and in 6.8% among patients without it. The risk of pulmonary embolism was 3.3-fold higher in presence of EML4/ALK rearrangements in comparison with no EML4/ALK rearrangements [OR: 3.3 (95%CI 1.2- 9.2)].
Conclusions: In patients with lung adenocarcinoma, the presence of EML4/ALK rearrangements seems to be associated with a high risk of pulmonary embolism and could help in identifying patients at particular high risk which might benefit from an antithrombotic prophylaxis. These preliminary date need to be confirmed by further studies.

OC 04.6

Using proteomics to identify new biomarkers for cancer-associated thrombosis: a pilot study

Connolly G[1], Smith BH[1], Hagen F[1], Iyer R[2] and Khorana A[1]
[1]*University of Rochester, Rochester;* [2]*Roswell Park Cancer Institute, Buffalo, NY, USA*

Background: Thrombosis is a common and consequential problem in cancer patients but its mechanisms and predictors are incompletely understood. Proteomics is a powerful technique by which protein expression patterns can be measured, but there are limited data analyzing the plasma proteome of cancer patients for thrombotic outcomes.
Aims: To develop a reliable and reproducible method for studying differences in plasma protein expression amongst cancer patients receiving chemotherapy using proteomics.
Methods: We analyzed the plasma proteome of a cohort of cancer patients treated at the University of Rochester in this pilot study. Patients with lung or pancreatic cancer initiating chemotherapy were enrolled as part of an IRB approved protocol. Baseline and serial blood samples were collected and patients were followed prospectively for development of venous thromboembolism (VTE). Plasma samples collected in sodium citrate, adjusted to pH 7.0 and frozen at −80°C were thawed then depleted of albumin and immunoglobulin by sequentially applying them to a Cibacron blue resin and then protein G-Sepharose resin, in a batch mode. The partially depleted plasma was then size fractionated by SDS-polyacrylamide gel electrophoresis (SDS-PAGE). The plasma was then processed in four mass ranges by gel isolation and in-gel trypsin digestion, followed by mass spectrometry analysis for each mass range separately. Each depleted plasma sample was subjected to an 80 min liquid chromatography-mass spectrometry (LC-MS/MS) run. Mascot searches were then conducted for protein matches with the NCBI human proteome. Search results for the study were uploaded into ProteoIQ and Scaffold software platforms and spectral counting was used for relative quantification of plasma proteins between study groups. Mean peptide expression level in patients with and without thrombosis was compared using two sample *t*-test.
Results: The cohort consisted of seven patients with primary lung cancer and eight patients with pancreatic adenocarcinoma. The average age of the population was 58 years of age and 53% (8/15) were female. The majority (80%, 12/15) had stage IV cancer. VTE developed in four patients during study follow-up consisting of two patients with deep vein thrombosis (DVT), one with pulmonary embolism (PE), and one with both DVT and PE. The average time from chemotherapy initiation to VTE was 37 days with range of 17–67 days. We were able to complete proteomic analysis as described above identifying 50 637 spectra representing 2145 unique peptide sequences from 149 proteins and 116 protein groups when applying thresholds requiring three peptide minimum and 95% probability of protein match. We identified nine proteins that were differentially expressed ($P < 0.05$) between patients with and without thrombosis including proteins known to be important for hemostasis and thrombosis like fibronectin and plasminogen.
Summary: A method for measuring plasma protein expression in cancer patients undergoing chemotherapy using proteomic techniques was successfully developed. This small pilot study was underpowered to accurately compare plasma protein expression profiles but we plan to apply these techniques in an ongoing study of a larger cohort of cancer patients with the goal of identifying predictive biomarkers and better elucidating mechanisms involved in this complex process.

OC 05 – Coagulation Factors VIII, IX and XI

OC 05.1

Residues of the 39-loop restrict the plasma inhibitor specificity of factor IXa

Rezaie AR and Yang L
St. Louis University School of Medicine, St. Louis, MO, USA

Background: The two plasma inhibitors, protein Z-dependent protease inhibitor (ZPI) and tissue factor pathway inhibitor (TFPI), effectively inhibit the activity of FXa, however, neither inhibitor exhibits any reactivity with the homologous protease FIXa. We recently demonstrated that the residues of the 39-loop in FXa modulate the specificity of FXa interaction with plasma inhibitors. This loop in FXa is highly acidic and contains three Glu residues at positions 36, 37 and 39. On the other hand, this loop is shorter by one residue in FIXa (residue 36 is missing) and it contains a Lys and an Asp at positions 37 and 39, respectively.
Aim: The aim of this study was to investigate the molecular basis for the lack of the reactivity of FIXa with these plasma inhibitors and to determine whether the unique structural features of the 39-loop are responsible for the resistance of FIXa to inhibition by plasma inhibitors.
Methods: We used recombinant DNA methods to generate a FIX mutant in which residues of the 39-loop (residues 31–41) have been substituted with corresponding residues of FX. We expressed the FIX chimera in HEK-293 cells and following purification to homogeneity and activation to FIXa characterized its biochemical properties in established inhibition assays.
Results: We discovered that the FIXa chimera is highly susceptible to inactivation by both ZPI and TFPI. Thus, the inactivation rate of the chimeric FIXa by ZPI in the presence of protein Z, negatively charged membrane vesicles and calcium ions approached near the same diffusion-limited rate ($> 10^6$/M/s) that has been observed with the protein Z-dependent inhibition of FXa by ZPI. Interestingly, sequence alignments indicated that, similar to FXa, residue 37 is a Glu in mouse and that mouse FIXa is also susceptible to inhibition by the PZ-ZPI complex.
Conclusion: Our results suggest that structural features within residues of the 39-loop are primarily responsible for the resistance of FIXa to inhibition by plasma inhibitors ZPI and TFPI.

OC 05.2

Activated factor XI enhances procoagulant tissue factor activity on endothelial cells by cleaving tissue factor pathway inhibitor

Puy C, Tucker EL, Gruber A and McCarty OJT
Oregon Health & Science University, Portland, OR, USA

Background: Activated factor XI (FXIa) has been shown to be inhibited by aprotinin, a basic pancreatic trypsin inhibitor and analog of tissue factor pathway inhibitor (TFPI). TFPI is a kunitz-type protease inhibitor and the primary inhibitor of the tissue factor (TF)/activated factor VII (FVIIa)/activated factor X (FXa) complex on the surface of endothelial cells. Based on the fact that the catalytic domain of FXIa can bind to kunitz protease domain, we hypothesized that FXIa can inactivate TFPI to regulate the hemostatic function of endothelial cells, which may help explain why some congenital factor XI deficiencies can be associated with bleeding.
Aims: The aim of the present study was to determine whether FXIa regulates TF-dependent FX activation on endothelial cells.
Methods and Results: Conversion of FX to FXa in the presence of FVIIa was measured on the surface of activated endothelial cells using a chromogenic assay. Human umbilical vein endothelial cells (HUVEC) were stimulated for 5 h with tumor necrosis factor-α (TNFα) to induce TF expression and promote FX activation by the TF-FVIIa complex. The addition of a blocking anti-TF antibody inhibited the generation of FXa, indicating that the activation of FX is dependent of the TF-FVIIa complex. Our data show that treatment of TNFα-stimulated HUVECs with FXIa (0–100 nM for 2 h) led to increased TF-dependent activity in a FXIa concentration-dependent manner. We did not observe any hydrolysis of the FXa substrate in the absence of both FVIIa and FX, indicating that FXIa did not activate FX or cleave the chromogenic substrate. Time course studies (0–5 h) demonstrated that the increase in FXa activity in response to 50 nM FXIa was detectable after 1 h, with a maximum effect observed after 3 h. Induction of FXa generation required the presence of Zn^{++} and the proteolytic activity of FXIa. The serine protease inhibitor, aprotinin, blocked the effect of FXIa. We next determined whether FXIa cleaved TFPI from endothelial surface using a cell surface immunoassay. We observed that after FXIa treatment, the detection of the Kunitz 1 domain from TFPI was lost from endothelial cells surface in a FXIa concentration-dependent manner. The presence of aprotinin blocked the effect of FXIa. Using a cell surface immunoassay we observed that FXIa did not affect the total TF or TFPI antigen expression. The proteolytic cleavage of TFPI by FXIa on endothelial cells was characterized by western blot. Treatment of HUVECs with FXIa resulted in a reduction in the 50-kDa form of TFPI and an increase in the 38-kDa species of TFPI as a function of FXIa concentration, suggesting that FXIa cleaves TFPI in the endothelial cell microenvironment.
Summary/Conclusions: We propose that in addition to FXI's well established role in the stabilization of hemostatic plugs via increased thrombin generation by activation of FIX, FXIa could support hemostasis by limiting the TFPI-mediated inactivation of the TF/FVIIa-dependent extrinsic pathway on endothelial cells. The identification of TFPI as a substrate for FXIa may have pathophysiological implication for the regulation of TF/FVIIa activity during hemostasis and thrombosis.

OC 05.3

Role for coagulation factor XI during pneumococcal pneumonia independent of factor XII activation

Stroo I[1], Van 't Veer C[1], Roelofs JTH[1], Meijers JC[2], Castellino FJ[3], Zeerleder S[4] and Van Der Poll T[1]
[1]Academic Medical Center; [2]Academic Medical Center Amsterdam, Amsterdam, the Netherlands; [3]University of Notre Dame, Notre Dame, IN, USA; [4]Sanquin Research, Amsterdam, the Netherlands

Background: Severe bacterial infections such as pneumococcal pneumonia are associated with activation of coagulation. Coagulation can play an active role in the containment and elimination of bacteria by the fibrin network. Fibrin can be formed via two distinct coagulation pathways, the tissue factor (extrinsic) pathway or the intrinsic pathway both converging in the formation of thrombin. Factor XI (FXI) is the key component of the intrinsic pathway and can be activated either via factor XII (FXII), part of the contact system, or via thrombin that is generated via both coagulation pathways.
Aim: To determine whether the intrinsic coagulation pathway is involved in pneumococcal pneumonia and whether this is dependent on FXII activation.
Methods: Pneumonia was induced by intranasal inoculation with 5×10^5 CFU of *S. pneumoniae* serotype 2 (D39) in male wildtype (WT), FXI-KO and FXII-KO mice. Mice were sacrificed 12 or 48 h following infection, blood, organs and bronchoalveolar lavage fluid (BALF) were collected to determine bacterial loads, inflammatory markers and pathology.
Results: Bacterial loads in lung, blood and distant organs were significantly higher at 48 h in FXI-KO mice. In line, 48 h following infection

increased lung cytokine and chemokine levels were detected in FXI-KO mice. Several parameters of lung damage were assessed revealing significantly increased pathology in FXI-KO mice mainly caused by presence of endothelialitis. Endothelial damage was confirmed by enhanced plasma and lung E-selectin levels. No differences in any of the examined parameters were observed between WT and FXII-KO mice. In a separate experiment BALF was collected following induction of pneumonia. Although FXI-KO mice again showed higher bacterial counts in blood and distant organs, BALF bacterial loads and leukocyte influx were comparable between WT and FXI-KO or FXII-KO mice.

Conclusion: FXI deficiency increased bacterial dissemination during *S. pneumoniae* induced pulmonary infection, while FXII deficiency did not influence the host response. These results indicate that FXI protects against pneumococcal pneumonia via a mechanism independent of FXII activation. The critical role for intrinsic coagulation during pneumococcal pneumonia most likely involves thrombin-mediated activation of FXI.

OC 05.4

Regulation of human factor XI by a hepatic microRNA

Salloum-Asfar S[1], Teruel R[1], Arroyo AB[1], Garcia-Barberá N[1], Chaudhry A[2], Schuetz E[2], Luengo-Gil G[1], Vicente V[1], González-Conejero R[1] and Martínez C[1]

[1]Centro Regional de Hemodonación, Hospital Morales Meseguer. UMU. IMIB, Murcia, Spain; [2]St. Jude Children's Research Hospital, Memphis, TN, USA

Background: Plasma levels of factor XI (FXI) are variable in healthy population. Indeed, high levels of FXI increase the risk of thromboembolic disease or may suppose a septic survival advantage. Despite intensive research in recent years, the genetic and environmental factors that regulate FXI expression are still largely unknown. Recently, microRNAs (miRNAs) have appeared as novel regulators of protein expression in physiological and pathological processes.

Aim: To evaluate the regulation of FXI by miRNAs in human liver.

Methods: A miRNA array was performed using total RNA extracted from two healthy human liver samples. Mature hepatic miRNAs potentially regulating human *F11* 3′UTR mRNA were selected using four algorithms. Human liver carcinoma cells (HepG2) were transfected with miR-181a-5p mimic or non-specific scrambled control (Scr). The effect of miRNA overexpression was assessed by analyzing *F11* mRNA and intra- and extracellular FXI by qRT-PCR and western blot, respectively. Human colon cancer cells deficient for Dicer (HCT116-DK) were used for luciferase assays. One hundred fourteen healthy livers were analyzed to quantify mRNA levels as well as miR-181-5p by qRT-PCR.

Results: *In silico* prediction yielded six miRNA candidates that might regulate FXI expression. We focused on miR-181a-5p because it has the highest probability to bind to *F11* mRNA. Transfection of HepG2 cells with miR-181a-5p mimic compared with Scr provoked a significant decrease of FXI levels both, intracellularly (100% *vs.* 53 ± 16%; $P = 0.02$); and extracellularly (100% *vs.* 71 ± 7%; $P = 0.04$). This miRNA also caused a statistically significant decrease of *F11* mRNA (100 ± 17% *vs.* 71 ± 9%, $P = 0.03$). Luciferase assays in HCT116-DK cells demonstrated a direct interaction between miR-181a-5p and 3′UTR of *F11* mRNA since miR-181a-5p provoked a decrease of the luciferase activity in comparison with Scr (100 ± 17% *vs.* 71 ± 27%, $P = 0.04$). To validate these results *ex vivo*, we evaluated the potential correlation between the expression of miR-181a-5p and *F11* mRNA in 114 liver samples. Our results showed an inverse and significant correlation between *F11* mRNA levels with miR-181a-5p levels (Pearson's = −0.23; $P = 0.017$). In contrast, the lack of correlation between miR-181a-5p and *F9* mRNA levels, which may be expected according to *in silico* predictions, is important to strengthen the specificity of miR-181a-5p on *F11*mRNA levels. Actually, both FXI and FIX plasma levels have been previously shown to parallel, and our data also demonstrated that mRNA levels of these two factors strongly correlated in healthy livers (Pearson's = 0.477; $P < 0.001$).

Conclusions: The present study identifies miR-181a-5p as the first endogenous modulating agent of FXI. Our results strongly suggest that miR-181a-5p takes part in the complex regulation of FXI and might contribute to the inter-individual plasma variability of this key hemostatic factor. Our results demonstrate that the effect of miR-181a-5p on *F11* mRNA levels is highly specific. Further studies are necessary to identify potential associations of miR-181a-5p levels with disorders involving FXI, mainly thrombosis.

OC 05.5

Abnormal plasma clot structure and stability distinguish bleeding risk in patients with severe factor XI deficiency

Zucker M[1], Salomon O[1], Seligsohn U[1] and Wolberg AS[2]

[1]Sheba Medical Center, Tel Aviv, Israel; [2]University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Background: Factor XI (FXI) deficiency is a rare, autosomal, recessive disorder. Many patients with low plasma FXI levels are asymptomatic or exhibit only mild bleeding; however, others experience severe bleeding usually associated with trauma. Interestingly, neither FXI antigen nor activity levels, nor routine activated partial thromboplastin time (APTT) assays, are able to predict bleeding risk in FXI-deficient patients.

Aims: (i) Characterize the formation, structure and stability of plasma clots from patients with severe FXI deficiency, and (ii) Determine whether these measurements distinguish asymptomatic patients ('non-bleeders') from those with a defined clinical history of bleeding ('bleeders').

Methods: Sixteen Israeli severe FXI-deficient patients were divided into 'bleeders' (patients who bled following one or two tooth extractions) or 'non-bleeders' (patients who underwent two or more tooth extractions that were not associated with bleeding) ($n = 8$ patients per group). Groups were similar with respect to gender and age. Informed consent was obtained in compliance with the medical ethics committee. Whole blood was collected via venipuncture into sodium citrate and corn trypsin inhibitor. The first 5 mL of blood were discarded, and platelet-poor plasma was prepared by sequential centrifugation of whole blood. Clot formation was triggered by mixing recalcified plasma with dilute tissue factor and phospholipids in the absence or presence of tissue plasminogen activator and/or thrombomodulin. Clot formation, fibrinolysis, and fibrin network structure were measured by turbidity and laser scanning confocal microscopy, respectively.

Results: 'Non-bleeders'and 'bleeders' had similar low levels of FXI (3.0 ± 1.4 *versus* 3.3 ± 3.0%, respectively), and normal levels of platelets, factor VIII, factor XIII, von Willebrand factor, fibrinogen, and thrombin activatable fibrinolysis inhibitor. 'Non-bleeders' and 'bleeders' had similar prothrombin times (105 ± 13 and 104 ± 16 s, respectively) and prolonged APTT (56 ± 6 and 68 ± 24 s, respectively). Compared to 'non-bleeders,' 'bleeders' exhibited lower clot stability in the presence of tissue plasminogen activator, with significantly longer lag times (1020 ± 399 *versus* 693 ± 245 s, respectively, $P < 0.04$), smaller turbidity change (0.40 ± 0.12 *versus* 0.58 ± 0.14 O.D., respectively, $P < 0.008$), and reduced area under the turbidity curve (674 ± 210 *versus* 1176 ± 386 arbitrary units, respectively, $P < 0.004$). Compared to 'non-bleeders,' 'bleeders' also exhibited significantly lower fibrin network density than 'non-bleeders' (177387 ± 22610 *versus* 234574 ± 42621 arbitrary units, respectively, $P < 0.005$). In the presence of thrombomodulin, differences were even more profound; 7 of 8 'bleeder' patients failed to form a clot, whereas only 3 of 8 'non-bleeder' patients did not clot in the same time.

Summary/Conclusions: Plasma clot structure and stability assays distinguished 'non-bleeder' and 'bleeder' patients: compared to

'non-bleeders,' FXI-deficient patients with a history of bleeding exhibited reduced fibrin network density and lower plasma clot stability. Plasma clot formation assays may provide information on hemostatic mechanisms in FXI-deficient patients and have clinical utility in predicting bleeding risk in these patients.

OC 05.6
The endothelial lectin CLEC4M is a novel clearance receptor for factor VIII

Swystun L, Notley C, Sponagle K, James PD and Lillicrap D
Queen's University, Kingston, ON, Canada

Introduction: Plasma levels of the glycoprotein coagulation factor VIII (FVIII) represent a balance between synthesis and clearance, where elevated FVIII represents a risk factor for thrombosis, and decreased FVIII is associated with the bleeding disorder hemophilia A. However, the mechanisms which regulate FVIII clearance remain incompletely characterized. Previous studies have demonstrated that FVIII interacts with the lectin receptor DC-SIGN. Additionally, we have previously identified the DC-SIGN homolog CLEC4M as a clearance receptor for the FVIII binding partner von Willebrand Factor (VWF).
Aims: We hypothesize that CLEC4M is a clearance receptor for Factor VIII, which can bind and internalize FVIII alone or as a complex with VWF.
Methods: There is no murine ortholog for CLEC4M and thus hepatic CLEC4M expression was induced in normal C57/BL6 mice through hydrodynamic injection of CLEC4M cDNA in the pLIVE vector. Four days post-injection, VWF:Ag was quantified through ELISA and FVIII:C was measured with a chromogenic assay. Binding and internalization of FVIII by HEK293 cells stably expressing CLEC4M was characterized with an enhanced-sensitivity ELISA and immunofluorescence. Binding of FVIII to recombinant CLEC4M-Fc fusion protein was assessed with a modified ELISA.
Results: Plasma levels of VWF:Ag and FVIII:C were decreased by 46 and 44% respectively in mice expressing CLEC4M as compared with controls ($N = 17$, $P = 0.0094$, $P = 0.0110$). Expression of CLEC4M by hepatocytes (10–30% positive) from hydrodynamic injections was confirmed through immunohistochemistry.
Using a modified ELISA, CLEC4M-Fc bound to murine rVWF and rFVIII. CLEC4M-Fc also bound to human plasma-derived FVIII-VWF complex, human full-length rFVIII, and B-domain deleted rFVIII; binding of CLEC4M-Fc to B-domain deleted FVIII was decreased by 50% relative to full-length on a per unit basis ($P = 0.0061$). Binding was dose-dependent, saturable, calcium-dependent, and reversible. Binding was inhibited by the mannose polysaccharide mannan ($P < 0.0001$), and competed by 50% with soluble FVIII ($P = 0.0086$) or FVIII-VWF complex ($P = 0.01$). Binding was blocked with a polyclonal anti-FVIII antibody (90%, $P < 0.0001$), and with monoclonal antibodies to A2 (30%, $P = 0.0316$), C1 (50%, $P = 0.0004$), and C2 (45%, $P = 0.0029$) domains. Removal of FVIII N-linked, and total glycan content attenuated binding to CLEC4M-Fc by 75% and 62% respectively ($P < 0.0001$).
Immunofluorescence demonstrated that binding of recombinant FVIII was increased on 293 cells that stably expressed CLEC4M relative to cells that did not express CLEC4M. Internalization of FVIII by CLEC4M-expressing cells was confirmed with Z-stack analysis and 3D reconstruction. CLEC4M-expressing cells exposed to physiological levels of FVIII and the VWF-FVIII complex had a two-fold increase in levels of FVIII in cell lysates in a dose and time-dependent manner relative to controls as measured by ELISA. The CLEC4M-mediated increase in FVIII levels in cell lysate could be attenuated by 50% with mannan ($P = 0.0013$).
Conclusion: CLEC4M binds FVIII alone or as part of the VWF complex, and facilitates receptor-mediated endocytosis of FVIII and/or VWF-bound FVIII. Characterization of the interaction between CLEC4M and FVIII may lead to better understanding as to how plasma levels of FVIII are regulated.

OC 06 – Fibrinogen

OC 06.1
A new mechanism for modulation of fibrin formation by shear: the knob–hole interactions display 'catch-slip' kinetics

Litvinov RI and Weisel JW
University of Pennsylvania, Philadelphia, PA, USA

Background: Fibrin polymerization, which underlies the formation of clots and thrombi, is driven by intermolecular interactions between knobs 'A' and complementary holes 'a'. These interactions dictate the rate of fibrin formation and provide the fibrin network with mechanical stability, which determines how clots and thrombi respond to mechanical force, such as blood shear. Many aspects of fibrin formation and properties remain unknown, including those associated with impaired blood flow. We hypothesized that the A:a knob-hole bonds display a complex dynamic behavior when subjected to mechanical stress, perhaps due to existence of multiple bound states and/or a broad interface extending beyond the N-terminal α chain motif (GPR) and the complementary pocket in the γ-nodule.
Aims: To resolve the mechanism of A:a knob-hole interactions in fibrin by precise nano-mechanical measurements of formation and dissociation of A:a knob-hole bonds at the single-molecule level.
Methods: We used an optical trap-based system to measure bond lifetimes corresponding to the forced dissociation of single receptor-ligand pairs under a constant tensile force. Briefly, a microscopic ligand-coated latex bead is trapped by a focused laser beam and repeatedly brought into contact with a receptor-coated pedestal. When the ligand (fibrinogen or fragment D, bearing holes 'a') on the bead binds to the receptor (monomeric fibrin or fibrin fragment E, bearing knobs 'A') on the pedestal, the bead is displaced from the trap center to generate a controlled pulling force. The time needed to separate the surfaces is then measured to characterize the interaction properties.
Results: We investigated the dependence of the average bond lifetime of the A:a knob-hole complex on tensile force and found it to follow an unusual non-monotonic behavior. The strength of knob-hole interactions first increased with forces up to 40 pN and then decreased with larger forces. Normally, bond lifetimes diminish with force ('slip' bonds). An increase of bond lifetime with force ('catch' bonds) is a rare and counterintuitive phenomenon, demonstrated for few receptor-ligand pairs. The A:a knob-hole 'catch-slip' behavior was revealed by interacting monomeric fibrin with fibrinogen as well as fragments desA-E/desAB-E with fragments D. The control for specificity was fibrinogen-fibrinogen binding/unbinding without knobs 'A' and the use of knob 'A'-mimicking inhibitory GPRPam peptide. The negative control for 'catch' bonds was a streptavidin-biotin complex, which displayed a pure 'slip' bond behavior with a monotonic decrease of the bond lifetimes with pulling forces from 10 to 50 pN.
Summary/Conclusion: The finding that single A:a knob-hole bonds show dual 'catch-slip' response to mechanical tension is a highly significant result, suggesting a complex energy landscape underlying these bimolecular interactions. This, in turn, implies that the A:a knob-hole bonds are heterogeneous and are characterized by multiple bound states, which dissociate following different unbinding pathways. The 'catch-slip' behavior of the A:a interactions may be a mechanism for shear stress-related modulation of fibrin formation, since the bond lifetime increases with force over a certain range. This behavior may underlie the predisposition to venous or arterial thrombosis and other complications associated with alterations in normal blood flow.

OC 06.2

DNA methylation profiling of the fibrinogen gene landscape in human cells and during mouse and zebrafish development

Neerman-Arbez M[1], Vorjohann S[1], Pitetti J-L[1], Nef S[1], Gonelle-Gispert C[2], Buhler L[2] and Fish RJ[1]

[1]University of Geneva Faculty of Medicine; [2]University Hospital Geneva, Geneva, Switzerland

Background: Fibrinogen is the soluble precursor of fibrin, the central blood clotting agent in wound healing. Two sets of the three polypeptide chains Bß, Aα and γ form hexameric fibrinogen. The chains are encoded by the genes *FGB, FGA* and *FGG*, which are clustered on a 50 kb region in humans with cluster conservation seen across terrestrial vertebrates. Fibrinogen gene expression is limited to hepatocytes and several studies indicate a coordinated regulatory mechanism. Transcription factor binding sites have been analyzed in all three promoter regions with hepatocyte nuclear factor-1 (HNF-1) and CCAAT-box/enhancer-binding protein (C/EBP) being recognized as key contributors to basal fibrinogen expression. Identifying additional mechanisms contributing to the coordinated liver-specific expression of the fibrinogen genes may provide explanations for the variability of fibrinogen blood levels.

Aims: The role of DNA-methylation in gene regulation has focused on CpG-rich 'islands' that are present in approximately 70% of protein-coding gene promoters. The three fibrinogen gene promoters are CpG-poor and do not contain CpG islands. CpG-methylation in CpG-poor gene promoters is thought to be dynamic with low methylation correlating with tissue-specific gene expression, but its direct effect on gene regulation as well as the role of non-promoter CpG methylation are not clear. To investigate the role of CpG-methylation in the regulation of fibrinogen gene expression this study aims to characterize the methylation status of CpGs across the fibrinogen locus in human cells as well as in developing mouse and zebrafish tissues.

Methods: For a representative overview of CpG-methylation we used DNA-methylation sequencing to analyze 33% (144 CpGs) of CpGs in the human fibrinogen locus with a focus on promoter regions, gene bodies and the liver enhancers CNC12 and PFE2 recently identified in our laboratory. We analyzed the methylation status of the fibrinogen locus in mouse and zebrafish tissues in relation to changing fibrinogen expression levels during development. Finally, we determined whether trimethylation of H3K4, a mark of active promoters which strongly correlates with hypomethylated CpGs, changes in the fibrinogen promoters during development.

Results: We observed low CpG-methylation in the three fibrinogen promoters, CNC12 and PFE2 in human fibrinogen-expressing samples (HuH7, HepG2, primary hepatocytes). In a gene reporter assay, CpG-methylation in the *FGA* promoter reduced promoter activity, suggesting a direct repressive function for CpG-methylation in the fibrinogen locus. In mouse and zebrafish livers CpG-methylation around fibrinogen genes reduced during development. This lowering appears to be preceded by increased fibrinogen expression and tri-methylation of H3K4 (H3K4me3) in fibrinogen promoters.

Summary/Conclusion: Our data support a model where changes in hepatic transcription factor expression and histone modification provide the switch for increased fibrinogen gene expression in the developing liver which is followed by reduction of CpG methylation.

OC 06.3

The B subunit for coagulation factor XIII accelerates the crosslinking of fibrin in human plasma

Souri M, Osaki T and Ichinose A

Yamagata University School of Medicine, Yamagata, Japan

Background: Coagulation factor XIII (FXIII) is a proenzyme of plasma transglutaminase consisting of two catalytic A subunits (FXIII-A) and two non-enzymatic B subunits (FXIII-B). FXIII-B used to be thought to have an inhibitory effect on the activation of FXIII, primary in purified system *in vitro*. We previously found that administration of FXIII-B into FXIII-B-knockout mice increased plasma level of FXIII-A *in vivo*. In addition, an addition of FXIII-B into plasma of FXIII-B-knockout mice enhanced crosslinking of fibrin *in vitro*.

Aim: The role(s) of FXIII-B in crosslinking of fibrin was explored in human.

Methods: Recombinant human FXIII-B (rFXIII-B) was prepared by a baculovirus expression system. Fibrin-crosslinking reaction was examined in citrated plasma by the addition of thrombin and calcium chloride. Generated fibrin clot was collected by centrifugation and subjected to SDS-PAGE followed by protein staining or Western blotting using antibodies for target proteins. FXIII remaining in the supernatant was quantified by ELISA.

Results: The addition of rFXIII-B into FXIII-B-deficient plasma *in vitro* accelerated crosslinking between fibrin-gamma chains. FXIII-B was co-immunoprecipitated with fibrinogen from FXIII-A-deficient plasma, although FXIII-A did not precipitate with fibrinogen from FXIII-B-deficient plasma. In normal plasma, FXIII-A was incorporated into fibrin clot, and FXIII-B was released from the clot dependent on the crosslinking of fibrin gamma-chains. In contrast, FXIII-B-deficient plasma showed reduced incorporation of FXIII-A into fibrin clot, and decreased cleavage of the activation peptide (AP) of FXIII-A by thrombin. Both the reduced FXIII-A-incorporation into fibrin clot and the decreased AP-cleavage by thrombin were restored by the addition of rFXIII-B.

Conclusion: These results strongly suggested that FXIII-B led FXIII-A to an adapted site of fibrinogen to the effective cleavage of the activation peptide by thrombin and to immediate crosslinking of gamma-chains. The binding sites of both fibrinogen and FXIII-B should be determined for further understanding the mechanism of fibrin-crosslinking by the possible cooperative action(s) of FXIII-A and FXIII-B.

OC 06.4

Fibrin formation under flow on biomimetic tissue factor microparticles

Onasoga A and Neeves KB

Colorado School of mines, Golden, CO, USA

Background: The interplay between thrombin generation, fibrin polymerization and flow determines the structure and stability of a thrombus. In purified systems containing only thrombin and fibrinogen, it has been shown that fibrin polymerization can only occur under a narrow set of conditions that are defined by the rate of thrombin generation and the shear rate [Neeves, *Biophys J* 98, 2010]. What is unknown is how the surface concentration of TF affects fibrin formation over a wide range of flow conditions and how coagulation factor deficiencies influence this phenomenon.

Aims: The objective of this work was to quantify fibrin formation and thrombin generation under flow as a function of TF surface concentration and shear rate in a plasma-based assay.

Methods: Tissue factor bearing particles were synthesized by coating 1 μm silica beads with 0.5, 5, or 50 molecules TF/μm^2 in a lipid bilayer (phosphatidylserine:phosphatidylcholine 30:70). The particles were patterned as 100 μm spots on a glass substrate using a microblotting technique to define a focal 'injury.' Normal pooled plasma, prothrombin, FVIII, FX and FXI deficient plasmas were perfused over the TF spots at wall shear rates of 100, 250, 500 and 1000/s for 10 min. Fibrin formation and thrombin generation were measured in real-time by epifluorescence using labeled fibrinogen and the thrombin substrate boc-VPR-AMC, respectively. Following the assay, fibrin gels were either (i) fixed and further imaged by confocal or scanning electron microscopy or (ii) digested by plasmin to quantify the amount of fibrin deposited using a D-dimer ELISA.

Results: As the shear rate was increased (100, 250, 500 and 1000/s) the initiation times to visible fibrin formation was prolonged (38 ± 8, 72 ± 10, 150 ± 13 and 216 ± 35 s). The rate of fibrin formation (1719, 1367, 351 and 97 RFU/s) and the final fibrin deposition (20, 18, 1.6, and 1.4 ng) decreased with increasing shear rate. Similarly, the diameters of the fibrin fibers decreased (162 ± 49, 99 ± 20, and 58 ± 15 nm). Thrombin generation was similar for all shear rates, except 50/s, were it was five-fold higher. This suggests above 50/s coagulation is kinetically limited, and below 50/s it is transport limited. Similar trends were observed at 50 molecules of TF/μm^2 except fibrin deposition was significantly higher. Fibrin fibers orient in the direction of flow. At shear rates of 50, 100, 250, 500 and 1000/s the median fiber angles were 46.3°, 34.8°, 17.8°, 13.5°, and 5.3° with respect to the direction of flow (0°). Preliminary studies using FVIII and FXI deficient plasmas resulted in approximately 50% and 40% less fibrin deposition compared to NPP, respectively, at 100/s. As expected, there was no observable fibrin formation in prothrombin and FX deficient plasmas.
Conclusions: A plasma-based flow assay was developed to measure transient fibrin deposition and thrombin generation. We found that for a given TF concentration, flow profoundly influenced fibrin deposition, fiber diameter, fiber orientation and local thrombin concentration.

OC 06.5

Evidence that fibrinogen gamma′ regulates plasma clot structure and lysis, and relationship to cardiovascular risk factors in black Africans

Pieters M[1], Kotze RC[1], Jerling JC[1] and Ariëns R[2]
[1]North-West University, Potchefstroom, South Africa; [2]University of Leeds, Leeds, UK

Background: Fibrinogen γ' is known to influence fibrin clot structure in purified experimental models but little is known regarding its influence on clot structure in plasma. Furthermore, the environmental and biological factors that affect its concentration are poorly described.
Aims: Our aim was to analyse whether γ' fibrinogen, total fibrinogen, and γ'/total fibrinogen ratio relate to plasma clot structure and lysis in a large population-based study of apparently healthy black South Africans. We also aimed to analyse the relationship between γ' fibrinogen and γ'/total fibrinogen ratio and traditional cardiovascular risk factors.
Method: We analysed fibrinogen γ', total fibrinogen concentration, γ'/total fibrinogen ratio and fibrin clot structure and lysis, determined through the use of turbidity analysis, in 2010 apparently healthy black South African men and women, aged 35–65, who formed part of the South African arm of the international PURE study and related them to traditional CVD risk factors.
Results: Fibrinogen γ' generally increased with increasing fibrinogen concentration, however a decreased γ'/total fibrinogen ratio was found at the highest total fibrinogen concentrations. Clot maximum absorbance increased with total fibrinogen and fibrinogen γ', in agreement with the formation of clots composed of increased fibrin material. However, the γ'/total fibrinogen ratio was associated with decreased maximum absorbance, in agreement with clots made of thinner fibrin fibres. Clot lysis time showed a stronger relationship with fibrinogen γ' than with total fibrinogen, whereby increased fibrinogen γ' delayed clot lysis times. Traditional CVD risk factors (excluding fibrinogen) explained 20% and 3% respectively of the variance in fibrinogen γ' and the γ'/total fibrinogen ratio, with CRP making the biggest contribution. More than 50% of the variance in fibrinogen γ' and γ'/total fibrinogen ratio is explained by factors other than total fibrinogen concentration or other traditional CVD risk factors.
Conclusions: These data show that physiological levels of γ' fibrinogen influence fibrin clot structure and lysis in plasma and that factors other than fibrinogen, likely involved in the inflammatory response, regulate plasma γ' fibrinogen concentration. Our findings support future studies of the role of γ' fibrinogen in thrombosis.

OC 06.6

Transcriptome analysis of the miR-29-mediated control of fibrinogen gene expression

Lukowski SW, Fish RJ, Dermitzakis E and Neerman-Arbez M
University of Geneva, Geneva, Switzerland

Background: Fibrinogen is a critical component of hemostasis. In humans, circulating fibrinogen levels are highly variable, ranging from 1.5 to 3.5 g/L. Increased plasma fibrinogen is a risk factor for cardiovascular disease, including stroke and deep vein thrombosis. Basal fibrinogen expression is regulated HNF-1 and C/EBP transcription factors and, in the acute phase response, in response to inflammatory signals such as interleukin-6 (IL-6) and glucocorticoids. However, the molecular mechanisms underlying the coordinated transcription of the five major fibrinogen mRNAs remain unclear. Previously, we have demonstrated the potential role of microRNAs (miRNAs) in the fine-tuning of fibrinogen expression and shown that the overexpression of a single miRNA family (hsa-miR-29abc) member can inhibit the expression of the five major fibrinogen transcripts and fibrinogen protein production by 40–60%. The miR-29 family does not directly target the fibrinogen genes to control their expression, therefore the mechanism is more likely to be the result of an indirect interaction via regulatory transcripts or transcripts for regulatory proteins. Identifying a master regulator of fibrinogen gene expression is vital to understanding plasma fibrinogen variation in normal populations and its contribution to hemostasis in humans.
Aims: The aim of this study is to uncover novel pathways that regulate the levels of circulating fibrinogen. We aim to identify and characterize key members of a fibrinogen regulatory network and to understand the extent to which microRNAs actively regulate liver-expressed or hemostasis-related genes within this network.
Methods: HepG2 cells were transfected in biological replicates with 30 nM of miR-29c precursor miRNA or a scrambled negative control miRNA, and untransfected cells were used as an additional control. At 48 h post-transfection, total RNA was extracted and RNA-seq libraries were prepared using the Illumina TruSeq RNA v2 and Small RNA kits. mRNA and small RNA transcriptomes were sequenced to an average read depth of 70 M combined reads per sample on an Illumina Hi-Seq 2000. Bioinformatic analysis was performed using the 'Tuxedo' pipeline comprising the tophat, cufflinks and cuffdiff software packages.
Results: Our analysis revealed more than 2900 transcripts that are differentially expressed following miR-29c overexpression in HepG2 cells compared to cells containing the negative control miRNA precursor or untransfected HepG2 cells. Of this subset of transcripts, 1212 were significantly up-regulated (log2 fold-change 0.5–5.6) and 1746 were down-regulated (log2 fold-change 0.5–4.4).
Summary/Conclusions: miR-29c-mediated repression of gene expression in HepG2 cells significantly altered the mRNA abundance of several transcription factors that regulate fibrinogen gene and protein expression. In addition, we observed significant changes in key members of the coagulation cascade and the fibrinolysis pathway, as well as a number of related miRNAs. Our analysis reveals several strong candidates that are likely to act as upstream regulators of fibrinogen, and provides insight into mechanisms that may be exploited to finely control fibrinogen biosynthesis.

OC 07 – Haemostatic Factors and Arterial Vascular Disorders

OC 07.1

Impact of incident venous thromboembolism on future risk of arterial thrombotic disease

Lind C[1], Flinterman LE[2], Enga KF[1], Severinsen MT[3], Kristensen SR[4], Brækkan SK[1], Cannegieter SC[5], Overvad K[2] and Hansen JB[1]
[1]*Hematological Research Group, University of Tromsø, Tromsø, Norway;* [2]*Section for Epidemiology, Aarhus University, Aarhus;* [3]*Department of Haematology, Aalborg University Hospital;* [4]*Cardiovascular Research Center, Aalborg University Hospital, Aalborg, Denmark;* [5]*Department of Clinical Epidemiology, Leiden University Medical Center, Leiden, the Netherlands*

Background: Growing evidence support a possible association between venous thromboembolism (VTE) and subsequent arterial thrombotic events (myocardial infarction (MI) and ischemic stroke). However, the evidence is established either by findings in selective patient cohorts (e.g. patients who survived pulmonary embolism) or from a large population-based prospective registry study unable to adjust for obvious confounders such as body mass index (BMI).
Aims: To study the association between incident VTE and future risk of arterial thrombotic events adjusted for obvious confounders, and to determine the population attributable risk (PAR) of arterial thrombotic disease by VTE in a large prospective cohort of subjects recruited from the general population.
Methods: Individual participant data from the Tromsø Study (Tromsø) (screening visits in 1994–1995) and the Diet, Cancer and Health Study (DCH) (screening visits 1993–1997) were merged. Thus, our prospective cohort comprised information of 81 687 subjects, aged 24–97 years without a previous history of VTE or arterial thrombotic diseases at inclusion. Information on age, BMI, diabetes, smoking, hypertension, hypercholesterolemia, physical activity and education was obtained by physical examination, blood samples and questionnaires. All first-time events of VTE, MI and ischemic stroke during follow-up were identified and validated. Subjects were followed from baseline to the date of an incident arterial event, death or migration or to the end of the study period [April 30, 2008 (DCH) and December 31, 2010 (Tromsø)]. Cox regression models with age as time scale and VTE as a time-dependent variable were used to determine risk estimates. The analyses were adjusted for age, sex, BMI, diabetes, smoking, hypertension, hypercholesterolemia, physical activity and education. The study was approved by the regional committees for research ethics in Tromsø and Aarhus and all subjects gave their informed written consent.
Results: There were 6344 incident arterial thrombotic events (3666 MIs and 2678 ischemic strokes) and 1208 incident VTE events during a median of 12.2 years of follow-up. Subjects suffering from a VTE event had a 35% higher risk of a future arterial event (adjusted HR 1.35; 95% CI 1.09–1.66). Stratified analyses revealed that the association between VTE and subsequent arterial thrombosis applied particularly to women and those below 65 years of age. Women below 65 years with VTE had 3.6-fold higher risk of MI (adjusted HR 3.62; 95% CI 1.49–8.80) and 3.2-fold higher risk of ischemic stroke (adjusted HR 3.16; 95% CI 1.18–8.47). No association between VTE and subsequent arterial thrombosis was found in men above 65 years of age. The population attributable risk (PAR%) of arterial thrombosis by incident VTE was only 0.9%, and the VTE event explained 64% of the risk (attributable risk) for arterial thrombosis in VTE patients.
Conclusions: Our prospective cohort study implies that women and subjects below 65 years of age with incident VTE have increased risk of future arterial thrombotic disease, including myocardial infarction and ischemic stroke. However, only 1% of the arterial thrombotic events in the population can be attributed to VTE.

OC 07.2

Procoagulant tumor-derived microparticles: phenotypic and functional approaches for their detection in an *in vitro* model of tumor cells-containing blood

Bez J[1], Bouriche T[1], Ruf W[2] and Poncelet PH[1]
[1]*BioCytex, MARSEILLE, France;* [2]*The Scripps Research Institute, La Jolla, CA, USA*

Background: Tumor-derived microparticles (tumor-MP) can be expected in the peripheral blood of cancer patients and these may often be highly pro-coagulant due to expression of phosphatidylserine (PS) and tissue factor (TF). Their measurement in plasma may thus help evaluating thrombotic risk and even serve for the early diagnostics of hidden tumors. However, these rather elusive tumor-MP are not yet easily detected and efforts are still needed to define optimal techniques.
Aims: (i) To use an *in vitro* model of cancer cells admixed in whole blood to generate large volume plasma samples containing highly procoagulant TF+ tumor-MP. (ii) To compare phenotypic and functional approaches in tumor-MP detection and evaluate possible interactions between normal blood cells and admixed tumor cells.
Methods: Cultured cells from a human colon cell line (CY1) expressing high amounts of TF (> 200 000 molecules/cell, as measured by Quantitative Flow CytoMetry (FCM)) were spiked at different levels (0, 10, 100 and 1000 cells/μL) into ACD-anticoagulated blood issued from transfusion bags (100 mL per level), or the corresponding platelet poor plasma (PPP) or platelet rich plasma (PRP) as controls. After a 3 h incubation period at 37 °C with gentle agitation, the platelet-rich buffy-coat and PPP were obtained (2500 g 15 min) and the platelet free plasma (PFP, again 2500 g 15 min) recovered and frozen as aliquots. Buffy-coat cells (WBC+Plt) with/without tumor cells (CY1) were analyzed in 4-color FCM using anti-EPCAM-FITC, CD14-APC and CD45-PC5 to discriminate WBC and tumor cell subsets, plus a series of PE-labeled MAbs to study various markers including TF (CD142), platelet- (Plt), monocyte-, granulocyte- and lymphocyte-related markers plus tumor-associated markers (EGFr, CEA, E-cadherin) and shared antigens (e.g. CD9, 24, 61, HLA). TF-linked procoagulant activity of PFP was tested using a FXa generation assay on their washed MP (2 × 24 000 ***g*** 1 h). Distribution of MP subsets in each PFP was studied by 5-color IF in CMF using a 3 laser instrument (Gallios, Beckman-Coulter) set-up for standardized size-related cut-off at 0.3 μm-eq. using Megamix-Plus FSC beads (BioCytex). The three major subsets were delineated with AnnV-FITC (PS+ MP), CD41-PC7 (PMP), CD235a-APC-A750 (Ery-MP) and CD15-Pac.Blue (Leu-MP) plus a large series of PE-MAbs as described above.
Results: In spiked blood samples, unusual cell-surface markers highly expressed on CY1 cells (e.g. Epcam, TF, CD9, E-cadherin…) also appeared on all WBC subsets and platelets. This suggested an active generation of tumor-MP, some of which adhering to blood cells. This was confirmed by a high, spiking level-dependent, TF-dependent, procoagulant activity. No major difference of activity was noted between PFP derived from PPP, PRP or whole blood samples spiked with tumor cells at the same level, suggesting that in all three cases the procoagulant activity came from the generated tumor-MP without major influence of WBC, red cells or platelets.
Conclusions: When incubating whole blood (or plasma) with TF+ tumor cells, a high amount of TF+ tumor-MP is released which harbour antigens absent from blod-borne MP. Although some adhere to WBC and Plt, most of them remain in the plasma, thus generating high levels of TF-dependent procoagulant activity.

OC 07.3

High on-treatment platelet reactivity in patients with unprotected left main disease treated by percutaneous coronary intervention: the ALMA (angioplasty of left main – lariboisiere) registry

Drouet L[1], Dillinger J-G[1], Kchaou I[1], Sideris G[1], Bal dit Sollier C[2], Voicu S[1], Manzo Silberman S[1], Logeart D[1] and Henry P[1]
[1]AP-HP; [2]IVS, Paris, France

Background: the clinical benefit of platelet antiaggregation monitoring to tailor antiplatelet therapy is highly debated. The apparent clinical benefit is influenced by the patient population: higher is the thrombotic risk, more sensitive is the outcome on the exact degree of platelet inhibition.
Aims: In patients with unprotected left main disease (ULMD), angioplasty is emerging as an alternative technique. High on-treatment platelet reactivity (HOPR) despite aspirin and/or thienopyridines is associated with acute events after angioplasty. We aimed to determine the rate and potential clinical impact of HOPR in patients treated by angioplasty for ULMD.
Methods: One hundred and twenty-five consecutive patients referred for angioplasty of ULMD prospectively were included in a monocentric registry (ALMA). For the first 64 patients (ALMA-1), angioplasty was performed under aspirin and clopidogrel treatment without platelet reactivity assessment. For the last 61 patients (ALMA-2), platelet reactivity assessment (light transmission aggregometry triggered by arachidonic acid and ADP and measurement of VASP index by platelet flow cytometry) were systematically performed before angioplasty: in case of HOPR for aspirin, aspirin was given twice daily and in case of HOPR for clopidogrel, daily clopidogrel dose was doubled or replaced by prasugrel.
Results: Overall, patients mean age was 69 ± 13 y.o., 37% were diabetic, 37% had NSTEMI and 62% had multivessel disease. Mean SYNTAX score was 22.8 ± 9.2. In ALMA-2, 28% patients had HOPR for aspirin and 29% patients had HOPR for clopidogrel. Aspirin twice daily was given in 28% of patients, clopidogrel double dose in 6% and prasugrel in 23%. Compared to ALMA-1, the rate of 1-year MACCE was decreased in ALMA-2 (8.2 vs. 20.8%; $P = 0.04$) as a composite endpoint of cardiovascular death and stent thrombosis (0.0 vs. 8.3%; $P = 0.02$).
Conclusion: HOPR for aspirin and clopidogrel is frequent in patients undergoing angioplasty for ULMD and appears to be strongly associated with subsequent major events, adaptatation of the dual antiplatelet therapy to platelet inhibition monitoring is correlated with a more favourable clinical outcome.

OC 07.4

FXIII levels and different major adverse cardiac events (MACEs) in acute myocardial infarction: a potential prognostic biomarker

Gemmati D[1], Zeri G[2], Mari R[2], Orioli E[2], Moratelli S[2], Ferrari R[3], Grossi M[3], Ansani L[3] and Serino ML[2]
[1]University of Ferrara; [2]Ctr. Hemostasis & Thrombosis – University of Ferrara; [3]University of Ferrara, Cardiology Section, Ferrara, Italy

Background: FXIII fall in the early phases of myocardial infarction (MI) could impair heart healing, cause cardiac rupture and anomalous left ventricular remodelling. Monitoring of FXIII levels in the acute phases of MI could be considered a novel prognostic biomarker together with the classical ischemic routine biomarkers. Thus, FXIII might predict healing suggesting implications in prognosis and therapy.
Aims: We recently recognized acute FXIII drops in virtually all patients during the first post-MI days. This behaviour had a wide range of distribution (Δ-drop ranged from 10% to > 50%). Our objective is to investigate if FXIII drop, and/or its late recovery, could be considered a novel MI marker, and if a FXIII prognostic threshold could be recognized.
Methods: Informed consent and approval medical ethics committee were obtained. We recruited 334 MI patients (72% male) from the Coronary Care Unit of Hospital-University of Ferrara. We performed 1-year follow-up and the combined end-point was re-MI, death, heart failure, u-angina, and stroke/ictus (MACEs). FXIII level was assessed by a commercial kit [Instrumentation Laboratory, Italy] at the recruitment (t_0) and every 24-h for five additional days (t_{1-5}) post-MI. Control samples were drawn at 30-day (t_{30}) to have steady state FXIII levels.
Results: Globally, 25.5% of patients experienced MACE (re-MI, 3.4%; death, 10.5%; heart failure, 8.0%; u-angina, 2.7%; stroke/ictus, 1%). In the group of MACE(+) FXIII was: t_0 90.43 ± 31.1; t_{4-5} 77.2 ± 28.7; t_{30} 97.84 ± 25.9. In the group of MACE(−) FXIII was: t_0 100.7 ± 30.8; t_{4-5} 85.6 ± 25.23; t_{30} 106.9 ± 25.7. All the comparisons were statistically significant and the output was that MACE(+) group had the highest FXIII falls: (MACE+ vs MACE-: $P_{t0} = 0.0086$; $P_{t4-5} = 0.03$; $P_{t30} = 0.06$). Within group comparisons showed similar Results (MACE+: $_{t0}$ vs $_{t4-5}$, $P = 0.01$; MACE−: $_{t0}$ vs $_{t4-5}$, $P = 0.0001$). Interestingly, the FXIII drop behaviour was very different according to the different end points considered. In particular, re-MI cases strongly diverged from the other MACEs, being apparently not affected by the fall of FXIII levels [FXIII% lowest mean value (t_{4-5}): 92.5 ± 31.5]. On the contrary, cases who died within the first weeks after MI, presented with significant lower FXIII levels since the recruitment (t0), and the lowest FXIII% mean value (t_{4-5}) was 69.5 ± 28.5.
Conclusions: Post-MI MACEs still remain critical influencing prognosis and survival. FXIII could be considered a candidate molecule in cardiovascular diseases, and its employment is strongly promising. Understanding whether FXIII level monitoring may be useful to select cases with poor clinical outcome could pave the way to consider FXIII as a tailored treatment to improve myocardial healing, recovery of functions and survival.

OC 07.5

Effect of factor XIII polymophisms on the risk of myocardial infarction

Bereczky Z, Mezei Z, Balogh L, Katona E, Balogh E, Czuriga I, Édes I, Muszbek L and Bereczky Z
University of Debrecen, Medical and Health Science Center, Debrecen, Hungary

Background: Coronary artery disease (CAD) is still a major health issue in the Western world in both women and men. In our previous study elevated factor XIII (FXIII) levels were demonstrated to be associated with increased risk of myocardial infarction (MI) in females, but not in males. Among FXIII polymorphisms Val34Leu polymorphism of FXIII A subunit (FXIII-A) has been intensively investigated and meta-analysis of the reported data demonstrated a protective effect against myocardial infarction. Moreover, in the Hungarian population FXIII-A Val34Leu polymorphism was protective against MI in patients with elevated fibrinogen levels. FXIII-A Tyr204Phe polymorphism was reported to be associated with decreased FXIII levels and Phe204 was associated with a mild increased risk of ischemic stroke in young women. The His95Arg polymorphism in FXIII B subunit (FXIII-B) gene was found to be a risk factor of venous thrombosis. FXIII-B Intron K nt29756 C>G polymorphism leads to a novel splice acceptor site and a protein 15 amino acid longer at the C-terminus. It may have a profound effect on disease susceptibility, however no study on cardiovascular patients has been reported, as yet.
Aims: Investigation of the role of FXIII-A Tyr204Phe, FXIII-B His95Arg and IntronK (nt29756C>G) polymorphisms in cardiovascular diseases.

Methods: Consecutive patients (n = 900) with suspected CAD were subjected for coronary angiography and recruited for the study. Among them, patients without significant coronary stenosis and the history of myocardial infarction were considered as clinical controls (n = 276). Age and sex matched individuals (n = 1000) representing the Hungarian general population were also enrolled. FXIII-A Tyr204Phe, FXIII-B His95Arg and intron K nt29576C>G polymorphisms were detected by real time PCR using melting point analysis and FRET detection on a LightCycler 480 instrument (Roche). Clinical and laboratory data were analyzed by SPSS 19.0 statistical package.
Results: The rare allele frequencies of the FXIII-A Tyr204Phe, FXIII-B His95Arg and IntronK (nt29756C>G) polymorphisms in the general Hungarian population were 0.02, 0.08 and 0.15, respectively, which are similar to the results for Caucasians available in the HapMap database. The allele frequencies in the clinical controls did not differ significantly from the respective values in the general population. Individuals carrying the rare allele of FXIII-B IntronK polymorphism had significantly ($P < 0.0001$) lower FXIII activity (94 ± 21% vs. 103 ± 21%) and $FXIIIA_2B_2$ antigen (20.7 ± 4.7 mg/L vs. 23.1 ± 5.0 mg/L) levels compared to individuals homozygous for the frequent allele. FXIII-B IntronK polymorphism decreased the risk of MI by 60% in patients with fibrinogen level in the upper tertile (OR, 0.37; 95% CI, 0.17;0.84, P = 0.017). Moreover, an interactive effect was demonstrated between FXIII-B IntronK and FXIII-A Val34Leu polymorphisms; OR for MI in the case of double carriers with elevated fibrinogen was 0.031 (95% CI, 0.01;0.21, $P < 0.0001$).
Conclusions: The effect of certain FXIII subunit polymorphism on the rik of MI prevails only at elevated fibrinogen level. FXIII-B Intron K polymorphism decreases FXIII level and is protective against MI in patients with fibrinogen level in the upper tertile.

OC 07.6

D-dimer levels are differently associated with the risk of acute coronary syndrome in men and women of the european prospective investigation in the cancer (EPIC)-Italy cohort

Iacoviello L[1], Agnoli C[2], De Curtis A[1], Di Castelnuovo A[1], Krogh V[2], Matullo G[3], Panico S[4], Riccieri F[5], Sacerdote C[6], Tumino R[7], Vineis P[8] and De Gaetano G[1]

[1]Catholic University, Campobasso; [2]National Cancer Institute, Milano; [3]Human Genetic Foundation HuGef, Torino; [4]Federico II University of Naples, Napoli; [5]Hunan Genetic Foundation, HuGef; [6]Cancer Prevention Centre (CPO) Piemonte, Torino; [7]Cancer Registry ASP, Ragusa, Italy; [8]Imperial College, London, UK

Background: Fibrin D-dimers can be considered as a measure of fibrin turnover, being the balanced products of formation (via thrombin) and lysis (via plasmin) of crosslinked fibrin. We evaluated the association between D-Dimers and risk of acute coronary syndrome (ACS) in four out of five centers of the EPIC-Italy study.
Materials and Method: We conducted a case-cohort study on 1467 (712 men; 755 women) volunteers of the EPIC-Italy cohort, by comparing subjects who developed ACS (MI fatal or nonfatal, coronary revascularization, sudden death) in a mean follow-up of 11.93 years.
Using a nested case-cohort design in the EPIC-Italy study (n = 34 148), we identified a random subcohort (n = 830) and incident acute coronary syndrome cases (n = 634 plus 13 cases originated from the random subcohort) occurring between baseline (1993–1997) and end of 2006 (Varese and Naples), of 2007 (Ragusa) or 2008 (Turin); D-Dimer levels were measured in citrate plasma, utilizing HemosIL, an automated latex immunoassay on IL coagulation System ACL9000. Inter and intra-day CV were 7.6% and 5.4% respectively. The relative risk (RR) and 95% confidence intervals (CI), adjusted by relevant confounders and stratified by center, were estimated by aCoxregression model using Prentice method.
Results: Individuals in the highest compared with the lowest quartile of PAI-1 had significantly increased risks of ACS (RR: 2.50; 95%CI: 1.54–4.06; P for trend < 0.001) in univariate analysis; adjustment for sex, age, education, smoking habit, BMI, total physical activity, hypertension, diabetes and hyperlipidemia treatment, did not modify the association (RR: 2.62; 95%CI:1.50–4.55) (P for trend = 0.005). The risk of ACS increased by 44% for each increase in 1 standard deviation of D-Dimers. No association was found in women.
Conclusions: Our data support the evidence for a link between D-dimers and ACS in men but not in women.

OC 08.1

Prognostic role of MIR146A polymorphisms in atrial fibrillation

Roldan V, Salloum-Asfar S, Gallego P, Arroyo AB, Garcia-Barbera N, Teruel R, Caparros E, Vicente V, Gonzalez-Conejero R and Martinez C

Centro Regional de Hemodonación. Hospital Morales Meseguer. UMU. IMIB, Murcia, Spain

Background: Atrial fibrillation (AF) is a prevalent disease in which the underlying atherosclerosis, a chronic inflammation of the vessel wall with monocytes driving the initiation and progression of atherosclerotic lesions, increases the incidence of arterial thrombosis. At this time, there are limited biomarkers able to forecast new thrombotic events in anticoagulated patients with AF. In this framework, microRNAs (miRNAs) have emerged as critical players in cardiovascular biology. In particular, miR-146a-3p is recognized as an important negative regulator of inflammation. To date, neither the role of miR-146a-3p nor the role of functional polymorphisms (miRSNPs) rs2431697 (~1 kb upstream of *MIR146A*) and rs2910164 (within *MIR146A*), both affecting miR-146a-3p levels in monocytes, have been related with cardiovascular disease.
Aim: To evaluate the prognostic role of functional *MIR146A* miRSNPs in a large cohort of anticoagulated permanent AF patients.
Methods: We studied 904 patients (50% male; median age 76) with permanent AF who were stabilized for at least 6 months (INR = 2–3) CHADS2DS2-VASc score was calculated. Patients were followed-up for 2 years [median = 957 days (range 789–1078)] and adverse cardiovascular events (stroke, acute coronary syndrome, and acute heart failure) were recorded. MiRSNPs were genotyped by Taqman® analysis. *In vitro* studies were performed in immunoselected monocytes from healthy controls homozygous for the two genotypes of rs2431697 (n = 9 of each genotype). Monocytes were activated with10 ng/mL LPS, previously shown to increase miR-146a-3p levels. MiR-146a-3p and *IL6* mRNA levels were measured by qRT-PCR.
Results: The frequencies of these two miRSNPs in AF patients were similar to those reported in Caucasians (ancestral alleles: rs2431697, C = 0.48; rs2910164, G = 0.74). MiRSNP rs2910164 had no association with adverse cardiovascular events. However, on multivariate analysis (adjusted by CHADS2DS2-VASc score) we found that TT genotype of rs2431697 was associated with adverse cardiovascular events (HR, 95%CI: 1.56, 1.04–2.33; P = 0.030). In order to better define the functional effect of miR-146a, we studied the effect of rs2431697 in miR-146a-3p levels in monocytes from healthy subjects. After 2 h activation, LPS induced an increase of miR-146a-3p levels, which was slightly higher in CC carriers (increase *vs.* no LPS; TT = 15%, CC = 27%). Interestingly, after 24 h incubation, monocytes from CC individuals had a 65% increase of miR-146a-3p levels while TT individuals only increased their levels by 28%. These data suggest that TT individuals when submitted to an inflammatory stress may be prone to a highest pro-inflammatory state due in part to lower levels of miR-146a-3p. Indeed, *IL6* mRNA levels, previously shown to

be influenced by miR-146a-3p, were inversely correlated with those of miR-146a-3p. Thus, after 24 h of LPS activation, TT monocytes showed a higher increase of *IL6* expression than CC (52% *vs*. 26%).
Conclusions: Our study established *MIR146A* rs2431697 as a prognostic biomarker for adverse cardiovascular events in anticoagulated AF patients. According to our data, patients with AF who carry the TT genotype of rs2431697 might have a minor response to pro-inflammatory signals than CC, resulting in reduced levels of miR-146a-3p and a final increased production of pro-inflammatory targets such as IL-6, which might contribute to the higher risk of adverse cardiovascular events of these patients.

OC 08.2

Inflammatory markers and metalloproteinases profiles predict death in in the acute phase of ischemic stroke treated with tissue plasminogen activator thrombolysis

Gori AM[1], Nencini P[2], Giusti B[1], Mascia N[1], Armillis A[1], Piccardi B[1], Palumbo V[2], Pracucci G[1], Abbate R[1] and Inzitari D[1]
[1]University of Florence; [2]Careggi Univ Hospital, Florence, Italy

Background: Inflammatory mediators and metalloproteinases (MMPs) are altered in the acute phase of ischemic stroke and play a detrimental role on severity and hemorrhagic transformation of ischemic brain lesions after thrombolysis.
Aim: This study aimed to evaluate the effect of inflammatory and MMPs profiles on mortality in stroke patients submitted to thrombolysis.
Methods: Blood was taken at baseline and 24 h after thrombolysis from 327 patients (mean age 68, mean NIHSS 11.9) with acute ischemic stroke. Circulating molecules were measured using Bio-plex suspension array system [MMP-1, MMP-8, MMP-9, tissue inhibitor of metalloproteinase -1 (TIMP-1), C-reactive protein (CRP), haptoglobin, alpha2-macroglobulin (A2M), interleukin-1 receptor antagonist (IL-1RA), interleukin-6 (IL-6), interleukin-10 (IL-10), interleukin-12 (IL-12), tumor necrosis factor-alpha (TNF-alpha), vascular endothelial growth factor (VEGF)]. Baseline values and delta median values [(post tPA-baseline)/baseline] of each parameters were analyzed in 3 month-survivors and non-survivors.
Results: Baseline levels of CRP, haptoglobin, A2M, IL-10, IL-12 and IL-6 and delta values of MMPs 1, 8, 9 and TIMP-1 were significantly different in patients who died with respect to survivors [CRP: 8.25 (2.17–15.49) mg/L vs 2.96 (1.44–8.35) mg/L; haptoglobin: 3.12 (1.24–10.70) mg/mL; A2M: 2.26 (1.83–4.23) mg/mL vs 1.78 (1.24–2.60) mg/mL; IL-6: 6.25 (4.16–11.53) pg/mL vs 4.01 (2.16–7.90) pg/mL; $P < 0.01$ respectively, IL-10: 3.58 (1.16–16.70) pg/mL vs 9.80 (2.99–23.10) pg/mL; IL-12: 18.20 (9.23–42.10) pg/mL vs 24.20 (11.70–52.90) pg/mL, $P < 0.05$ respectively], whereas IL-1RA, TNF-alpha and VEGF levels [IL-1RA: 16.0 (4.98–65.40) pg/mL vs 17.44 (10.3–29.80) pg/mL; TNF-alpha: 1.61 (0.17–3.00) pg/mL vs 2.40 (0.58–5.67) pg/mL; VEGF: 82.2 (43.70–130.5) pg/mL vs 105.8 (56.40–203.7) pg/mL] did not significantly differ between non-survivors and survivors. Adjusting for age, sex, glycemia, baseline NIHSS, history of atrial fibrillation, or congestive heart failure, history of inflammatory diseases or infections occurred within the last 7 days before stroke onset, only deltaMMP-9 and baseline A2M remained significantly and independently associated with 3 month-death [OR (95% CI): baseline A2M: 1.49 (1.12–2.00); deltaMMP9:1.58 (1.11–2.26), $P < 0.01$]. ROC analysis demonstrated that the addition of baseline A2M and deltaMMP-9 (model 2) to a model that included factors known to affect the outcome (model 1) significantly improved the area under the curve for the detection of mortality in ischemic stroke patients [model 1: AUC = 0.82 (95% CI 0.75–0.90); model 2: AUC = 0.88 (95% CI 0.83–0.93), $P < 0.05$].
Conclusion: our findings suggest that A2M and deltaMMP-9 are significant and independent markers of mortality and that may be used to improve prediction of unfavourable outcome in the clinical setting of ischaemic stroke patients treated with thrombolytic therapy.

OC 08.3

Circulating nucleosomes and neutrophil activation as a measure of the formation of Neutrophil Extracellular Traps (NETs) during sickle cell painful crisis

Schimmel M[1], Nur E[1], Biemond BJ[1], Van Mierlo GJ[2], Solati S[2], Brandjes DPM[3], Otten HM[3], Schnog J-J[4] and Zeerleder S[2]
[1]Academic Medical Center; [2]Sanquin Research and Landsteiner Laboratory AMC; [3]Slotervaart Hospital, Amsterdam, the Netherlands; [4]Sint Elisabeth Hospital, Willemstad, the Netherlands

Background: Sickle cell disease (SCD) is characterized by recurrent acute vaso-occlusive painful crisis frequently leading to SCD related complications, like acute chest syndrome. The complex pathophysiology of the vaso-occlusive painful crisis is mediated by activation of endothelial cells, adhesion of sickled erythrocytes and polymorphonuclear neutrophils (PMN), oxidative stress, coagulation activation and an increased release of inflammatory mediators, resulting in ischemic organ damage. Recently, PMN have been demonstrated to form Neutrophil Extracellular Traps (NETs) upon activation. During this process, DNA and DNA-binding proteins are extruded from neutrophils exposing a mesh consisting of nucleosomes, histones and neutrophil proteases. NET formation has been shown to propagate coagulation in sepsis and deep venous thrombosis. Moreover, nucleosomes and histones exposed on NETs have been shown to be strongly cytotoxic to endothelial cells. Beside the exposure on NETs, nucleosomes can be actively released into the circulation from dead cells. Circulating nucleosomes detected in sepsis have been reported to correlate with markers of coagulation and inflammation as well as with organ dysfunction and mortality. *The aim* of this case–control study was to assess plasma levels of circulating nucleosomes and neutrophil activation as evidenced by human neutrophil elastase-α_1-antitrypsin (EA) complexes, as indirect measure of NET formation in plasma.
Methods: After obtaining informed consent, nucleosomes and EA complexes were measured using ELISA in blood samples of race matched controls (24), sickle cell patients during steady state (74) and sickle cell patients with painful crisis (70). Markers of inflammation and endothelial activation were also measured. For statistical analysis, patients were divided in two groups: patients with the relatively severe genotypes HbSS and HbSβ^0-thalassemia (HbSS/HbSβ^0-thal) and patients with the relatively milder HbSC and HbSβ^+-thalassemia genotypes (HbSC/HbSβ^+-thal). The study protocol was approved by the local medical ethical committee.
Results: Plasma levels of nucleosomes in both patients with HbSS/HbSβ^0-thal and HbSC/HbSβ^+-thal were significantly higher during painful crisis (median; IQR, 20.2 U/mL: 8.9–129.0, $P < 0.001$; 11.7 U/mL: 5.1–67.7, $P = 0.045$) as compared to those in steady state (6.0 U/mL: 3.0–9.8; 7.1 U/mL: 4.6–9.6). EA levels were higher in HbSS/HbSβ^0-thal and HbSC/HbSβ^+-thal patients during painful crisis (75.1 ng/mL: 56.5–102.4, $P < 0.001$; 62.0 ng/mL: 48.0–96.7; $P = 0.051$) as compared to levels during steady state (45.7 ng/mL: 34.7–59.7; 50.2 ng/mL: 33.3–67.7), but just failed to reach statistical significance in HbSC/HbSβ^+-thal patients. During painful crisis, EA levels correlated with levels of nucleosomes in both HbSS/HbSβ^0-thal (Sr = 0.55, $P < 0.001$) and HbSC/HbSβ^+-thal patients (Sr = 0.90, $P \leq 0.001$). In steady state HbSS/HbSβ^0-thal patients, levels of nucleosomes correlated with endothelial markers sVCAM-1 and vWF:Ag (Sr = 0.421, $P = 0.003$; Sr = 0.452, $P = 0.001$). Six patients who developed an acute chest syndrome during painful crisis were among those with the highest nucleosome and EA levels. A significant (Sr = 0.441, $P < 0.001$) correlation was found between levels of nucleosomes and duration of hospitalization.
Conclusion: We demonstrate increased levels of circulating nucleosomes in sickle cell patients with painful crisis reflecting NET formation which strongly correlates with PMN activation and disease severity.

OC 08.4

Activated protein C inhibits lung inflammation in asthma patients after intrabronchial allergen challenge

De Boer DJ[1], Majoor CJ[1], Marieke B[1], Meijers JC[2], Zeerleder S[3], De Vos AF[1], Van 't Veer C[1], Van Der Zee J[4] and Van Der Poll T[1]
[1]Academic Medical Center, University of Amsterdam; [2]Academic Medical Center Amsterdam; [3]Sanquin; [4]Onze Lieve Vrouwe Gasthuis, Amsterdam, the Netherlands

Background: Allergic lung inflammation in asthma is associated with a pulmonary prothrombotic and antifibrinolytic state. Activated Protein C (APC) exerts anticoagulant, pro-fibrinolytic and anti-inflammatory effects that could be beneficial in allergic lung inflammation. House dust mites (HDM) are common allergens and natural carriers of lipopolysaccharide (LPS). LPS exposure is strongly associated with asthma severity.
Aim: To investigate the effect of recombinant human (rh)APC on allergic lung inflammation provoked by intrabronchial HDM and LPS administration in asthma patients.
Methods: A double-blind, randomized, placebo-controlled trial was conducted in 24 HDM allergic asthma patients. Male and female, mild to intermittent asthma patients of 18–45 years of age were eligible for screening. Asthma medications were discontinued 2 weeks before the study. Patients received intravenous rhAPC (24 μg/kg/h, $n = 12$) or placebo ($n = 12$) for 11 h. Four hours after the start of the infusion a first bronchoscopy was performed to challenge one lung segment with saline (serving as control) and a contralateral segment with a combination of HDM (50 biological units) and LPS (75 ng). Eight hours after provocation (1 h after stopping rhAPC or placebo) a second bronchoscopy was conducted to obtain bronchoalveolar lavage fluid (BALF) from challenged segments. The protocol was approved by the institutional Medical Ethics Review Committee and all patients gave written informed consent. Comparisons were done by Wilcoxon or t-test where appropriate.
Results: Patient characteristics were similar at baseline, including lung function tests and biochemical screening. RhAPC treatment resulted in increased plasma APTT values compared to placebo ($P < 0.05$). Cell counts in BALF were increased after HDM+LPS challenge compared to saline ($P = 0.001$) primarily as a consequence of eosinophil and neutrophil influx. RhAPC significantly reduced total cell counts in BALF by 43% ($P < 0.05$ versus placebo), which was due to a decrease in neutrophil influx ($P < 0.05$) and accompanied by an attenuated rise in BALF levels of elastase-1-antitrypsin complexes (indicative of neutrophil degranulation, $P < 0.01$). HDM+LPS challenge caused a procoagulant response in the bronchoalveolar space of both treatment groups, as reflected by increased BALF levels of D-dimer, thrombin-antithrombin complexes (TATc) and plasminogen-activator inhibitor type I (PAI-1). In addition, HDM+LPS exposure resulted in increased protein leakage in BALF, local activation of the complement system (increased BALF C3a, C3bc and C4bc levels) and local release of nucleosomes (all $P < 0.05$ versus saline). Relative to placebo, rhAPC decreased PAI-1 ($P < 0.05$), C3b ($P < 0.05$) and nucleosome ($P < 0.05$) levels in BALF. Remarkably, intravenous rhAPC did not significantly impact on BALF D-dimer or TATc levels.
Conclusions: Bronchial allergen provocation in asthma patients results in local activation of coagulation and multiple inflammatory pathways. Intravenous rhAPC inhibited distinct inflammatory responses in this human model of acute allergic inflammation without influencing coagulation. These data indicate that rhAPC exerts anti-inflammatory effects in the lungs of asthma patients by mechanisms that do not rely on its anticoagulant properties.

OC 08.5

Increased adhesive properties of neutrophils and inflammatory markers in VTE patients with residual vein occlusion and high D-dimer levels

Zapponi KC, Bittar F, Mazetto BM, Barnabé A, Santiago-Bassora D, De Paula EV, Orsi LA, Conran N and Annichino-Bizzacchi JM
State University of Campinas, Campinas, Brazil

Background: Venous Thromboembolism (VTE) is a multifactorial disease that affects 1–3:1000 individuals worldwide. The venous thrombus develops via a multicellular process on the surface of the endothelium and presents a laminar structure comprised of layers of platelets, leukocytes, erythrocytes and fibrin. The relationship between inflammation and coagulation is bidirectional, and has been mainly evaluated through protein interactions between pro-inflammatory cytokines and elements of the coagulation cascade. Inflammatory cells such as neutrophils, have not been previously correlated with thrombotic or procoagulant processes.
Aims: To evaluate the adhesive properties of neutrophils, erythrocytes and platelets, as well as the expression of neutrophil adhesion molecules in patients with VTE, correlating them with markers of the systemic inflammatory response, and with the presence of residual vein obstruction (RVO) and higher D-dimer.
Methods: Study group consisted of thirty chronic VTE patients (1–6 years after the acute episode) followed in our outpatient clinic, as well as age, gender and ethnic background-matched healthy individuals. Adhesive properties of neutrophils, erythrocytes and platelets were determined by a static adhesion assay using ligands such as fibrinogen (FB) and fibronectin (FN). The expression of neutrophils adhesion molecules (CD11a, CD11b, CD18) was evaluated by flow cytometry. Levels of inflammatory markers (IL-6, IL-8, TNF-α, PCR) were evaluated by ELISA and nephelometry. RVO was evaluated by Doppler ultrasound.
Results: No significant difference could be observed in the platelets (basal: 16.37% vs. 14.59%, $P = 0.309$; and stimulated with thrombin: 33.45% vs. 26.62%, $P = 0.200$) and erythrocytes adhesion (7.28% vs 7.49%, $P = 0.859$) between chronic VTE patients and healthy individuals. Interestingly, in patients with a higher risk of recurrent VTE (defined by the presence of high levels of D-dimer) and RVO, a significant increase in neutrophils adhesion compared to healthy individuals was observed (24.68% vs. 19.07%, $P < 0.05$). Inflammatory markers (IL-6, IL-8, TNF-α and CRP) were also significantly elevated (2.08 pg/mL vs 0.90 pg/mL, $P = 0.01$; 28.72 pg/mL vs 16.46 pg/mL, $P = 0.02$; 4.50 pg/mL vs 2.11 pg/mL, $P = 0.04$; 0.35 pg/mL vs 0.14 pg/mL, $P = 0.09$, respectively) in this subgroup compared to patients with a standard risk of recurrent VTE. Adhesive properties of neutrophils was correlated with IL-6 ($r = 0.3815$ and $P = 0.0375$) and D-dimer levels ($r = 0.3831$ and $P = 0.0367$). Neutrophils adhesion molecules (CD11a, CD11b and CD18) were not altered in any of the groups.
Conclusions: Our results suggest that, after an acute episode of VTE, patients do not exhibit increased adhesive properties of platelets and erythrocytes. However, neutrophils adhesive properties were increased in patients with higher D-dimer levels and RVO, independently of the expression of neutrophil adhesion molecules. A hypothesis for this increase could be due to alterations in affinity of surface adhesion molecules to their ligands, as a consequence inflammatory processes associated with the hypercoagulability that is characteristic of this disease.

OC 08.6

Does platelet activation mediate pathogenesis of malaria infection?

Jobe SM[1], Schenk M[1], Zhou C[1], Choo H[1], Gibbins JM[2] and Lamb TJ[1]

[1]Emory University, Children's Healthcare of Atlanta, Atlanta, GA, USA; [2]University of Reading, Reading, UK

Background: Platelet activation by malaria parasites is thought to cause pathology in malaria infection by acting as a bridge for infected red blood cells to adhere to the endothelium leading to blockage of the blood vessels in the brain, and in turn cerebral malaria. This event has most commonly been investigated using the *Plasmodium berghei* ANKA mouse model that causes experimental cerebral malaria (ECM) in C57BL/6 mice. Platelet depletion in mice using an anti-platelet monoclonal antibody can protect against death from ECM, but only when performed within the first few days of infection. This early effect of protection suggests that platelets mediate lethal inflammation in acute malaria infection, rather than act to enhance blood vessel blockage in chronic infection.

Aims: Investigate the role of platelets in mediating inflammation and pathology in experimental cerebral malaria.

Methods and Results: Platelet depletion using monoclonal antibodies involves clearance of antibody-opsonized platelets. Fc triggering by the opsonized platelets and subsequent IL-10 production by macrophages may offer an alternative explanation for the protection offered by platelet depletion in these experiments. IL-10 can act to down-regulate the anti-malarial inflammatory response. Consistent with this hypothesis, following antibody removal of platelets the number of splenic T cells secreting protective IL-10 significantly was increased. Indeed, unlike antibody-mediated platelet removal, inactivation of platelets using aspirin or Plavix© neither protected against the manifestations of ECM nor increased the numbers of IL-10-producing T cells in the spleen.

To ascertain whether platelet presence truly alters the inflammatory landscape of mouse malaria infection we analyzed the effects of platelet depletion on malaria pathogenesis and immune response using a novel non-antibody-mediated method of platelet depletion. In this model, megakaryocyte and platelet-limited ectopic expression of the simian diphtheria toxin (DT) receptor allows for selective and nearly complete platelet depletion following DT administration. Upon DT administration platelets were ablated. However, unlike in antibody-mediated platelet depletion, no protective effect against the development of ECM was observed upon DT-mediated platelet ablation. Similarly, IL-10 production was unaffected.

Conclusions: Our results suggest that studies showing a protective effect in ECM of platelet removal by mAb depletion may in fact reflect an artifact of the method of platelet depletion, and indicate that platelets do not play a critical role in the pathogenesis of ECM.

OC 09 – Novel platelet Inhibitors

OC 09.1

Discovery of novel GPVI receptor antagonists by structure-based repurposing

Coxon CH, Taylor L, Vasudevan SR, Jones CI, Churchill GC and Campbell D

University of Oxford, Oxford, UK

Background: Current strategies for managing cardiovascular risk caused by platelet aggregation rely largely on the use of thienopyridines and aspirin. Although these drugs are effective in a large number of people, they have limitations. Increased bleeding risk and drug 'resistance' underpins a drive for new antiplatelet therapeutics. Under pathological conditions, collagen exposure leads to the recruitment and activation of platelets leading to the formation of an occlusive thrombus. Platelet activation by the primary platelet collagen receptor, GPVI, is central to cell activation. Perturbation of collagen-GPVI interactions using GPVI-Fc fusion proteins or single chain antibody fragments (scFvs) can reduce thrombus formation *in vivo* with minimal effects on bleeding, highlighting GPVI as a viable target for antiplatelet therapy.

Aims: We hypothesised that the GPVI-collagen interaction is amenable to perturbation by small molecules and that disruption of this receptor-ligand interaction would be sufficient to reduce inhibit platelet activation and aggregation. Drug repurposing is being fiercely promoted and supported by academic, government and industrial partners to reduce the bottle neck associated with traditional drug discovery approaches and accelerate the bench-to-bedside transition. We therefore used to a structure-based repurposing approach by docking a database of FDA approved drugs into the GPVI receptor ligand binding site.

Methods: For *in silico* docking, the crystal structure of human platelet glycoprotein VI (PDB ID 2gi7) was processed using our own set of parameters and used to dock the NIH Clinical Collection into the GPVI ligand binding site, with an emphasis on the electrostatic environment around Lys 41. The docking was performed using Fred 2.2.5 and a database of ~900 compounds with conformers pre-generated using Omega 2.2.3; molecules were docked and scored with FRED's default consensus scoring. We evaluated biologically the top 20 compounds from the *in silico* screen using both Ca^{2+} release and platelet aggregation assays in washed human platelets.

Results: Fourteen out of the top 20 compounds inhibited CRP-induced Ca^{2+} release by 50% or more. The ability of these compounds to elicit dose-dependent effects on GPVI-mediated Ca^{2+} release and platelet aggregation was further assessed and three compounds were found to inhibit the GPVI receptor in a selective and dose-dependant manner, with IC_{50} values of between 40 mM and 400 nM. Global tyrosine phosphorylation following GPVI activation was reduced by all three compounds as assessed by western blotting; no effect was observed on thrombin- or ADP-induced platelet activation. Our most potent and selective inhibitor, torasemide, inhibited thrombus formation in whole human blood under physiological rates of shear.

Summary/Conclusions: We have identified the first selective small molecule inhibitors of GPVI. By coupling *in silico* screening with medium-throughput approaches to assess platelet function, we were able to quickly and effectively identify novel small molecule inhibitors of the GPVI-collagen interaction. Most importantly, our lead compound, torasemide, can inhibit thrombus formation on collagen under physiological conditions *in vitro*, validating our approach and supporting our hypothesis. These compounds will serve as starting points for the development of new, better antiplatelet agents.

OC 09.2

Parmodulins target the intracellular side of PAR1 to selectively interfere with Gaq but not Ga12/13 signaling and block thrombus formation, but not hemostasis

Aisiku OR[1], Peters CG[1], Dilks JR[1], Gunnink S[1], Dockendorff C[2], Smith DA[1], Denker B[3], Huang M[1] and Flaumenhaft R[1]

[1]Beth Israel Deaconess Medical Center, Boston, MA; [2]Marquette University, Milwaukee, WI; [3]Harvard Medical School, Boston, MA, USA

Background: Protease-activated receptor-1 (PAR1) serves a critical role in coupling the coagulation cascade to platelet-mediated thrombosis. Small molecules that inhibit at the binding site of the tethered ligand of PAR1 have been developed and recently tested in clinical trials. However, bleeding complications including hemorrhagic stroke have been observed.

Aim: Our goal is to develop allosteric PAR1 modulators that bind outside of the PAR1 ligand binding pocket, stabilizing alternative confor-

mations of the receptor and interfering with procoagulant PAR1 signaling without having significant effects on hemostasis.

Results: We have performed two independent high throughput screens of 16 000 and 300 000 compounds, respectively, to identify molecules that inhibit PAR1-mediated platelet granule release. We now demonstrate that these molecules act by a common mechanism, defining a new class of PAR1 inhibitors termed parmodulins. The first screen identified an alkylated quinolone that inhibits PAR1-mediated platelet activation with an IC50 of 4 μM (parmodulin-1; aka JF5, PNAS, 108:2951). The second screen identified a 1,3-diaminobenzene that inhibits PAR1 with an IC50 of 0.3 μM (parmodulin-2; aka ML161, ACS Med Chem Lett, 3:232). Both compounds failed to inhibit the binding of a radiolabeled PAR1 peptide agonist, [3H]TRAP, to the ligand binding pocket of PAR1 on platelet membranes. In contrast, an orthosteric PAR1 inhibitor, SCH79797, blocked binding of [3H]TRAP to PAR1. To determine whether these allosteric PAR1 modulators act on the extracellular or intracellular face of PAR1, we tested the ability of the antagonists to inhibit signaling in COS7 cells overexpressing different PARs. Both parmodulins and SCH79797 inhibited $[Ca^{2+}]i$ flux induced through PAR1, but not PAR4. We next constructed a PAR1 (amino acids 1–365),4(amino acids 334–385) chimera consisting of the extracellular and transmembrane loops of PAR1 and the C-terminus of PAR4 distal to the DPXXY motif. Parmodulins failed to inhibit activation of the PAR1,4 chimera. In contrast, the orthosteric PAR1 inhibitor SCH79797 inhibited the chimeric receptor. Together with the [3H]TRAP binding studies, these results indicate that parmodulins act at the cytosolic face of PAR1. Parmodulins inhibited PAR1-mediated $[Ca^{2+}]i$ flux, aggregation, and secretion. However, they failed to block PAR1-mediated shape change, signaling through Rho and src kinase in platelets, or inhibit $G_{\alpha 12}$-mediated loss of barrier function elicited by a PAR1 agonist in MDCK cells overexpressing $G_{\alpha 12}$. Thus, parmodulins inhibit signaling downstream of $G_{\alpha q}$, but not that downstream of $G_{\alpha 12/13}$. Although parmodulin-2 failed to inhibit human PAR4, it did inhibit platelet aggregation stimulated through mouse PAR4, which differs from human PAR4 at the cytosolic face. When tested in a murine model of thrombus formation following laser-induced injury of cremaster arterioles, parmodulin-2 (5 mg/kg) reduced platelet accumulation during thrombus formation by 72%. However, parmodulin-2 (5 mg/kg) failed to affect bleeding times in a tail clip assay of hemostasis.

Conclusions: These studies define a class of small molecules that target the intracellular face of PAR1 to selectively modulate downstream signaling and inhibit thrombosis, but not hemostasis. The approach of targeting its intracellular face represents a novel approach in the development of PAR1 antagonists and has broader implications for modulating GPCR function in disease states.

Antiplatelet and antithrombotic activity of 2NTX-99, a novel molecular entity combining dual thromboxane inhibition with NO-donor properties

Momi S[1], Mezzasoma AM[1], Guglielmini G[1], Casagrande C[2] and Gresele P[1]

[1]University of Perugia, Perugia; [2]University of Milan, Milan, Italy

Background: Dual thromboxane (Tx) antagonists (Tx-synthase inhibitors/Tx receptor antagonists) have superior antiplatelet effects and a stronger antithrombotic activity in animal models than aspirin. This is in part due to the increase of intraplatelet cAMP deriving from the enhanced formation of prostaglandin (PG)I2 and PGD2. Nitric oxide (NO) is a naturally occurring vasodilator and platelet inhibitor provided also with antiatherosclerotic properties. NO exerts most of its biological effects by raising intracellular cGMP levels though the stimulation of soluble guanylyl cyclase (sGC). Intraplatelet cGMP and cAMP synergize in inhibiting platelet function. It seems thus logical to combine the pharmacologic effects of dual Tx-antagonists with those of a NO-donor to get a stronger antiplatelet and antithrombotic effect. A potential benefit of NO supply has previously been shown with molecules in which a NO-donor was added to aspirin or to statins. Picotamide, a dual Tx antagonist, has been structurally modified giving a new orally active molecule, 2NTX-99.

Aims: Aim of the present studies was to test whether the combination of a dual Tx inhibitor with a NO-donor provides additive effects on platelet activation *in vitro* and on thrombosis *in vivo*.

Methods: Platelet function was evaluated by platelet adhesion to collagen under flow (3000/s); arachidonic acid (AA)-, U46619- and collagen-induced platelet aggregation; AA-induced TxA2 production; serum TxB2 generation; platelet release of b-TG and intraplatelet cGMP. The antithrombotic effect of 2NTX-99 was evaluated in a model of pulmonary tromboembolism in mice induced by the injection of collagen+ epinephrine, U46619 or hardened rat red blood cells (HRBC).

Reference compounds were picotamide, isosorbide mononitrate (ISMN) or sodium nitroprusside (SNP), pure NO donors, 2NTX-101 (the denitrated metabolite of 2NTX-99).

Results: 2NTX-99 reduces dose-dependently platelet adhesion, similar to ISMN, an effect reversed by ODQ, a sGC-inhibitor while picotamide only marginally reduces platelet adhesion, an effect not modified by ODQ.

2NTX-99 inhibits U46619-induced platelet aggregation (IC50 = 9.8 ± 1.5 μM) significantly more than 2NTX-101 and picotamide (IC50 = 182.4 ± 1.5 μM and 452.8 ± 1.6 μM, respectively); similar results were observed with AA and collagen.

2NTX-99 significantly inhibited the release of b-TG from AA-stimulated platelets with an IC50 of 14.7 ± 0.3 μM; picotamide was also effective (IC50 = 29 ± 0.5 μM) while 2NTX-101 was not. 2NTX-99 inhibited the formation of TxB_2 by AA-stimulated platelets (IC50 = 3.77 ± 0.16 μM) significantly lower than picotamide (IC50 = 21 ± 0.2 μM) and 2NTX-101 (IC50 = 32 ± 0.3 μm). Serum TxB2 was inhibited by 2NTX-99 more efficiently than by picotamide or 2NTX-101 (IC_{50} = 5.42 ± 0.23 μM; 20.23 ± 0.26 μM and 40.7 ± 2.2 ± 2.2 μm, respectively). Finally, intraplatelet cGMP was enhanced dose-dependently by 2NTX-99 (500 μM: +330%) and by SNP (100 μM: +370%), an effect completely abolished by ODQ, while it was not changed by picotamide or 2NTX-101.

Serum TxB2 was dose- and time-dependently inhibited in mice treated with 2NTX-99. 2NTX-99 administration (300 mg/kg) significantly enhanced plasmatic levels of NO2/NO3, the final metabolites of NO (2NTX-99 = 127 ± 5.3 μM vs control 34 ± 3 μM, $P < 0.01$), while picotamide and 2NTX-101 were ineffective. Finally, 2NTX-99 reduced dose-dependently platelet pulmonary thromboembolism induced by all the thrombogenic stimuli used while picotamide was less effective in these models.

Summary/Conclusion: In conclusion, the combination of a dual Tx antagonist with a NO-donor provided enhanced antiplatelet and antithrombotic effects.

OC 09.4

Delayed targeting of CD39 to thrombus with an activated-platelet antibody allows for effective antithrombotic treatment without prolonging bleeding times

Hohmann JD[1], Wang X[1], Krajewski S[2], Straub A[2], Hagemeyer C[1] and Peter K[1]

[1]Baker IDI Heart and Diabetes Institute, Melbourne, Vic., Australia; [2]Eberhard-Karls University, Tübingen, Germany

CD39, a NTPDase with strong antithrombotic properties, has previously been shown to be protective in models of stroke, transplantations, pulmonary embolism and myocardial infarction by hydrolyzing/removing the platelet agonist ADP and thus inhibit ADP receptor-mediated platelet activation. However, CD39's high potency comes with an increased bleeding risk, as noted with ADP receptor inhibitors in clinical use. We hypothesized that a delayed targeting CD39 to

thrombi will allow localized enrichment to effective concentrations at the growing thrombus despite a low systemic and thus safe concentration with a low risk of bleeding side effects.
CD39 was recombinantly fused to a single-chain antibody (scFv) specific to the active conformation of GPIIb/IIIa on activated platelets. This targeting was shown by binding to microthrombi on flow adhesion assays. Targeted CD39 (Targ-CD39) was significantly more effective at preventing ADP-induced platelet activation (flow cytometry) and platelet aggregation assays using light transmission aggregometry, than its non-targeted control (NT-CD39, CD39 fused to a non-functional scFv). In a mouse model of ferric chloride-induced carotid artery thrombosis NT-CD39, while being protective against vessel occlusion, showed a significant bleeding risk as demonstrated by mouse tail transection. Targ-CD39 concentrates at the thrombus site, allowing a lower dose to be administrated. A dose ~10× lower is able to prevent vessel occlusion to a similar extend as the high dose NT-CD39. An equimolar dose of NT-CD39 at this low concentration is ineffective at preventing vessel occlusion. The improved efficiency in preventing thrombosis as a result of the targeting also means that the systemic dose of CD39 administered as part of the Targ-CD39 construct is below that causing a bleeding time prolongation in mice.
Interestingly, intravital microscopy reveals that the scFv binding to platelets comes with a delay of up to 40 s, representing the time it takes for GPIIb/IIIa to become activated on adhering platelets. This allows for the build up of a sealing platelet layer before CD39 becomes enriched and thereby blocks platelet aggregation and thrombus formation.
Delayed targeting CD39 to its desired site of action enables administration of such a low concentration as to avoid the previously observed bleeding tendencies while still being a highly effective antithrombotic drug. Thus, enriching CD39 to activated platelets at thrombi prevents the previously limiting bleeding side effects and advances CD39 towards potential clinical use.

OC 09.5

Endocannabinoids limit collagen-induced platelet activation and restrict aggregate formation under flow

Maas C, De Angelis V, Koekman AC, Roest M, Weeterings C and De Groot PG

University Medical Center Utrecht, Utrecht, the Netherlands

Background: With a worldwide growing number of aging persons, the incidence of cardiovascular disease is rising. As a result, there is an increasing need for alternative antithrombotic strategies. Neurons and hematopoietic cells in the bone marrow express endocannabinoid receptors, through which endogenous endocannabinoid agonists adjust their cellular functions. Intriguingly, circulating platelets also present endocannabinoid receptors on their surface.
Aims: To investigate the effects of endocannabinoids on platelet function.
Methods: We studied the influence of the endogenous endocannabinoid anandamide on platelet aggregation, α-granule release, and activation of glycoprotein IIb/IIIa by light transmission aggregometry and flow cytometry. Platelet spreading and aggregate build up were analyzed by real-time video microscopy under flow. Moreover, we studied the effects of anandamide on calcium mobilization and Syk phosphorylation during platelet activation. Finally, we investigated the influence of *Cannabis sativa* consumption by human volunteers on *ex vivo* platelet activation and thrombus formation under flow.
Results: We here report that anandamide inhibits platelet aggregation and α-granule release in response to both collagen and arachidonic acid, while it does not affect platelet activation through thrombin receptor PAR-1. Anandamide reduces IIb/IIIa activation and inhibits platelet spreading on fibrinogen under flow. Moreover, anandamide disturbs aggregate formation under flow over immobilized collagen at arterial shear rates. While anandamide reduces thrombin-induced calcium mobilization by approximately 50%, it fully prevents calcium mobilization in response to collagen. We investigated this observed additional influence of anandamide on the collagen pathway in further detail. We subsequently found that collagen-induced Syk phosphorylation is perturbed by anandamide, which can be attributed to the inability of Syk to associate to the Fc-gamma receptor. In comparable fashion to these *in vitro* studies, collagen-induced platelet aggregation and aggregate formation under flow *ex vivo* was impaired in whole blood of human donors that had consumed *Cannabis sativa* for 10 consecutive days. During this period, no symptoms of a bleeding tendency were observed in these donors, nor were they previously reported for the use of *Cannabis sativa*. This defective platelet responsiveness was fully restored after a wash-out period of 10 days.
Conclusions: Endocannabinoid receptor agonists have the potential to negatively regulate platelet activation and aggregate formation both *in vitro* and *in vivo*. Understanding the mechanisms involved may lead to the development of new strategies for the treatment of thrombotic disease.

OC 09.6

Extracellular fibrinogen-binding protein (Efb) from *Staphylococcus aureus* inhibits fibrinogen binding, platelet aggregation and whole blood thrombus formation

Pula G[1], Posner M[1], Merget B[1], Canobbio I[2], Upadhyay A[1] and Bagby S[1]

[1]*University of Bath, Bath Spa, UK;* [2]*University of Pavia, Pavia, Italy*

Background: *Staphylococcus aureus* releases a variety of extracellular factors that participate in the infection and pathogenesis processes induced by this bacterium. Amongst these factors, Efb has been shown to directly bind to both platelets and fibrinogen, leading to the inhibition of platelet aggregation *in vitro* and the reduction of haemostasis *in vivo*. Although the molecular mechanism underlying the inhibition of platelet aggregation by Efb remains to be elucidated, this bacterial protein represents a promising antiplatelet agent for the development of a novel antithrombotic treatment.
Aims: In this study we aimed to assess the efficacy of Efb as an antiplatelet agent *in vitro* and investigate its mechanism of action.
Method: In order to locate the protein domain responsible for the antiplatelet properties of Efb, we generated different constructs representing the N-terminal and C-terminal regions of the protein. N-terminal and C-terminal constructs and full length Efb were tested for their ability to impair the aggregation of platelets *in vitro* in response to different physiological stimuli, including thrombin, collagen, ADP, and the thromboxane A2 analogue U46619. The aggregation response of platelets resuspended in either plasma or isotonic physiological buffer (washed platelets) was tested by turbidimetry. The same constructs were also analysed for their ability to interfere with washed platelet static adhesion and whole blood thrombus formation under physiological flow conditions. Fibrinogen binding and the activation of the main platelet receptor for fibrinogen integrin αIIbβ3 (or inside-out signalling) were assessed by flow cytometry in the presence of the Efb constructs using a fluorochrome-labelled fibrinogen and an activation-dependent antibody, respectively. Finally, the effect of Efb constructs on integrin αIIbβ3 downstream signalling (also known as outside-in signalling) was investigated by phospho-specific immunoblotting.
Results: Two independent antiplatelet domains were identified corresponding to two previously reported fibrinogen binding domains, one located in the N-terminus and the other in the C-terminus of Efb. Both truncation constructs and full length Efb require the presence of fibrinogen in the platelet suspension to exert their antiaggregatory effect in response to thrombin, ADP and U46619, whilst the responses to different collagen concentrations were not affected. Surprisingly, whole blood thrombus formation onto fibrinogen- or collagen-coated surfaces were equally inhibited by Efb and the truncation mutants, possi-

bly suggesting that fibrinogen-mediated platelet-platelet binding is critical for thrombus formation but not for aggregation in response to collagen. Flow cytometry experiments confirmed that fibrinogen binding induced by physiological stimulation of platelets was inhibited by N-terminal and C-terminal constructs and by full length Efb. Experiments on inside-out and outside-in signalling of integrin αIIbβ3 suggested that the Efb constructs act by interrupting the positive feedback initiated by integrin αIIbβ3 binding of fibrinogen and Src family kinase activation.

Summary/Conclusions: In summary, this project confirmed the antiplatelet properties of Efb, localised the antiplatelet activity in two distinct fibrinogen-binding domains of Efb, and characterised the effect of these domains on platelet functional responses and signalling. Overall, due to its strong antiplatelet activity, Efb is a promising candidate for the development of novel antithrombotic drugs.

OC 10 – Platelet Granule Secretion

OC 10.1

Role of novel SNARE proteins syntaxin 8, VTI1A and VTI1B in regulating platelet secretion and function

Golebiewska EM[1], Harper MT[1], Savage JS[1], Goggs R[1], Wiegand C[2], Von Mollard GMF[2] and Poole AW[1]

[1]University of Bristol, Bristol, UK; [2]University of Bielefeld, Bielefeld, Germany

Background: A number of novel roles for platelets beyond traditional haemostasis and thrombosis have emerged in recent years, including inflammation, cancer metastasis and lymphatic and arterial development. Since many cytokines and growth factors are stored in platelets, granule secretion may play a role in these processes. Despite its importance, the exact mechanisms of platelet secretion are unclear, although the ubiquitous SNARE machinery and the v-SNARE VAMP8 in particular are thought to be essential. We sought to identify potential VAMP8 interacting proteins and elucidate their role in platelet secretion. Syntaxin-8 (STX8), VTI1A and VTI1B have all been reported to interact with VAMP8 in other cells. In addition, recent transcript evidence confirmed the presence of all three mRNAs in both human and mouse platelets.

Aims: We aimed to characterize the novel SNAREs STX8, VTI1A and VTI1B in platelets and identify their roles in secretion and, in turn, platelet function.

Methods: STX8, VTI1A and VTI1B global mouse knockouts were used for analysis of platelet function and granule secretion in particular. Parameters measured included ATP secretion, aggregation, P-selectin expression, β-hexosaminidase secretion and *in vitro* thrombus formation.

Results: STX8, VTI1A and VTI1B were all expressed in human and mouse platelets. Several interactions between VAMP8, STX8, VTI1A and VTI1B were also confirmed by co-immunoprecipitation.

The roles of STX8, VTI1A and VTI1B were investigated using platelets from mice deficient in these proteins. Platelet number or mean platelet volume, as well as dense and alpha granule numbers and glycoprotein surface expression levels were unchanged between *Vti1a*−/−, *Vti1b*−/− or *Stx8*−/− and their wild type counterparts.

Dense granule secretion was significantly impaired in response to low (0.05–0.075 U/mL) thrombin concentration in *Stx8*−/− platelets, suggesting an important role for STX8 in platelet secretion. In contrast, no difference in α-granule or lysosome secretion was observed, supporting the proposed SNARE selectivity for different granules. Interestingly, despite VTI1B interaction with VAMP8 in resting and activated platelets, there was no difference in any of the granule secretion in *Vti1b*−/− or *Vti1a*−/− platelets. This may reflect existence of different SNARE complexes in platelets or functional redundancy between SNAREs.

Stx8−/− platelets also showed a defect in aggregation in response to thrombin. This defect was rescued by exogenous ADP in a $P2Y_{12}$-dependent manner, suggesting that the reduced aggregation was due to the reduced dense granule secretion observed.

Vti1a−/− and *Vti1b*−/− platelets aggregated to thrombin and formed thrombi *in vitro* normally, further suggesting that different SNAREs play different roles in platelet activation.

Finally, the reduction in dense granule secretion in *Stx8*−/− platelets was also reversed by co-stimulation with exogenous ADP. This was also dependent on $P2Y_{12}$ signalling, suggesting complex interactions between platelet signalling and SNARE-mediated secretion.

Conclusions: Importantly, STX8 regulates platelet dense granule (but not α-granule or lysosome) secretion and in turn aggregation in response to low concentrations of thrombin. This defect can be overcome by exogenous ADP indicating the synergistic relationship between a $P2Y_{12}$ signalling pathway and SNARE machinery in platelets, and reveals further the molecular mechanism by which granule secretion in platelets is tightly and specifically controlled.

OC 10.2

Alpha-granule proteins are localized in a 'cap' on the surface of procoagulant platelets to promote their incorporation into aggregates

Panteleev MA[1], Abaeva A[1], Canault M[2], Kotova YN[1], Obydennyi SI[1], Yakimenko AO[1], Kolyadko VN[1], Ataullakhanov F[1], Nurden AT[3] and Alessi M-C[2]

[1]Center for Theoretical Problems of Pharmacology, Moscow, Russia; [2]Université de la Méditerranée, Marseille; [3]Hôpital Xavier Arnozan, Pessac, France

Background: Strong platelet activation leads to the formation of a procoagulant subpopulation that is often called 'coated platelets'. It is characterized by increased phosphatidylserine (PS) expression, high α-granule protein retention on their membranes, and inactivated integrin $\alpha_{IIb}\beta_3$. Because of this lack of active integrins, it is unclear how these platelets can get incorporated into thrombi and fulfil their procogulant function.

Objective: We investigated the structure, function and formation mechanisms of the α-granule protein 'coat' of the PS-expressing platelets.

Methods: Platelets were isolated from blood of healthy donors or patients with bleeding disorders (Glanzmann's thrombasthenia, Bernard-Soulier syndrome, dysfibrinogenemia, factor XIII deficiency, kindlin 3 deficiency) using centrifugation and gel filtration. They were activated with different agonists (in the presence of various inhibitors where indicated), labeled with fluorescently labeled antibodies or annexin V, and analyzed with flow cytometry and Nipkow disc confocal microscopy. In addition to isolated platelets, whole blood thrombi were formed on collagen in parallel-platelet flow chambers at venous and arterial shear rates, and different platelet subpopulations in thrombi were characterized with confocal microscopy.

Results: Confocal microscopy revealed that fibrin(ogen) and thrombospondin colocalized as a 'cap', a single patch on the PS-positive platelet surface, with thrombospondin. The surface fibrin(ogen) was strongly decreased in the presence of fibrin polymerization inhibitor GPRP, and also in platelets from a patient with dysfibrinogenemia involving a polymerization defect. In contrast, a fibrinogen-cleaving protease ancistron increased the amount of fibrin(ogen) and thrombospondin retention on the surface of the PS-positive platelets stimulated with collagen-related peptide. Transglutaminases also induced the cap formation, but platelets from patients with factor XIII deficiency had normal fibrin(ogen) retention, and a pan-transglutaminase inhibitor T101 only mildly decreased it. In aggregates, the fibrin(ogen) cap was located at the point of attachment of the procoagulant platelets. Without this 'cap', their ability to aggregate was drastically decreased. Because of this one-sidedness of their aggregation, procoagulant platelets were predominantly distributed in a necklace-like fashion along the outer face of both stirring-induced aggregates and whole blood thrombi formed under venous and arterial shear conditions.

Conclusions: These data show that the fibrin(ogen)-covered 'cap', predominantly formed as a result of fibrin polymerization, is a critical mechanism that allows 'coated' (or rather 'capped') platelets to become incorporated into thrombi despite their lack of active integrins.

OC 10.3
Functional regulation of platelet membrane systems by the F-BAR protein PACSIN2

Falet H
Harvard Medical School, Boston, MA, USA

Proteins of the Bin-Amphiphysin-Rvs (BAR) and Fes-CIP4 homology BAR (F-BAR) families bind and deform membranes, promoting tubular invaginations that are reminiscent of the platelet open canalicular system (OCS) and megakaryocyte (MK) demarcation membrane system. Here we investigated the role of the F-BAR protein PACSIN2 in platelets and MKs, as PACSIN2 is the only F-BAR protein known to bind to the cytoskeletal and scaffold protein filamin A (FlnA), deficiency of which results in macrothrombocytopenia (Falet et al. J Exp Med 2010; Jurak Begonja et al. Blood 2011). Human and mouse platelets contained 1 μM PACSIN2, but not its paralogs PACSIN1 or PACSIN3. Spinning disk laser fluorescence confocal microscopy revealed a specific association between PACSIN2 and tubular membrane structures in human and mouse platelets. However, PACSIN2 did not co-localize with secretion organelles or dense tubular system markers, i.e. CD62P, CD63, LAMP1, and SERCA3. Endogenous PACSIN2 and over-expressed EGFP-PACSIN2 associated with tubular membrane structures in mouse bone marrow-derived MKs, reminiscent of the DMS. Immunoprecipitation of PACSIN2 from human platelet lysates pulled down FlnA. The interaction required FlnA immunoglobulin-like repeat 20 and an unstructured stretch at the tip of PACSIN2F-BAR domain, and was functionally relevant, as FlnA potentiated the membrane tubulation activity of PACSIN2F-BAR domain *in vitro*. Further, PACSIN2 localization was disrupted in FlnA-null platelets and MKs. PACSIN2-null mice had a mild thrombocytopenia, enlarged spleens, and increased spleen and bone marrow megakaryopoiesis. PACSIN2-null mice had a bleeding disorder, as evidenced by tail bleeding time. PACSIN2-null platelets had an abnormal morphology, with more and narrower OCS channels, compared to WT platelets. Further, PACSIN2-null platelets had increased activation of their collagen receptor, the integrin β1, in response to thrombin. Together, the data indicate that PACSIN2 orchestrates the intracellular membrane architecture of platelets and MKs in cooperation with FlnA, and regulate the function the integrin β1 in platelets.

OC 10.4
Identification of secretion-related PKC substrates in platelets by a proteomic and pharmacological approach

Van Den Bosch MTJ, Poole AW and Hers I
University of Bristol, Bristol, UK

Background: Platelet cell surface receptors induce intracellular signalling events leading to the activation of protein kinase C (PKC), the major regulator of platelet function. Upon stimulation, platelets release a wide variety of mediators, thereby promoting thrombus formation. Of the PKC family members expressed in platelets, the conventional isoforms PKCα and PKCβ have a positive regulatory role in the secretion of granules, and genetic deletion of these isoforms in mice has been shown to result in impaired secretion and thrombosis. The underlying molecular pathway from PKC to secretion, however, is poorly understood.
Aims: We aimed to identify substrates of conventional PKC isoforms in human platelets which are potentially involved in platelet secretion and thrombus formation.
Methods: The kinetics of dense and α-granule secretion were assessed by luminometry and flow cytometry, respectively. We performed immunoprecipitations with a phosphoserine PKC substrate antibody followed by mass spectrometry to identify proteins phosphorylated by PKC. Candidate proteins were validated as PKC substrates by western blotting. Protein function was investigated using a pharmacological approach. Platelet aggregation, granule secretion, and integrin αIIbβ3 activation were assessed.
Results: There was a clear difference between the kinetics of dense and α-granule release, peaking at 1 and 10 min after platelet activation, respectively. Phosphoserine PKC substrate phosphorylation was maximal after 2 min and was markedly impaired by the broad-spectrum PKC inhibitor BIM-IX. One of the candidate proteins identified by mass spectrometry as a potential PKC substrate was cytohesin-2. We showed that cytohesin-2 phosphorylation was induced by platelet stimulation and blocked by BIM-IX. The cytohesin inhibitor SecinH3 significantly enhanced platelet dense granule secretion and aggregation, but did not affect α-granule secretion or integrin αIIbβ3 activation.
Summary/Conclusion: The proteomics-based approach employed here is an effective strategy for identifying PKC substrates in platelets. It will serve as the basis for further molecular studies to investigate the functional significance of the phosphorylation events downstream of PKC. We identified cytohesin-2 as a PKC substrate in platelets and our results suggest it to be a negative regulator of dense granule secretion.

OC 10.5
Platelet granule release patterns under flow

Tersteeg C, Seinen C and Heijnen HF
UMC Utrecht, Utrecht, the Netherlands

Background: Recent studies have suggested that alpha granules are heterogeneous both in morphology and protein content and this heterogeneity may give rise to differential release kinetics. A strictly timed release of granule contents is important for the platelet contribution in modulating haemostasis and inflammatory responses. The exact mechanism by which platelets regulate the fine-tuning of alpha granule release is not known.
Method: To better understand the mechanism of potential differential secretory patterns, particularly under flow, we have used live cell imaging and electron microscopy tomography to visualize granule release profiles.
Results: We present data on alpha granule dynamics in flow in relation to their secretory behaviour. Platelets were allowed to adhere to fibrinogen and von Willebrand Factor (VWF) under low shear conditions (300/s), and granule dynamics were monitored using time laps video microscopy. While a subpopulation of the alpha granules are mobile and move continuously along microtubules in the cell's periphery, others remain stationary located in the central region. A subset of VWF-containing granules was selectively targeted towards downstream exit sites where they fuse with the platelet membrane and release VWF as strings in the direction of the flow. Furthermore immunoelectron microscopy cross-sections of release profiles show that CD63 positive exosomes are secreted both at basolateral and luminal sites. These observations indicate that cargo release occurs at multiple sites and is probably under control of shear forces. Shear forces also induce the formation of membrane tethers. Surprisingly, platelet granules are able to move into extending membrane tethers thereby contributing to a spatial segregation of alpha granule secretory events. Electron tomography analysis of platelet release profiles revealed fusion of tubular alpha granules with the plasma membrane, but no fusion of dense tubular system membranes.
Conclusion: Together, our observations suggest that shear-driven granule motion and differential release may be tightly connected. We are currently developing ways to capture short-lived fusion events and cargo release patterns under physiological flow conditions at high spatial resolution.

OC 10.6

Platelet dense granule secretion is required for infarct progression, but not for intracranial haemostasis in the ischaemic brain

Stegner D[1], Deppermann C[2], Kraft P[1], Morowski M[2], Kleinschnitz C[1], Stoll G[1] and Nieswandt B[2]

[1]University Hospital Würzburg; [2]University Hospital and Rudolf Virchow Center for Experimental Biomedicine, Würzburg, Germany

Background: Ischaemic stroke is a frequent and serious disease with limited treatment options. Previous studies indicated that inhibition of early steps of platelet adhesion may offer a novel and safe treatment strategy in acute stroke. In contrast, inhibition of platelet aggregation by GPIIb/IIIa blockade did not reduce infarct size but induced severe intracerebral haemorrhage. The pathophysiological role of amplification mechanisms during platelet activation in the setting of acute ischaemic stroke has not been determined.

Aims: The aim of this study was to determine the functional significance of platelet dense granule secretion for infarct progression and intracerebral haemostasis in ischaemic stroke.

Methods: We generated mice deficient in Munc13-4 (*Unc13d−/−* mice) and assessed the function of their platelets by flow cytometry, aggregometry, flow adhesion assays and biochemical methods. Further, these mice were subjected to models of arterial thrombosis and the transient middle cerebral artery occlusion (tMCAO) of ischaemic stroke.

Results: In line with reports on *Unc13dJinx* mice, *Unc13d−/−* mice were unable to secrete dense granule content and displayed infinite tail bleeding times. Further, ablated dense granule secretion resulted in severely defective thrombus occlusion in two *in vivo* models of arterial thrombosis. Remarkably, *Unc13d−/−* mice displayed reduced infarct sizes and significantly better neurological outcome at 24 h after induction of tMCAO and this protection was not associated with increased intracranial bleeding risk.

Summary/Conclusion: Collectively, our data argues for a critical role of dense granule secretion in infarct progression, but not for safeguarding the brain vasculature following focal cerebral ischaemia. This indicates that interference with amplification processes of platelet activation might be an effective, yet safe therapeutic strategy in ischaemic stroke.

OC 11 – Platelet Ion Channels and Protein Kinases

OC 11.1

Chloride channels regulate platelet calcium signalling and procoagulant activity

Harper MT and Poole AW

University of Bristol, Bristol, UK

Background and Aims: Thrombin generation is central to arterial thrombosis. Activated platelets expose a phosphatidylserine (PS)-containing procoagulant surface that accelerates thrombin generation at sites of vascular damage. Plasma membrane phosphatidylserine is normally restricted to the inner leaflet of resting platelets. However, a sustained increase in intracellular calcium concentration during platelet activation triggers phospholipid scrambling and PS exposure in the outer leaflet.

The molecular identity of the calcium-dependent scramblase is not known. Mutations in TMEM16F have been found in patients with Scott syndrome, whose platelets do not expose PS and are poorly procoagulant. However, exactly what role TMEM16F has in phospholipid scrambling is unclear. Since related TMEM16 family members form chloride channels, we tested whether it was possible for a chloride channel to regulate platelet PS exposure.

Methods: Platelet phosphatidylserine exposure was determined by annexin V binding and flow cytometry. Intracellular calcium signalling was monitored in fura-2-loaded platelets. Changes in membrane potential were detected by $DiBAC_3(4)$ fluorescence.

Results: Platelet phosphatidylserine exposure, measured by annexin V binding in response to thrombin plus collagen-related peptide (C+T), was inhibited by about 50% by a range of chloride channel blockers, suggesting a role for chloride channels. C+T-induced phosphatidylserine exposure was similarly reduced in chloride-free saline. Moreover, chloride channel blockers reduced platelet-dependent thrombin generation. However, phosphatidylserine exposure induced by ionomycin, a calcium ionophore, was unaffected by chloride channel block, suggesting that chloride channels are not involved in responding to increased intracellular calcium, but may perhaps instead regulate agonist-induced calcium signalling. Consistent with this idea, chloride channel blockers substantially reduced C+T-induced calcium signalling. This was due to inhibition of calcium entry but not intracellular calcium release.

To understand how chloride channels regulate platelet calcium signalling, we investigated their role in platelet membrane potential. Using a membrane potential-sensitive fluorescent dye, we found that C+T induced hyperpolarization within 1 min. This was completely blocked by chloride channel block or by absence of extracellular chloride, and instead the platelets depolarized. We propose that chloride entry through chloride channels induces platelet hyperpolarization. This acts to maintain the driving force for calcium entry through plasma membrane calcium channels, leading to a sustained increase in intracellular calcium concentration. This is necessary to trigger full PS exposure and promote thrombin generation. In the absence of chloride-mediated hyperpolarization, agonist stimulation leads to platelet membrane depolarization. This reduces further calcium entry and limits platelet calcium signalling and phosphatidylserine exposure.

Summary/Conclusion: We have demonstrated a novel role for chloride channels in regulating platelet phosphatidylserine exposure through control of membrane potential and calcium entry. Importantly, our data suggest that a chloride channel is unlikely to be the scramblase itself, but instead a major regulator of platelet PS exposure through its control of platelet calcium signalling.

OC 11.2

Transient receptor potential channels (TRPCs) contribute to platelet phosphatidylserine exposure

Harper MT[1], Camacho Londano JE[2], Quick K[3], Camacho Londano J[4], Phillip SE[4], Birnbaumer L[5], Freichel M[2] and Poole AW[1]

[1]University of Bristol, Bristol, UK; [2]University of Heidelberg, Heidelberg, Germany; [3]University College London, London, UK; [4]Saarland University, Homburg, Germany; [5]NIH, Research Triangle Park, NC, USA

Background and Aims: Phosphatidylserine (PS) exposure on platelet surfaces is essential for generation of thrombin in thrombosis. The mechanisms underlying this process remain elusive, although sustained cytosolic Ca^{2+} signalling forms one of the major regulatory pathways. Platelets express at least two major Ca^{2+} entry pathways: store-operated Ca^{2+} entry (SOCE) that is activated by intracellular Ca^{2+} store depletion, and a less well-defined 'store-independent' Ca^{2+} entry pathway, which can be activated by DAG analogues. We aimed to define the nature of the store-independent pathway and to understand how these different Ca^{2+} entry pathways contribute to PS exposure.

Results: Using gene knockout mouse and pharmacological approaches we show the store-independent pathway involves Na^+ entry through TRPC6 and TRPC3 that is coupled to Ca^{2+} influx via reverse-mode Na^+/Ca^{2+} exchange (NCX). This Ca^{2+} entry pathway is stimulated in an agonist-specific manner by thrombin but not by collagen-related peptide (CRP), although it appears to make little contribution to Ca^{2+} signalling or PS exposure unless SOCE is blocked. However,

when thrombin and CRP are combined, the TRPC6/3-NCX pathway synergises with SOCE to promote sustained Ca^{2+} signalling and PS exposure.

Conclusion: We propose that SOCE and TRPC6/3-NCX-dependent store-independent calcium entry provide distinct pathways that may be critical to allow appropriate PS exposure in a stimulus-specific, context-dependent manner. The requirement for stimulation of thrombin and collagen pathways suggests that the TRPC6/3-NCX pathway may be part of a coincidence detection system.

OC 11.3

The Scott syndrome protein anoctamin 6 (TMEM16F) regulates multiple cell death responses including membrane phospholipid scrambling in platelets

Mattheij N[1], Braun A[2], Van Kruchten R[1], Cosemans JMEM[1], Van Der Meijden PEJ[1], Baaten C[1], Ehlen HWA[3], Schreiber R[4], Vortkamp A[3], Collins PW[5], Bevers EM[1], Ousingsawat J[4], Kunzelmann K[4], Nieswandt B[2] and Heemskerk JWM[1]

[1]Maastricht University, Maastricht, the Netherlands; [2]University of Würzburg, Würzburg; [3]University Duisburg-Essen, Essen; [4]University of Regensburg, Regensburg, Germany; [5]Medical School of Cardiff University, Cardiff, UK

Background: Anoctamins (Ano) are a family of predicted transmembrane proteins that mediate ion conductances. Ano1 (TMEM16A) has been proposed to act as Ca^{2+}-dependent Cl^- channel. Recently, Ano6 (TMEM16F) was identified as an essential component for Ca^{2+}-dependent phospholipid scrambling and hence, of phosphatidylserine exposure in non-vital platelets. Dysfunctional mutations in TMEM16F have been linked to the Scott syndrome, a rare bleeding disorder characterized by impaired Ca^{2+}-dependent phospholipid scrambling of platelets and other blood cells. Murine Ano6 has been proposed to act as a Ca^{2+} channel, and was found to generate a Ca^{2+}-dependent Cl^- channel in murine macrophages.

Aim: Establish the phenotype of blood cells from anoctamin-deficient mice and of platelets from a Scott patient, compound heterozygous for two TMEM16F mutations.

Methods: Ano6-deficient mice were generated by homologous recombination using the AW-0382 stem cell clone or the PAC-379 clone (PAC library RPCL21). Ano1-deficient mice were described before. Platelets and erythrocytes were studied from wildtype and heterozygously or homozygously deficient mice. Immortalized B-cell lines were used from two Scott syndrome patients ($Scott^{UK}$ and $Scott^{USA}$). Platelets and red cells were examined from $Scott^{UK}$.

Results: Ano1-deficient mice were vital, and their platelets were without phenotype. In two independent laboratories, breeding of heterozygous Ano6 animals, generated from AW-0382 stem cells, failed to produce homozygous mutant offspring, due to early embryonic lethality. Some of the unborn embryos showed major bleeding or exencephaly. Heterozygous platelets were without phenotype, in particular showed unchanged Ca^{2+}-dependent (ionomycin or convulxin/thrombin) phospholipid scrambling. Homozygous Ano6-deficient mice, generated from the PAC-379 clone, were born at 30% of the expected ratio. Their platelets were greatly reduced in Ca^{2+}-dependent phospholipid scrambling, bleb formation and integrin closure, but were moderately reduced in apoptosis-dependent (ABT-737) phospholipid scrambling. Their red cells were also impaired in Ca^{2+}-dependent phospholipid scrambling. While heterozygous platelets were normal, heterozygous red cells demonstrated reduced scrambling activity.

Platelets from $Scott^{UK}$ were impaired in Ca^{2+}-dependent phospholipid scrambling, bleb formation and integrin closure. Apoptosis-dependent scrambling was far less affected. Similarly, Ca^{2+}-dependent phospholipid scrambling was absent in $Scott^{UK}$ red cells, and in $Scott^{UK}$ and $Scott^{USA}$ B-cells, while apoptosis-dependent scrambling was normal.

At various voltage protocols, Ca^{2+}-dependent chloride and cation conductances were abolished in $Scott^{UK}$ and $Scott^{USA}$ B-cells, suggesting an important role for Ano6 in Ca^{2+}-dependent chloride and cation channel activities. Apoptosis (ABT-737) did not provoke such conductances. In control B-cells, chloride currents were abrogated by a range of specific chloride channel inhibitors. However, neither these inhibitors nor depletion of extracellular chloride affected Ca^{2+}-dependent phospholipid scrambling in B-cells or platelets.

Summary/Conclusion: In mouse, homozygous Ano6 deficiency is partly lethal, but platelets from the surviving mice phenocopy the platelets from Scott syndrome patients. In blood cells from mice and patients, Ano6 appears to be involved in a range of Ca^{2+}-dependent cell death responses, namely phospholipid scrambling, membrane bleb formation, integrin closure and chloride/cation channel currents. We conclude that Ano6 is an essential regulatory protein controlling these but not in apoptotic cell responses.

OC 11.4

Ste20 kinase MINK is involved in platelet function and thrombus formation

Yue M, Yu S, Jiang L, Xu C, Luo D, Liu P, Zhou Q, Lu L and Hu H

Zhejiang University, School of Medicine, Hangzhou, China

Background: Ste20 kinase MINK is involved in many important cellular processes such as cell growth, rearrangement of cytoskeleton, and cell motility. However, the role of MINK in platelets is still unclear.

Aims: To determine the role of MINK in platelet activation and thrombus formation.

Methods: *In vivo*, the tail-bleeding assay and ferric chloride-induced mesenteric arteriole thrombosis model were used to exam the role of MINK in hemostasis and thrombosis. *In vitro*, the ability of platelet adhesion and spreading were tested by a microfluidic perfusion assay and spreading assay, respectively. Platelet aggregation and ATP secretion were monitored by aggregometry. We also employed immunoblotting to detect signaling pathway.

Results: In tail-bleeding assay, MINK(−/−) mice exhibited longer bleeding time than wild-type mice (589.0 ± 68.1 s vs 406.6 ± 70.5 s). In a ferric chloride-induced mesenteric arteriole thrombosis model, vessel occlusion time were two times longer in MINK(−/−) mice than in wild-type mice. In an *in vitro* microfluidic whole-blood perfusion assay, thrombus formation on a collagen matrix under arterial shear conditions was significantly reduced for MINK(−/−) platelets. Moreover, MINK(−/−) platelets demonstrated an impaired aggregation and secretion in response to low doses of thrombin *in vitro*. Furthermore, platelet spreading on fibrinogen was largely hampered in MINK (−/−) platelets, the difference could be attributed to impaired ADP secretion upon MINK deficiency. Signaling events associated with MINK appeared to be involving protein kinase C, p38, and ERK2. Hence, MINK may be an important signaling molecule that mediates MAPK signaling and participates in platelet biology and thrombus formation.

Conclusions: MINK is involved in platelet activation an thrombus formation *in vivo* and *in vitro*.

OC 11.5

Characterisation of platelets lacking the p110a PI3K isoform and its role in primer mediated enhancement of platelet activation

Blair T, Moore SF, Williams CM, Aitken EW and Hers I

University of Bristol, Bristol, UK

Platelets are found to be hyperactive in a range of diseases such as obesity and type 2 diabetes mellitus. It is thought that one contributing factor to this is the priming of platelets by increased levels of circulating growth factors. These growth factors can't induce platelet activation alone but are able to enhance the actions of physiological platelet

stimuli in a PI3K-dependent manner. We have previously demonstrated that IGF-1-mediated enhancement of platelet activation is blocked in the presence of the p110α PI3K isoform inhibitor PIK-75. Therefore targeting p110α could be a potential strategy for reducing platelet hyperactivity.

To address the role of p110α in platelet function and in primer-mediated enhancement of platelet function, we used the *Pf4-Cre* system to generate megakaryocytic lineage specific p110α knock-out mice. We confirmed that p110α was absent in platelets from p110α$^{-/-}$ mice, whereas expression levels of p110β, p110δ and p110γ were normal. In addition, we found no changes in association of p110β and p110δ with p85 or in expression of membrane receptors. The loss of p110α had no significant effect on PAR-4 and collagen-related peptide-induced aggregation, integrin activation, a-granule secretion and Akt phosphorylation. This suggests that p110α plays no or a redundant role in platelet activation downstream of PAR-4 and GPVI.

Similar to findings in human platelets, pre-treatment of mouse platelets with the primers TPO, IGF-1 or IGF-2 resulted in enhanced PAR-4-mediated integrin activation and platelet aggregation. Surprisingly, the potentiatory effect of these primers on platelets lacking p110α was comparable to that of wild-type platelets. Furthermore TPO and IGF-2-induced Akt phosphorylation was still present in p110α$^{-/-}$ platelets, whereas IGF-1-mediated Akt phosphorylation was slightly reduced. As there may be redundancy between the p110α and p110β isoforms, we also treated platelets with the p110β inhibitor TGX-221. However, TGX-221 only partially inhibited TPO enhanced integrin activation in p110α$^{+/+}$ and p110α$^{-/-}$ platelets. In contrast, the pan-PI3k inhibitor wortmannin blocked the effect of primers in wild-type and p110α$^{-/-}$ platelets.

In summary, we demonstrate that p110α plays a minor or redundant role in platelet activation by PAR-4 and GPVI. In addition, we rule out that p110α is the sole PI3K isoform involved in primer-mediated enhancement of platelet activation, suggesting that redundancy between PI3K isoforms is an important mechanism by which platelet function is controlled.

OC 11.6

The Class II PI3K, PI3K-C2a, regulates internal membrane reserves and biomechanical integrin aIIbβ3 adhesive function in platelets

Hamilton JR[1], Mountford JK[1], Petitjean C[1], Schoenwaelder SM[1], Dickins RA[2] and Jackson SP[1]

[1]Monash University; [2]Walter & Eliza Hall Institute, Melbourne, Vic., Australia

Background: Phosphoinositide 3-kinases (PI3Ks) are a family of eight broadly-expressed enzymes important for signalling in a range of cells, including platelets. Much is known regarding the function of Class I PI3Ks, and p110β inhibitors are in clinical development as anti-platelet agents. In contrast, little is known about the function of Class II PI3Ks.

Aims: To examine the role of Class II PI3Ks in platelet function.

Methods and Results: We detected expression of two of the three Class II PI3Ks – PI3K-C2α and PI3K-C2β, but not PI3K-C2γ – in human and mouse platelets *via* Western blot. Platelets from PI3K-C2β$^{-/-}$ mice functioned normally in all assays examined. We generated PI3K-C2α$^{-/-}$ mice, which died *in utero* prior to haematopoiesis, preventing analysis of platelet function. To overcome this, we generated a novel RNAi-based *in vivo* mouse model in which inducible expression of a shRNA against PI3K-C2α in adult mice reduced protein expression in platelets to < 5% of normal levels. These PI3K-C2α-deficient mice exhibited significantly impaired haemostasis (increased tail bleeding time) and thrombosis (unstable occlusion of electrically injured carotid artery) in *in vivo* models. These phenotypes were reproduced in wild-type mice reconstituted with PI3K-C2α-deficient haematopoietic cells, strongly suggesting they resulted from defective platelet function. Despite this, agonist-induced platelet activation and accumulation of the PI3K lipid products (PtdIns(3)P and PtdIns(3,4)P_2) were normal in PI3K-C2α and combined PI3K-C2α/β deficient platelets, suggesting PI3K-C2α does not play an acute signalling role in platelets. Strikingly however, transmission electron microscopy revealed that platelets from PI3K-C2α-deficient mice had a 37% increase in size and altered distribution of the open canalicular membrane system. Detailed analysis of the adhesion behaviour of PI3K-C2α-deficient platelets revealed that haemodynamic shear stress induced significant changes in the structure of the open canalicular system that was associated with enhanced biomechanical adhesive function of the major platelet integrin $\alpha_{IIb}\beta_3$, and led to increased platelet-fibrinogen interactions and accelerated thrombus growth. These dysregulated thrombi were highly unstable, leading to thromboembolism from an immobilized collagen substrate.

Conclusions: Our studies define a novel role for the Class II PI3K, PI3K-C2α, in the haemostatic and thrombotic function of mouse platelets and suggest that PI3K-C2α regulates the function of cell surface platelet adhesion receptors by maintaining plasma membrane structure and/or function. Further, these studies provide the first example of a signalling enzyme regulating plasma membrane reserve and linked to biomechanical cell adhesion.

OC 12 – Recurrent Venous Thrombosis – I

OC 12.1

Secondary prevention of recurrent venous thromboembolism: systematic review and meta-analysis of bleeding complications among patients receiving anticoagulation

Castellucci LA, Le Gal G, Wells P, Gandara E, Rodger M and Carrier M

Ottawa Hospital Research Institute, Ottawa, ON, Canada

Background: The risk of recurrent venous thromboembolism (VTE) in patients with unprovoked VTE following the completion of an initial 3–6 month course of anticoagulation is approximately 10% in the subsequent year. In non-high bleeding risk patients, the American College of Chest Physicians recommends long-term anticoagulation in unprovoked VTE patients. As a result, clinicians are faced with the challenge of balancing risks and benefits of prolonged anticoagulation. Warfarin, aspirin and the novel oral anticoagulants (rivaroxaban, apixaban, dabigatran, and ximelagatran) have all been evaluated for the secondary prevention of recurrent VTE. Herein, we meta-analysed the safety profiles of anti-thrombotic therapy options in VTE patients.

Aim: To report the major bleeding and fatal bleeding rates in patients receiving oral anticoagulants (warfarin, direct Xa inhibitors and direct thrombin inhibitors) or ASA, and placebo/observation for the secondary prevention of recurrent VTE.

Methods: A systematic literature search was conducted to identify potential studies on MEDLINE, Embase, and Cochrane Central Register of Controlled Trials. Pooled proportions and their associated 95% confidence intervals (CI) for major bleeding and fatal bleeding were calculated.

Results: Fourteen randomized controlled trials (warfarin = 7; dabigatran = 2; rivaroxaban = 1; apixaban = 1; ximelagatran = 1; ASA = 2) met all the inclusion criteria and 11, 922 patients were included in our analysis. The rates of major and fatal bleeding among patients randomized to observation or placebo was 0.39%/ 100 patient-years (95% CI, 0.24–0.58; I^2 = 0%) and 0.12%/ 100 patient-years (95% CI, 0.04–0.23; I^2 = 0%), respectively. The rates of major bleeding and fatal bleeding for warfarin (target INR 2-3) were higher than placebo at 1.65%/ 100 patient-years (95% CI, 1.07–2.36; I^2 = 50.7%) and 0.087%/ 100 patient-years (95% CI, 0.024–0.19; I^2 = 0%) respectively. The rates of major and fatal bleeding for ASA were comparable to

placebo with a rate of 0.58%/100 patient-years (95% CI, 0.28–1.0) and 0% (95% CI, 0–0.29) respectively. Similarly, patients receiving a novel oral anticoagulant (oral direct Xa or thrombin inhibitor) had rates of major and fatal bleeding comparable to placebo. Patients receiving direct Xa inhibitors (apixaban or rivaroxaban) had major and fatal bleeding rates of 0.39%/ 100 patient-years (95% CI, 0.097–0.88; I^2 = 51.5%) and 0% (95% CI, 0–0.16; I^2 = 0%) respectively, whereas patients receiving a direct thrombin inhibitor (dabigatran or ximelagatran) had rates of 0.67%/ 100 patient-years (95% CI, 0.42–0.98; I^2 = 0%) and 0% (95% CI, 0–0.096; I^2 = 0%) for major and fatal bleeding episodes, respectively.

Summary/Conclusions: Rates of major and fatal bleeding among VTE patients receiving ASA or novel anticoagulant therapy for secondary prevention of VTE are low. Warfarin is associated with a higher risk of major bleeding than placebo. However, it appears that bleeding rates for novel anticoagulants and ASA are no different than placebo.

OC 12.2

Risk profile and clinical outcome of symptomatic isolated subsegmental pulmonary embolism

Den Exter PL[1], Van Es J[2], Klok FA[1], Kroft LJM[1], Kruip JHA[3], Kamphuisen PW[4], Büller HR[2] and Huisman MV[1]

[1]Leiden University Medical Center, Leiden; [2]Academic Medical Center, Amsterdam; [3]Erasmus Medical Center, Rotterdam; [4]University Medical Center Groningen, Groningen, the Netherlands

Background: Improved imaging techniques have led to an increased detection of subsegmental pulmonary embolism (SSPE). The clinical significance of SSPE is often doubted by clinicians and remains to be determined.

Aims: To investigate whether SSPE forms a distinct subset of thromboembolic disease compared to more proximally located pulmonary embolism (PE).

Methods: In this, *post-hoc* analysis of two prospective outcome studies, 3703 consecutive patients with clinically suspected PE were included. Patients with SSPE were contrasted to patients with more proximal PE, and to those in whom PE was ruled out, as regards the prevalence of thromboembolic risk factors and the 3-month risk of recurrent venous thrombembolism (VTE), bleeding complications, and mortality.

Results: PE was confirmed in 748 patients, of whom 116 (16%) had SSPE; in 2995 patients PE was ruled out. No differences were seen in the prevalence of VTE risk factors, the 3-month cumulative risk of recurrent VTE (3.6% vs 2.5%; P = 0.42) and mortality (10.7% vs 6.5%; P = 0.17) between patients with SSPE and those with segmental or more proximal PE. Multivariate analyses demonstrated age > 60 years (OR 1.6; 95%CI: 1.07–2.42), recent surgery (OR 2.3; 1.23–4.20), estrogen use (OR 2.5; 1.34–4.81) and male gender (OR 2.1; 1.38–3.32) to be independent predictors for SSPE, when compared to patients without PE.

Conclusions: In contrast to common belief that SSPE represents a clinically less severe subset of PE, this study shows that patients with SSPE mimic those with more proximally located PE as regards their risk profile and clinical outcome.

OC 12.3

The REVERSE I and II studies: impact of using. Men continue and HERDOO2 clinical decision rule to guide anticoagulant therapy in patients with first unprovoked venous thromboembolism

Rodger M[1], Kovacs M[2], Le Gal G[1], Anderson D[3], Righini M[4], Beaudoin T[1] and The Reverse Investigators[1]

[1]Ottawa Health Research Institute, Ottawa; [2]London Health Sciences Center, London, ON; [3]Dalhousie University, Halifax, Canada; [4]Geneva University Hospital, Geneva, Switzerland

Background: Whether or not to continue oral anticoagulants (OAC) after short-term therapy for unprovoked VTE is one of the most important unanswered questions in the clinical care of patients with venous thromboembolism (VTE). In REVERSE I (RI), a multinational prospective cohort study, we developed a clinical decision rule (CDR) to identify low risk patients with unprovoked VTE who could safely discontinue OAC after completing 5–7 months of OAC: 'MEN continue and HERDOO2'. This CDR labels all men as high risk of recurrent VTE as well as women with 2 of the following: (i) Hyperpigmentation, Edema or Redness (HER) on exam in either leg, (ii) VIDAS D-Dimer>250 ug/L, (iii) Obesity-BMI > 30 or (iv) Older age > 65. We are validating the rule by applying the CDR in a second ongoing multi-national cohort study (REVERSE II (RII)) where low risk patients discontinue anticoagulants and high risk patients are recommended to continue anticoagulants (but may discontinue).

Aims: We sought to compare the overall 1-yr risk of recurrent VTE in the REVERSE I patients (all discontinued OAC at 5–7 months) to patients enrolled in REVERSE II who completed 1-yr follow-up prior to August 2012 (continuation or discontinuation of OAC informed by 'MEN continue and HERDOO2').

Methods: REVERSE I and II are multi-national prospective cohort studies of first unprovoked VTE patients. Symptomatic suspected major recurrent VTE (proximal DVT and/or PE) during 1-yr follow-up off of OAC was investigated with reference to baseline imaging and then independently adjudicated and compared between studies.

Results: Baseline characteristics of RI and RII patients were comparable: RI: 664 enrolled participants, mean age of 53 (range 17–95) and 49% were female; RII: 673 included in this analysis, mean age of 55 (range 18–93) and 49% female. In RI, 183 (28%) participants were classified as low risk (all discontinued anticoagulants) and 481 (72%) were classified as high risk (all discontinued anticoagulants). In RII, 177 (26%) participants were classified as low risk (156/177, (88.1%) discontinued anticoagulants) and 496 (74%) were classified as high risk (436/496, 87.9% continued anticoagulants). In RI, out of 239 suspected VTE, 64 were adjudicated as recurrent VTE during 1 year follow-up, resulting in an annual risk of recurrent VTE of 10.7% (95% CI: 8.2–13.6%). In RII, out of 81 suspected VTE, 17 were adjudicated as recurrent VTE during 1 year follow-up; an annual risk of recurrent VTE of 2.6% (95% CI:1.5–4.1%). Hence, using the CDR in RII resulted in an 8.1% absolute reduction in annual risk of recurrent VTE compared to RI. This 8.1% absolute recurrent VTE reduction was at a cost of five major bleeds in RII patients during 1 year follow-up (i.e. 0.8% (95% CI: 0.2–1.8%). It is also notable that use of the CDR resulted in a 66% reduction in suspected recurrent VTE over 1 year follow-up (RII: 81 vs RI: 239).

Summary/Conclusions: Use of the 'Men continue and HERDOO2' clinical decision rule to guide anticoagulant therapy results in significantly fewer suspected recurrent VTE and fewer adverse events of confirmed recurrent VTE or bleeding.

OC 12.4

D-dimer and ultrasound in combination italian study (DULCIS) to establish the optimal duration of anticoagulation for venous thromboembolism on behalf of the DULCIS investigators

Cosmi B[1], Legnani C[1], Erba N[2], Ghirarduzzi A[3], Poli D[4], Testa S[5], Prandoni P[6], Pengo V[7], Falanga A[8] and Palareti G[1]

[1]S.Orsola-Malpighi University Hospital, Bologna; [2]Transfusion Centre and Haemostasis and Thrombosis Centre, Vimercate; [3]Arcispedale Santa Maria Nuova, Reggio Emilia; [4]University of Florence and Centro Trombosi, A.O. U. Careggi, Firenze; [5]General Hospital, Cremona; [6]University of Padua, Thromboembolism Unit; [7]University of Padova, Dept. Cardiac Thoracic and Vascular Sciences, Padova; [8]Ospedali Riuniti, Haemostasis and Thrombosis Centre, Bergamo, Italy

Background/Aims: to evaluate the efficacy and safety of a procedure employing the evaluation of residual vein obstruction (RVO) and D-dimer to establish the individual risk of recurrence and thus the necessity to prolong or stop anticoagulation after idiopathic deep vein thrombosis (DVT) and/or pulmonary embolism (PE). The specific aims of the study were: (i) to obtain a recurrence rate < 5% per year in the first and second year after anticoagulation is suspended according to the procedure (ii) to allow anticoagulation suspension in at least 40% of all subjects.

Materials and Methods: Multi-centre management study in which D-dimer was measured after at least 3 months of anticoagulation in patients with RVO < 4 mmin case of a previous DVT and/or normal pulmonary arterial pressure with echocardiography in case of previous PE and those who had undergone at least 12 months of therapy for previously altered RVO. If D-dimer was below age and gender specific cut-offs, anticoagulation was stopped and D-dimer was re-assessed after 15, 30, 60 and 90 days. If all the D-dimer measurements were below the cut-offs, anticoagulation was definitely stopped and patients were followed-up for two years and recurrent proximal DVT and/or PE were recorded. If one of these D-dimer measurement was above the cut-offs, anticoagulation was resumed for at least 6 months and patients were then re-evaluated.

Results: Thousand and two out of 2501 screened patients (40%) were enrolled in 17 centres. Of these, 516 (47%) stopped anticoagulation for normal D-dimer with 26 recurrences (3.7% patient-years; 95% CI: 2–5%). In 371 subjects in whom anticoagulation was resumed, 18 major or clinically relevant bleeds were observed (4.8%; 95% CI:3.8%). In 115 patients in whom D-d was altered but anticoagulation was not resumed, 12 recurrent events were observed (7.7% patient-years; 95% CI:11–12%).

Conclusions: A strategy based on RVO and D-dimer allows stopping anticoagulation in 47% of patients with a low risk of recurrence after a first episode of idiopathic VTE.

OC 12.5

D-Dimer levels over time and the risk of recurrent venous thromboembolism: an update of the Vienna Prediction Model

Eichinger S, Heinze G and Kyrle PA

Medical University of Vienna, Wien, Austria

Background: Patients with unprovoked venous thromboembolism (VTE) have a high recurrence risk and are candidates for extended anticoagulation. However, many patients stay recurrence free and are unnecessarily exposed to anticoagulants. The Vienna Prediction Model has been developed to discriminate patients with unprovoked VTE with a low recurrence risk from those with a high risk based on the patient's sex, the location of VTE, and D-Dimer, but allows risk assessment only at one single time point (3 weeks after anticoagulation).

Aim: to update and expand the model based on a larger number of events and a longer observation time, in order to assess the recurrence risk also from time points later than 3 weeks after anticoagulation on.

Methods: We analysed the data set of the Austrian Study on Recurrent Venous Thromboembolism, a prospective cohort study in patients of legal age with a first VTE who had received anticoagulants for 3–18 months. Patients with VTE provoked by surgery, trauma, pregnancy, or female hormone intake; with a natural inhibitor deficiency, the lupus anticoagulant, or cancer were excluded. The study end point was recurrent symptomatic deep vein thrombosis (DVT) and/or pulmonary embolism (PE). We integrated D-Dimer levels measured at several time points after anticoagulation with the patient's sex and location of VTE. We generated nomograms to calculate individual risk scores and cumulative recurrence rates from 3 weeks, 3, 9, 15 and 24 months on after discontinuation of anticoagulation using a dynamic landmark competing risks regression approach. The ethics committee approved the study and all patients gave written informed consent.

Results: One hundred and fifty-nine of 738 patients had recurrence during a mean follow-up of 6 years. The cumulative probability of recurrence was 5.5% (95%CI 3.9–7.2%) after 1 year and 18.4% (95% CI 15.4–21.4%) after 5 years. D-Dimer levels varied between patients, but did not substantially – albeit statistical significantly ($P < 0.001$) – increase over time. The updated model has two improvements: we accounted for the competing risk of death or informative drop out by competing risks regression, and we considered various time points of prediction rather than predicting just once after anticoagulation. Subdistribution hazard ratios (95% CI) dynamically changed from 3 weeks to 3, 9, 15 and 24 months from 0.29 (0.19–0.43), 0.31 (0.21–0.46), 0.37 (0.24–0.55), 0.43 (0.27–0.68) to 0.55 (0.32–0.94) in women vs. men, from 1.60 (0.84- 3.05), 1.58 (0.83–3.00), 1.54 (0.80–2.96), 1.49 (0.74–3.00) to 1.43 (0.64–3.20) in patients with proximal DVT or PE compared to distal DVT, and from 1.37 (1.23–1.66), 1.36 (1.14–1.62), 1.34 (1.14–1.58), 1.32 (1.11–1.58) to 1.29 (1.02–1.63) per doubling D-Dimer levels. We created nomograms based on subdistribution hazard ratios from the multivariable dynamic model to predict the recurrence risk from 3 weeks, 3, 9, 15 or 24 months on after anticoagulation. A web-based calculator allows risk assessment from random time points on between 3 weeks and 24 months.

Conclusions: The updated Vienna Prediction Model integrates patient's sex, location of first VTE and serial D-Dimer measurements and allows prediction of recurrent VTE at a random time point after discontinuation of oral anticoagulation.

OC 12.6

Recurrent venous thrombosis in premenopausal women: effect of hormonal contraceptive use

Timp J, Stegeman BH, F Timp J, Flinterman LE, Helmerhorst FM, Rosendaal FR, Cannegieter SC and Van Hylckama Vlieg A

Leiden University Medical Center, Leiden, the Netherlands

Background: There is a large body of literature available on hormonal contraceptive use and the risk of a first venous thrombotic event. Despite guideline recommendations to discontinue hormonal contraceptive use after a thrombotic event, still a sizeable proportion of women continue or start using hormonal contraceptives after a venous thrombosis. The risk of recurrent venous thrombosis in women using hormonal contraceptives has not been studied extensively. The aim of this study was to evaluate the effect of hormonal contraceptive use on the recurrence risk in premenopausal women.

Methods: Patients with a first venous thrombosis included in the MEGA case-control study between 1999 and 2004, were followed for a recurrent venous thrombotic event up to 2009 ($N = 4731$). Included in the current analyses were premenopausal patients with a first venous thrombosis and for whom detailed information was available on hormonal contraceptive use during follow-up ($N = 702$). Time-dependent Cox-proportional hazards models were used to estimate hazard ratios

(HR) with 95% confidence intervals (CI), adjusted for age and BMI at baseline. Both the risk of recurrent venous thrombosis with hormonal contraceptive use at time of the first event and with hormonal contraceptive use during follow-up were calculated, as well as risks of recurrence for different types of hormonal contraceptives. Consent and ethical approval were obtained for this study.

Results: Seven hundred and two premenopausal women with a first venous thrombosis were followed for a total of 4673 woman-years (median 7.0 years; range, 12 days to 9.9 years) during which 74 recurrent events occurred resulting in a recurrence rate of 15.8 (95%CI: 12.6–19.8) per 1000 woman-years. Hormonal contraceptive use at the first thrombotic event was not associated with the risk of recurrent venous thrombosis ((HR 0.8, 95%CI: 0.5–1.5) for users versus non-users at the first event). Two hundred and ten women used hormonal contraceptives, mainly orally administered, during follow-up with a total follow-up of 545 woman-years. They experienced 21 recurrent thrombotic events resulting in a rate of 38.5 per 1000 woman-years, which was triple the rate of non-use during follow-up (HR 2.8, 95% CI: 1.7–4.7). Recurrence rates for women using combined oral contraceptives during follow-up ($N = 180$) were influenced both by the dose of ethinylestradiol as well as the type of progestagens. None of the women ($N = 20$, 70 woman-years of follow-up) using a levonorgestrel-releasing intra-uterine device during follow-up developed a recurrent venous thrombosis.

Conclusion: Hormonal contraceptive use after a first venous thrombosis increases the risk of a recurrent venous thrombotic event. When a non-hormonal contraceptive is excluded after careful consideration a levonorgestrel-releasing intra-uterine device may be a safe contraceptive to use after a venous thrombosis.

OC 13 – Von Willebrand Disease

OC 13.1

Genetic variations determine von Willebrand factor levels in patients with von Willebrand disease from the WiN study

Sanders YV[1], Van Der Bom JG[2], Cnossen MH[3], De Maat PM[1], Laros-van Gorkom BAP[4], Fijnvandraat KJ[5], Meijer K[6], Mauser-Bunschoten E[7], Eikenboom HCJ[8] and Leebeek FWG[1]

[1]Erasmus University Medical Center Rotterdam, Rotterdam; [2]Leiden University Medical Center & Sanquin Research, Leiden; [3]Erasmus University Medical Center/Sophia Children's Hospital, Rotterdam; [4]Radboud University Nijmegen Medical Centre, Nijmegen; [5]Emma Children's Hospital, Academic Medical Center, Amsterdam; [6]University Medical Center Groningen, Groningen; [7]Van Creveldkliniek/UMCU, Utrecht; [8]Leiden University Medical Center, Leiden, the Netherlands

Background: Von Willebrand disease (VWD), the most common inherited bleeding disorder, is caused by reduced concentration or activity of von Willebrand factor (VWF) and is characterized by recurrent mucocutaneous bleeding. There is a large variation in VWF levels in VWD patients, even in individuals with identical mutations. Recently, a meta-analysis of genome-wide association studies identified genes other than the VWF gene that contribute to the variation in VWF levels in healthy individuals. We hypothesize that genetic variations in these other genes may also influence VWF levels in individuals with VWD and thereby affect the bleeding phenotype.

Aims: To investigate the effect of genetic variations in STXBP5, SCARA5, ABO, STAB2, STX2, TC2N and CLEC4M genes on VWF levels in a large cohort of patients with moderate and severe type 1 and type 2 VWD and to determine the influence on bleeding phenotype.

Methods: We genotyped 709 patients with moderate and severe type 1 and type 2 VWD, defined as VWF levels ≤ 30 U/dL, from a nationwide cross-sectional study (Willebrand in the Netherlands – WiN study). Seven SNPs in STXBP5 (6q24), SCARA5 (8p21), ABO (9q34), STAB2 (12q23), STX2 (12q24), TC2N (14q32) and CLEC4M (19p13) were analyzed. We studied the relationship of variation in these SNPs with VWF:Ag, VWF:CB, VWF:Act and FVIII:C levels in 604 patients with type 1 ($n = 364$) and type 2 ($n = 240$) VWD, in whom centrally measured VWF levels were available. Exclusion criteria were pregnancy and the recent use of desmopressin or replacement therapy. VWF levels were adjusted for age, sex and blood group. We also studied the influence of variation in these SNPs on bleeding phenotype, which was determined using the validated Tosetto Bleeding Score. Consent and ethical approval is obtained.

Results: In type 1 VWD patients rs9390459 in STXBP5 was significantly associated with VWF:Ag levels: ($\beta = -0.03$ IU/mL per allele [95%CI −0.06 to −0.00], $P = 0.049$). Rs868875 in CLEC4M was associated with both VWF:Ag ($\beta = -0.04$ IU/mL [95%CI −0.08 to −0.01], $P = 0.023$) and VWF:Act levels ($\beta = -0.06$ IU/mL [95%CI −0.11 to −0.00], $P = 0.034$). In type 2 VWD patients rs9390459 in STXBP5 was significantly associated with VWF:CB ($\beta = -0.04$ IU/mL [95%CI −0.07 to −0.01], $P = 0.015$). Interestingly, in the type 1 index patients ($n = 195$) an association between FVIII:C and STAB2 ($\beta = -0.06$ IU/mL [95%CI −0.12 to −0.00], $P = 0.048$) and in type 2 index ($n = 72$) patients an association between SNP rs2402074 in TC2N and VWF:Ag levels ($\beta = -0.09$ IU/mL [95%CI −0.17; −0.02], $P = 0.014$) was found. Previously, we observed an association between VWF levels and bleeding score (*de Wee et al, Thromb Haemost 2012*). Although there is a modest effect of genetic variants on VWF levels, we did not observe a clear association between bleeding score and VWF level decreasing alleles.

Summary/Conclusion: In type 1 and type 2 VWD patients, genetic variants in STXBP5, CLEC4M and TC2N are associated with VWF:Ag, VWF:CB and VWF:Act levels. These genetic determinants seem not to be associated with the bleeding phenotype.

OC 13.2

Incidence of large VWF gene deletions and duplications in the French cohort of 1182 patients with von Willebrand disease (VWD)

Boisseau P[1], Ternisien C[1], Caron C[2], Giraud M[1], Talarmain P[3], Zawadzki C[2], Bezieau S[1], Fressinaud E[4], Goudemand J[2] and Veyradier A[4]

[1]CHU Hotel Dieu Nantes, Nantes; [2]CHRU De Lille, Lille; [3]CHU Hotel Dieur Nantes, Nantes; [4]Hopitaux Universitaires Paris Sud, Clamart, France

Background: The French reference center for VWD (CRMW) organizes a national biologic platform for the phenotype/genotype characterization of VWD. The inclusion criteria are: type 3 phenotype (VWF levels < 5 IU/dL), type 2 phenotype (discrepancy between VWF antigen and VWF functional activities), and type 1 phenotype limited to VWF levels < 30 IU/dL (as VWF levels above this threshold are usually not in linkage to*VWF* gene). Patients with a clear diagnosis of acquired von Willebrand syndrome were excluded. After an exhaustive sequencing of the 52 exons (including intron-exon boundaries), the 5' and 3′UTR and the promoter of *VWF* gene, at least one deleterious sequence variation was identified in 1153 patients (635 families) (69% with type 2, 23% with type 1, 5% with type 3 and 3% with an undetermined phenotype). However, the direct sequencing failed to detect any causative mutation in 29 patients (17 index cases (IC)), and revealed only one heterozygous genetic defect discrepant with the phenotypic severity in six patients (5 IC).

Aims and Methods: To search in these 35 patients (22 IC) a large *VWF* gene deletion/duplication using multiple ligation-dependent probe amplification (MLPA) (kits MRC Holland).

Results: Nine distinct large gene alterations (6 novel*) were identified at a heterozygous state in 22 patients (10 IC): deletion spanning exons 1–3, exons 6–18*, exons 19–20*, exons 32–34*, exons 33–34, whole

gene deletion; duplication exon 6*, exons 35–37*, exons 38–42*. These defects were detected: in three patients (2 IC) with type 3 VWD (associated to a nonsense mutation on the other allele); in one patient with type 2A(IIC) VWD (associated to a splice mutation on the other allele); in eight carriers of type three VWD with type 1 phenotype (one IC); in 10 patients (6 IC) with either type 1 or undetermined phenotype showing VWF levels between 7 and 25 IU/dL. No *VWF* gene defect was detected in seven unrelated patients with a type 1 phenotype (all with blood group O and VWF levels around 30 IU/dL); also, the abnormality of the second allele was not detected in two unrelated patients with type 3.

Conclusions: Large *VWF* gene alterations occur in about 2% of our large cohort of patients, and around 5% of patients with type three VWD. Hypothesis concerning the deleterious process of these defects are suggested. Some of these deletions/duplications may create a frame shift and then abolish *VWF* gene expression (feature of type 3 mutations). Some others may conserve the frame but the truncated or the longest translated VWF affects the structure of the multimeric VWF and provides a dominant negative effect interacting with the normal VWF allele. These deletions/duplications can hamper the correct dimerization or multimerization process and subsequent extracellular secretion of VWF inducing a type 1 VWD. Finally, only seven patients out of our 1182 patients (~0.5%) remain without identified *VWF* gene abnormality. Our results demonstrate that the screening of large deletions and duplications is an essential way to explain some VWD phenotype.

OC 13.3

Severity of bleeding tendency in von Willebrand disease is associated with von Willebrand factor string formation

Wang J-W[1], Dragt BS[2], Dirven RJ[3], Bouwens EAM[2], Voorberg J[2], Valentijn KM[3], Reitsma PH[3] and Eikenboom HCJ[3]

[1]YLL School of Medicine, National University of Singapore, Singapore, Singapore; [2]Sanquin-AMC Landsteiner Laboratory, Amsterdam; [3]Leiden University Medical Center, Leiden, the Netherlands

Background: von Willebrand disease (VWD) type Vicenza is caused by a p.Arg1205His von Willebrand factor (VWF) mutation. The characteristics of the phenotype are very low levels of plasma VWF, often in the presence of ultra-large VWF multimers. Rapid clearance has been implicated in the pathogenesis, however, other still unresolved mechanisms may add to the bleeding tendency. Two VWD type Vicenza patients from the same family, one heterozygous for VWF mutation p.Arg1205His and the other compound heterozygous for VWF mutations p.Arg1205His and p.Arg924Gln, showed remarkable differences in their bleeding tendency with Tosetto bleeding scores of respectively 3 and 18.

Aim: To understand the molecular mechanism underlying the disparate bleeding severity in the two VWD type Vicenza patients.

Methods: Blood outgrowth endothelial cells (BOECs) were isolated from peripheral blood. Storage and secretion of VWF was analyzed in patient-derived BOECs and in transfected HEK293 cells. VWF strings were characterized under both static and flow conditions. This study complies with the Declaration of Helsinki, and informed consent and ethics approval were obtained.

Results: VWF mutants p.Arg1205His and p.Arg924Gln were stored normally in (pseudo-)Weibel-Palade bodies (WPB) both in transfected HEK293 cells and in BOECs. Compared to normal BOECs, histamine-induced release of VWF propeptide (VWFpp) from BOECs of the two VWD patients was reduced (70% of total VWFpp from the normal BOECs versus 40% from the two patients' BOECs). Upon stimulation with histamine, approximately 30 VWF strings per 10 imaging fields were released from BOECs derived from a healthy donor or from the patient heterozygous for p.Arg1205His, whereas the quantity was less than on average 5 strings per 10 imaging fields for BOECs derived from the patient compound heterozygous for p.Arg1205His and p.Arg924Gln ($P < 0.01$). Instead, many extracellular VWF 'patches' appeared on the cell surface of BOECs derived from the compound heterozygous patient, indicating that VWF did not unfold when WPB fused with the cell-membrane to form secretory pods. Furthermore, the platelet binding ability of VWF strings released from the two patients' BOECs appeared somewhat reduced under flow conditions (0.12 ± 0.06 platelets per μm string for patients' BOECs versus 0.15 ± 0.07 platelets per μm string for normal BOECs; $P < 0.05$). The pathogenic nature of p.Arg1205His and p.Arg924Gln was also evaluated in transfected cells. In HEK293 cells, p.Arg1205His led to a significant reduction in total production of VWF, basal and regulated secretion of VWF, and to formation of shorter VWF strings. Similarly, p.Arg924Gln reduced regulated secretion of VWF and resulted in shorter VWF strings. The impairment in VWF production and secretion caused by p.Arg1205His was only partially corrected upon co-transfection of wild type VWF or p.Arg924Gln.

Conclusions: Synergistic effects of p.Arg1205His and p.Arg924Gln on VWF string formation may contribute to the more severe phenotype in the compound heterozygous patient. Failure of unfolding VWF into strings is a new pathogenic mechanism for VWD that remains undetected by the common diagnostic VWF assays.

OC 13.4

Characterisation of large in-frame deletions contributing to type 1 VWD pathogenesis in the MCMDM-1VWD study

Cartwright A[1], Hampshire DJ[1], Bloomer L[1], Al-Buhairan AM[1], Vijzelaar NCP[2], Budde U[3], Eikenboom HCJ[4], Schneppenheim R[5], Peake IR[1] and Goodeve AC[1]

[1]The University of Sheffield, Sheffield, UK; [2]MRC-Holland b.v., Amsterdam, the Netherlands; [3]Hemostaseology Department, Hamburg, Germany; [4]Leiden University Medical Center, Leiden, the Netherlands; [5]University Medical Center Hamburg-Eppendorf, Hamburg, Germany

Introduction: Type 1 von Willebrand disease (VWD1) results from a partial quantitative deficiency of von Willebrand factor. VWD1 mutations are largely missense, but also include small nucleotide insertions/deletions, splice and nonsense mutations. Investigation into the contribution of heterozygous exon deletions to VWD1 pathogenesis within the MCMDM-1VWD cohort, using multiplex ligation-dependent probe amplification (MLPA) analysis led to identification of six heterozygous deletions. Three novel deletions, involving exons 3 (p.G19_G74del), 32–34 (p.V1820_C1948delinsS) and 33–34 (p.G1874_C1948del) were identified in addition to three cases with a previously reported exon 4–5 deletion among 150 index cases (4%). The index cases with exon 3, 32–34 and 33–34 deletions had bleeding scores of 10, 6 and 4, VWF:Ag levels of 31 12 and 32 IU/dL, VWF:RCo of 20, 11 and 23 IU/dL and VWF:CB of 31, 12 and 15 IU/dL, respectively. Phenotype was more severe for these deletions than previously reported for the exon 4–5 deletion. The exon 32–34 deletion was associated with a slight multimer abnormality.

Aim: To characterise and determine deletion breakpoints and the mechanism by which the deletions exert an effect on VWF protein synthesis and secretion.

Methodology: Heterozygous deletion breakpoints were characterised through haplotyping of intronic SNPs followed by long-range PCR. *In silico* analysis of breakpoint regions was used to investigate repetitive elements and DNA sequence motifs that might explain mechanisms of deletion formation. VWF deletion mutants were created using site-directed mutagenesis. Recombinant vectors were transiently-transfected into HEK293T cells and Renilla was used as a transfection control. Conditioned media and cellular lysates were collected 48 h post-transfection and analysed by VWF:Ag ELISA, comparing to wild-type expression.

Results: Heterozygous deletions resulting in in-frame loss of exons 3 (c.56-335_220+1585), 32–34 (c.5455+277_5842+978delinsTGGACACA) and 33–34 (c.5620+872_5842+2440delinsGCAGCATAAGCATAAAGC) ranged in size from 1.5 to 5.2 kb. Breakpoints were mapped to intronic regions of *VWF* and deletion-specific PCR demonstrated fully penetrant dominant inheritance in each family. Breakpoint junctions for the exon 3 deletion lay within *Alu*-repeat elements; motif analysis revealed a topoisomerase I cleavage site adjacent to the 5′ junction, inferring single stranded annealing (SSA) as the likely deletion mechanism. Microhomology mediated end-joining (MMEJ) was hypothesised as the mechanism for deletion of exons 32–34 and 33–34. Expression of recombinant mutant VWF rVWFdel3 and rVWFdel32-34 demonstrated secretion reduced by 81% and 87% ($P < 0.0001$) respectively in the homozygous state in comparison with rVWFwt, with no significant increase in intracellular retention. Both deletions also resulted in significantly ($P < 0.0001$) reduced secretion (53% and 61%, respectively) in the heterozygous state. Additionally, there was reduction in intracellular VWF for rVWFdel3 (21%, $P < 0.05$) but a 41% ($P < 0.05$) increase in intracellular VWF for rVWFdel32-34 in the heterozygous state.

Conclusion: Molecular characterisation of VWD1 deletions indicates that SSA between *Alu*-repeat elements, as well as MMEJ are causal. *In vitro* expression data from this study suggests that deletions of exons 3 and 32–34 do not affect VWF secretion as significantly as reported for the exon 4–5 deletion (98% homozygous and 86% heterozygous). However, these in-frame VWF deletions do result in significantly decreased secretion of heterozygous mutant VWF.

OC 13.5

Distribution of the von Willebrand disease Types In 337 patients followed by a single hemophilia center since 2002: a comparison of von Willebrand disease patients classification after 10 years

Baronciani L[1], Canciani MT[1], Cozzi G[1], Garcia Oya I[1], Stufano F[1], Pagliari MT[1], Franchi F[2], Federici AB[2] and Peyvandi F[2]

[1]*Fondazione IRCCS Ca' Granda-Ospedale Maggiore Policlinico, Milan;* [2]*Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, University of Milan, Milano, Italy*

Background: von Willebrand Disease (VWD) is the most frequent bleeding disorder and it is caused by quantitative (type 1 and 3) or qualitative (type 2) defects of von Willebrand factor (VWF). Type 2 VWD is further divided into four categories: 2A, 2B, 2M and 2N. The accurate classification of VWD patients requires the evaluation of several laboratory tests.

Aims: To compare the current distribution of VWD types diagnosed at Angelo Bianchi Bonomi Hemophilia and Thrombosis Center (Milan, Italy) with the distribution obtained 10 years ago.

Methods: A total of 337 VWD patients referred to our center from 2002 through 2012 have been fully characterized. Laboratory diagnosis of VWD was made by VWF antigen (VWF:Ag), VWF ristocetin cofactor, factor VIII coagulant activity, VWF collagen binding, multimeric analysis in low and medium resolution gels, VWF propeptide/VWF:Ag ratio, VWF binding to FVIII, ristocetin induced platelet agglutination, intra-platelet VWF evaluation and in type 2 and 3 molecular characterization. We considered 0.6 the cut off of VWF:RCo/Ag ratio to differentiate type 1 from type 2 VWD. Patients with 'supranormal' multimers in plasma and R1205H mutation were classified as type 1 'Vicenza'.

Results: VWD type diagnosis was made on the basis of the revised classification of the ISTH Subcommittee on VWF (J Thomb Haemost 2006;4:2103). The distribution of the VWD population in the years 2002 and 2012 are reported as number of cases (%, percentage). 2002: type 1: 108 (34.2%); type 2A: 45 (14.3%); type 2B: 35 (11%); type 2M: 105 (33.2%); type 2N: 1 (0.3%); type 3: 22 (7%), total 316 (100%). 2012: type 1: 113 (33.5%); type 2A: 105 (31.2%); type 2B: 58 (17.2%); type 2M: 28 (8.3%); type 2N: 7 (2.1%); type 3: 26 (7.7%), total 337 (100%).

Discussion: The main difference between the two populations is the inversion in the percentages of type 2A and 2M patients. This finding appears to be related to the more precise approach to laboratory diagnosis due to the introduction of additional and more sensitive tests and to the improvement of multimeric analysis performed at low and medium resolution gels. Indeed, the identification of more VWD type 2A cases in 2012 was also due to the better characterization of a subgroup of type 2A IIE patients. These subjects, previously misclassified as types 1 or 2M, were revaluated thanks to their abnormal triplet structure and the presence of the mutations in the D3 domain. The reduced number of type 1 VWD patients was compensated by the fact that patients previously classified as type 2M Vicenza have been included now as type 1 Vicenza, following the most recent classification published in 2006. In conclusion, a detailed characterization of VWF variants have tendency to highlight dysfunctional defects reducing the number of patients with normal VWF multimeric pattern, like type 1 or 2M. The clinical significance of this VWD heterogeneity is still under investigation and may support or not the use of such comprehensive characterization.

OC 13.6

Type 2N von Willebrand disease (VWD): one variant, two diseases? Analysis of the French cohort

Goudemand J[1], Zawadzki C[1], Volot F[2], Boisseau P[3], Sigaud M[3], Pouymayou K[4], Itzhar N[5], Caron C[1], Fressinaud E[5] and Veyradier A[5]

[1]*University of Lille 2, Lille;* [2]*University of Dijon, Dijon;* [3]*University of Nantes, Nantes;* [4]*University of Aix-Marseille, Marseille;* [5]*University of Paris-Sud, Clamart, France*

Aims: Type 2N VWD is defined by a markedly decreased binding of VWF to FVIII, recessively inherited. Since its first description in France in 1989 this VWD variant has been reported in many countries. In order to better redefine the clinical and biological characteristics of these patients (pts) compared to original publications we reviewed the records of pts identified as type 2N VWD by the French Reference Center of VWD since May 2007. Only pts with a ratio FVIII/VWF:Ag < 0.6 were enrolled. Further phenotypic and genotypic analyses were centralized. The clinical data were collected by questionnaire or site monitoring.

Results: Seventy nine pts (70 families) were recruited (F/M ratio: 1.6). The median (range) age was 39 (7–85) y.o. All the pts have a low FVIII:C level and FVIII/VWF:Ag ratio:15 (2–43) IU/dL and 0.29 (0.01–0.55) respectively. Genetic analysis showed that the R854Q mutation is involved in 70 pts (89%) (Group A) who are either homozygous (32) or compound heterozygous for another type 2N mutation (7) or a null allele (31). The 9 other pts (Group B) are homozygous for another type 2N mutation (4) or a null allele (5). The FVIII:C level and FVIII/VWF:Ag ratio are much more decreased in these last patients: 4 (2–15) IU/dL and 0.07 (0.01–0.41) compared to Group A pts: 20 (5–45) IU/dL and 0.31 (0.12–0.56) respectively (median and range). By contrast there is no significant difference between pts who are homozygous for R854Q or compound heterozygous for another type 2N mutation or null allele (not shown). The bleeding score (BS) was calculated (Tosetto) in 40 pts, but the results are currently available in 27. The median (range) BS is much less lower in 23 Group A pts: 5 (−1 to 14) compared to four Group B pts: 15 (6–24). The age in both groups is comparable. Clinical history showed that Group B pts were mostly diagnosed during childhood and experienced much more haemarthrosis and life threatening hemorrhages than Group A pts. Those pts had an adulthood-onset disease and exhibited mainly post surgery bleedings. The response to desmopressin was tested in 52 pts. Good response was defined as FVIII:C > 50 IU/dL 2 h after desmopressin. All the 48 Group A pts but one (R854Q/T791M) were found

to be good responders. None of the four tested pts in Group B responded to desmopressin.

Conclusions: The presence or absence of the mutation R854Q in pts with type 2N VWD allows a clear distinction between two groups. In the 1st group (R854Q present) pts have only a moderate FVIII:C deficiency and lower FVIII:C/VWF:Ag ratio. They have little spontaneous bleeding events and good response to desmopressin. The 2[d] group (R854Q absent) is much rarer (11% in our series) but much more severe: pts have a very low FVIII:C defect (< 5 IU/dL) and FVIII:C/VWF:Ag ratio with early and severe bleeding manifestations and no response to desmopressin. Type 2 N VWD encompasses two strongly different phenotypic and clinical patterns closely related to the genotype.

OC 14 – Acquired Bleeding Disorders

OC 14.1

Treatment of acute bleeding episodes in acquired haemophilia with recombinant activated factor VII (rFVIIa): analysis from 10-year Japanese post-marketing surveillance

Seita I[1], Amano K[1], Higasa S[2], Sawada A[2], Kuwahara M[3] and Shima M[4]

[1]Tokyo Medical University, Tokyo; [2]Hyogo College of Medicine, Nishinomiya; [3]Novo Nordisk Pharma Ltd., Tokyo; [4]Nara Medical University, Kashihara, Japan

Background: Acquired haemophilia (AH) is a rare, spontaneous bleeding disorder caused by autoantibodies, usually against factor VIII. Control of acute bleeding is the first priority, and patients are treated with bypassing agents such as recombinant activated factor VII (rFVIIa, NovoSeven®). However, the data for the use of rFVIIa for AH is limited. To investigate the safety and efficacy of rFVIIa for the treatment of AH, data from Japanese post-marketing surveillance was collected.

Methods: A multi-centre, non-interventional, observational study was conducted from May 2000 to March 2010. Under routine clinical practice, the dosing regimen of rFVIIa was recorded, and clinical efficacy was evaluated as 'markedly effective' (clinical improvement within 8 h), 'effective' (clinical improvement within 8–12 h), 'moderate' (clinical improvement in > 12 h), or 'ineffective'. Adverse events were also recorded.

Results: Data from 132 patients were collected, including 57 (43%) females and 75 (57%) males. The mean values for patient characteristics were as follows: age, 67.9 years; FVIII activity, 4.1 IU/dL; and FVIII inhibitor titre, 101.1 Bethesda units/mL. Among 371 bleeding episodes, muscle bleeds were most common (40%), followed by subcutaneous haemorrhages (14%), joint bleeds (9%), haematuria (5%), and gastrointestinal bleeds (4%). Overall, 92% of bleeding episodes improved following treatment with rFVIIa (41% 'markedly effective', 10% 'effective', and 41% 'moderate'). Median (mean) treatment was of 2.0 (2.9) days' duration, with 3.0 (11.6) injections of 93.2 (99.5) μg/kg rFVIIa. Disseminated intravascular coagulation was reported in two patients; an 87-year-old female with rheumatoid arthritis and an 81-year-old male with pneumonia. Bowel necrosis was reported in a 70-year-old male with intracerebral haemorrhage, complicated with pneumonia. These three cases were determined by the reporters to be related to rFVIIa administration.

Conclusions: These data represent the largest report of rFVIIa use in AH from a single country. rFVIIa provided adequate haemostasis for the treatment of AH. Thromboembolic events were observed in elderly patients with severe complications.

OC 14.2

Treatment of bleeding episodes in acquired haemophilia with activated prothrombin complex concentrate: what is the optimal therapy?

Milan M[1], Gamba G[2], Ambaglio C[2], Montani N[2], Spiezia L[1] and Zanon E[1]

[1]2nd Chair of Internal Medicine, Padua University Hospital, Padua; [2]SS Diseases of Hemostasis, University of Pavia, Pavia, Italy

Background: Acquired Haemophilia A (AHA) is a rare condition associated with severe bleeding and high rate of mortality. Activated Prothrombin Complex Concentrate (aPCC) was described as being useful to treat AHA patients. Doses and duration of treatment are still a matter for debate.

Aims: To retrospectively compare, in a small Italian cohort of bleeding AHA patients, the efficacy of two different strategies of treatment with aPCC in the prevention of haemorrhagic relapses: acute phase treatment only vs acute phase plus low-dose prophylaxis.

Methods: All patients with AHA consecutively admitted to PaduaUniversityHospitaland PaviaUniversityHospitalbetween April 2008 and August 2012 were considered for enrolment. Information on the characteristics and treatment of bleeding episodes was collected according to the use of aPCC in the acute phase and subsequently during 4 weeks after the initial treatment. For all patients written informed consent was obtained.

Results: Sixteen bleeding episodes in fourteen AHA patients treated with aPCC for bleeding recurrence were considered. Eight were major haemorrhagic episodes (according to Schulman S et al. JTH 2005;3:692–4) and eight were minor bleeding. Ten bleeding episodes were treated with the use of aPCC limited to the acute phase. Meanwhile, in the other six episodes the acute phase treatment was followed by a low-dose prophylaxis with aPCC. Comparing the two strategies, no difference in the initial dose of drug used was found. In particular, for major bleeding, patients were treated with aPCC 205 ± 7.1 Ukg/day (mean M ± standard deviation SD) in the former regimen vs 162.2 ± 33.3 Ukg/day in the low-dose prophylaxis regimen (P = 0.137); and, for minor bleeding, with an initial mean dose of 64 ± 40.4 Ukg/day in the acute-phase treatment versus 85 ± 10 Ukg/day in the latter (P = 0.38). Low-dose prophylaxis was maintained with a mean dose of 82.5 ± 46.0 Ukg/day and for a mean period of 9.5 ± 2.1 days in case of major haemorrhage and with a mean dose of 28.5 ± 9.3 Ukg/day and for a mean period of 12.25 ± 10.7 days in minor episodes. Five cases of bleeding relapse were observed in patients treated with aPCC only during the acute phase and no bleeding events in AHA patients treated with low-dose prophylaxis strategy occurred. A two-fold increase in the risk of haemorrhagic recurrence in patients who did not receive the prophylactic treatment was found (OR 2.18, 95% confidence interval [CI]: 1.11–4.28, P = 0.02). This risk was not affected by adjustment for possible confounders (age, gender, type of bleeding, levels of inhibitor titre and factor VIII activity). No thromboembolic complication or other adverse events were reported in both treatments. In all patients the acute phase treatment with aPCC was started in association with immunosuppressive treatment (i.e. steroids ± cyclofosfamide) to obtain inhibitor eradication.

Conclusions: A low-dose prophylaxis regimen with aPCC in bleeding AHA patients seems to prevent the risk of haemorrhagic relapses. This approach appeared to be safe and well tolerated. Larger and prospective studies are needed to better clarify the role of this strategy.

OC 14.3

In vivo hemostatic potency of a factor VIII function-mimetic, bispecific antibody to factors IXa and X (ACE910) against on-going bleeds in an acquired hemophilia A model

Muto A[1], Kitazawa T[1], Yoshihashi K[1], Takeda M[1], Soeda T[1], Igawa T[1], Sampei Z[1], Shima M[2], Yoshioka A[2] and Hattori K[1]
[1]Chugai Pharmaceutical Co., Ltd., Gotemba, Shizuoka; [2]Nara Medical University, Kashihara, Nara, Japan

Background: We previously reported that a bispecific antibody to factors IXa and X, hBS23, mimicked the function of factor VIII (FVIII) even in the presence of FVIII inhibitors, and exerted preventive hemostatic activity *in vivo* (Nature Medicine 2012). By the further molecular engineering of hBS23, we identified an improved bispecific antibody, ACE910, which presented higher *in vitro* cofactor activity than hBS23 and *in vivo* hemostatic activity even against on-going bleeds (Early results were presented at the ASH meeting 2012).
Aims: To elucidate the *in vivo* hemostatic potency of ACE910, by examining its dose-dependent hemostatic effect against on-going bleeds.
Methods: A non-human primate model of acquired hemophilia A was established by injecting anti-primate FVIII neutralizing antibody which was not cross-reactive to porcine FVIII. When bleeds emerged following an artificial bleed-inducing procedure, either ACE910 (0.3, 1 or 3 mg/kg, $n = 4$ for each dose), recombinant porcine FVIII (rpoFVIII; 3.4 or 10 U/kg, $n = 4$ for each dose) or no test item ($n = 6$) was intravenously administered. rpoFVIII was additionally administered twice daily on the following 2 days. Bleeding symptoms, progressive anemia and expansion of bruised area, were monitored for 3 days.
Results: In this *in vivo* model, rpoFVIII 10 U/kg (twice daily) showed significant hemostatic effect against on-going bleeds, whereas the hemostatic effect of rpoFVIII 3.4 U/kg (twice daily) was not detected clearly. Since the minimal target plasma level against on-going bleeds, 10 to 20 U/dL of FVIII:C, would be achieved with rpoFVIII 10 U/kg but not with 3.4 U/kg, this reestablished model was found validated well in terms of the reactivity to FVIII. In this model, a single bolus of ACE910 1 or 3 mg/kg presented a hemostatic activity comparable to rpoFVIII 10 U/kg (twice daily) against on-going bleeds. The hemostatic effect of a single bolus of ACE910 0.3 mg/kg was not clearly detected. The mean plasma concentrations of ACE910 just after the intravenous administration were 6.6, 26 and 61 μg/mL in the ACE910 0.3, 1 and 3 mg/kg groups, respectively.
Conclusion: ACE910 demonstrated hemostatic effect against on-going bleeds in a non-human primate model of acquired hemophilia A. The hemostatic potency of a single bolus of ACE910 1 or 3 mg/kg was comparable to that of rpoFVIII 10 U/kg (twice daily).

OC 14.4

The prevalence and severity of shear stress-associated acquired von Willebrand factor abnormality in patients with mitral regurgitation

Chen D, Blackshear JL, Wysokinska M, Safford RE, Thomas CS, Shapiro BP, Ung S, Stark ME and Johns G
Mayo Clinic, Rochester, MN, USA

Background: Loss of the highest molecular weight multimers (HMWM) of von Willebrand factor (VWF) due to high intravascular shear stress has been well recognized in patients with aortic stenosis. However, the prevalence and severity of such a HMWM loss has not been thoroughly studied in patients with mitral regurgitation (MR).
Aims: In this study, we examined the prevalence and severity of VWF HMWM loss in patients with various degrees of MR.
Methods: A total of 47 patients (47% male and median age, 69.5 years) with MR were studied and their clinical and laboratory data were collected. Nineteen patients had severe organic MR, and 28 had mild or moderate MR. Separate seventeen patients were status post mitral valve replacement (MVR). Blood samples were tested for VWF antigen (VWF:Ag), VWF activity by enhanced immunoturbidity method (VWF:Lx), VWF multimer analysis and HMWM densitometry quantification (VWF:M) (Am J Cardiol. 2013;111:374–81), and ADP cartridge closure times of platelet function analysis (PFA-CADP). These laboratory results were compared with the severity of MR measured by regurgitatant volume (RV).
Results: The prevalence of loss of HMWM in patients with various degrees of MR was as follows: severe MR, 79%; moderate MR, 57%; mild MR, 21%. Two patients with severe MR developed Heyde syndrome. Conversely, only 6% of patients post MVR had loss of HMWM. RV significantly correlated with PFA-CADP ($r = 0.66$, $P < 0.001$), VWF:M ($r = -0.60$, $P < 0.001$) and VWF:Lx/Ag ratio ($r = -0.39$, $P = 0.007$). Over a median of 11.3 months, VWF multimer ratio ($P = 0.001$) and PFA-CADP ($P = 0.007$) were predictors of freedom from death ($n = 1$) or mitral valve surgery (MVS, $n = 15$). In the 15 patients who had MVS, post-operative samples revealed significant resolution of VWF abnormality indicated by marked improvement of VWF:M ($P < 0.001$), PFA-CADP ($P < 0.001$) and VWF:Lx/Ag ratios ($P < 0.01$).
Conclusions: Surprisingly the loss of VWF HMWM is quite common in patients with moderate -severe MR, and resolves after MVS. Heyde syndrome can occur in patients with severe MR. Since the degree of HMWM loss significantly correlates with MR severity, PFA-CADP, VWF:Lx/Ag ratio and VWF:M are potentially useful diagnostic and prognostic biomarkers in patients with MR.

OC 15 – ADAMTS-13

OC 15.1

ADAMTS13 meets von Willebrand factor strings: a single molecule approach

De Ceunynck KEP[1], Rocha SN[2], De Meyer SF[1], Uji-I H[2], Deckmyn H[1], Hofkens J[2] and Vanhoorelbeke K[1]
[1]KU Leuven Kulak, Kortrijk; [2]KU Leuven, Leuven, Belgium

Background: Single molecule fluorescence microscopy (SMFM) is a powerful technique to explore the individual nano-scale behavior of molecules. SMFM allows direct visualization of molecular motions and observation of diversity in a population of molecules, normally hidden in classical bulk experiments. We previously demonstrated that platelet-decorated VWF strings attached to the endothelium are cleaved multiple times by ADAMTS13 preferentially at sites of local elongations. However, it is currently unknown how ADAMTS13 locates a binding site on these long VWF strings. New insights in the working mechanism of ADAMTS13 on these strings could be revealed by visualizing the molecular motion of single ADAMTS13 enzymes.
Aim: To set-up a SMFM experiment to track the movement of individual ADAMTS13 enzymes on platelet-decorated VWF strings, hence increasing our understanding of individual ADAMTS13 enzymes at work.
Methods: Fluorescently labeled catalytically inactive ADAMTS13^{E225Q}-Atto647N (5.7 nM) was perfused over endothelial cell-anchored VWF strings in a parallel-plate flow chamber at a shear stress of 2.5 dyne/cm^2. VWF strings were indirectly visualized by green fluorescent labeling of platelets (100 nM Dioc). A customized SMFM microscopy set-up was developed to visualize individual ADAMTS13 enzymes.
Results: Single ADAMTS13 enzymes were detected by exciting ADAMTS13^{E225Q}-Atto647N with a powerful laser, using high magnifications (~2000×) and a sensitive EM-CCD camera. Due to nm scale visualization necessary for ADAMTS13 detection but not warranted for the observation of long VWF strings a two camera set-up was developed allowing the use of different magnifications to selectively detect platelet-decorated VWF strings and single ADAMTS13^{E225Q}

enzymes. Autofluorescence background signals from endothelial cells were reduced by performing excitation in total internal reflection-like mode. This set-up allowed us to visualize single ADAMTS13 binding to the strings in real-time. To now analyze enzyme trajectories and ADAMTS13 binding sites on these VWF strings customized single particle tracking software was developed. Initial analysis of ADAMTS13^{E225Q} binding to platelet-decorated VWF strings (n = 39) in real time under flow revealed three different kinds of motion. Enzymes could slow down without arrest on the VWF string (slow down), slow down and stop for only two to five frames (60 ms exposure time) (stop & go) or bind to the VWF string for a longer time (stop).

Conclusions: We were able to visualize the binding of single ADAMTS13 enzymes to platelet-decorated VWF strings. Further detailed analysis of all ADAMTS13 trajectories and binding sites will allow us to elucidate how ADAMTS13 preferentially localizes its binding site on these strings and how this correlates with ADAMTS13 binding at sites of local elongations.

OC 15.2

Spatially distinct regulation of von Willebrand factor by ADAMTS13 at the sites of platelet accumulation

Shida Y, Brown C, Mewburn J, Sponagle K, Riches J, Hough C and Lillicrap D

Queen's Univeristy, Kingston, Canada

Background: von Willebrand Factor (VWF) is a large multimeric glycoprotein that mediates platelet adhesion and subsequent platelet aggregation to the damaged blood vessel wall in both physiological hemostasis and pathological thrombosis. The metalloprotease ADAMTS13 regulates the functional activity of VWF appropriate for normal hemostasis by reducing VWF multimer size. The cleavage site for ADAMTS13 in the VWF A2 domain is inaccessible in the globular configuration of the protein and requires the application of tensile force mediated by platelets and hydrodynamic shear to facilitate cleavage.

Aims: Newly released ULVWF is anchored on endothelial cells and cleaved by ADAMTS13. Other potential sites where ADAMTS13 might regulate VWF size include in the circulation and at the sites of vessel injury. At this latter location, ADAMTS13 is hypothesized to regulate thrombus growth and prevent vessel occlusion. However, direct evidence to support this role is limited. To address this issue, we developed a mouse model system to directly visualize the involvement of ADAMTS13 in the thrombogenic process under flow conditions.

Methods: Full-length mouse ADAMTS13 cDNA was cloned into pcDNA3.1 and mCherry was cloned at the C terminus of ADAMTS13 with a 12AA linker. Recombinant mADAMTS13-mCherry protein was produced via HEK293T cells by transient transfection. mADAMTS13-mCherry was pre-incubated with mCherry antibody and goat anti-rabbit IgG-Alexa568 30 min before the following flow chamber experiment. Whole blood obtained from ADAMTS13 knockout mice with added mADAMTS13-mCherry was perfused into a collagen coated flow chamber at various shear rates (500/s, 2500/s, 7500/s). Platelets and ADAMTS13 were visualized and quantified with a Quorum WaveFX- X1 spinning disk confocal system. After the perfusion, thrombi were fixed and immunostaining was performed to further analyze the distribution of platelets, VWF and ADAMTS13.

Results: ADAMTS13-mCherry was visualized only under the highly elevated shear condition (7500/s) in the real-time flow system where the signal was mainly on the formed thrombi. It was also occasionally detected on the collagen surface, where it was associated with nearby platelets and resembled VWF strings in appearance. Image analysis of the thrombus demonstrated 42.1, 36.1, and 23.3% reductions in size with the addition of ADAMTS13 at 7500, 2500, and 500/s, respectively. Further analysis by immunostaining of the thrombus demonstrated a 2.3-fold-increase of ADAMTS13 total area at 7500/s compared to that at 2500/s. Moreover, 45.4% and 37.7% of this increase was associated with the top and middle layers of the thrombus. In contrast, at the low shear condition (500/s), ADAMTS13 signal was very limited to only 6% compared to 7500/s.

Summary/Conclusion: Direct visualization of ADAMTS13 was achieved in our flow chamber system using fluorescence-tagged ADAMTS13. Our multi-colour immunostaining revealed enhanced ADAMTS13 activity in the top and middle layers of thrombus at a highly elevated shear rate and was associated with reduction of thrombus size. It is speculated that the platelet surface contributes, along with platelet tethering and increasing hydrodynamic shear force, to accelerate VWF cleavage and limit thrombus size. These results have characterized a shear-dependent, spatially distinct regulatory mechanism for ADAMTS13 that limits thrombus growth directly at the sites of platelet accumulation.

OC 15.3

ADAMTS13 is autoinhibited by distal thrombospondin-1 (T) or CUB domains and is activated allosterically by VWF or antibodies against ADAMTS13 domain T8

Muia J[1], Zhu J[1], Haberichter SL[2], Friedman KD[2], Feys H[3], Vanhoorelbeke K[4], Westfield LA[1] and Sadler JE[1]

[1]Washington University School of Medicine, St. Louis, MO; [2]BloodCenter of Wisconsin, Milwaukee, WI, USA; [3]Red Cross Flanders, Brugge; [4]IRC, KULeuven Campus Kortrijk, Kortrijk, Belgium

Background: ADAMTS13 is a metalloprotease that cleaves von Willebrand factor multimers. Genetic or autoimmune deficiency of ADAMTS13 causes thrombotic thrombocytopenic purpura (TTP), which is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and tissue damage caused by microvascular thrombosis. ADAMTS13 is a multidomain protein with metalloprotease (M), disintegrin-like (D), thrombospondin-1 (T), Cys-rich (C) and spacer (S) domains, followed by seven T domains and two CUB domains. ADAMTS13 binds native VWF (Kd ≈70 nM), which requires ADAMTS13 domains T8-CUB1 and VWF domain D4. ADAMTS13 truncated after the spacer domain (MDTCS) does not bind native VWF but binds to unfolded VWF domain A2 (Kd ≈30 nM).

Aim: The regulation of ADAMTS13 is poorly understood, and ADAMTS13 has no known inhibitors *in vivo*. The multidomain structure of ADAMTS13 suggests that distal T or CUB domains might regulate its activity. We sought to characterize ADAMTS13 auto-regulatory mechanisms.

Methods: ADAMTS13 activity assays were performed with FRETS-rVWF71, a fluorogenic ADAMST13 substrate with increased sensitivity. Product generation was monitored as an increase in fluorescence emission at 660 nm upon excitation at 635 nm. Assays included 50 mM Bis-Tris or HEPES at the indicated pH, 150 mM NaCl, 10 mM $CaCl_2$, and varying concentrations of VWF. Recombinant ADAMTS13 and MDTCS were expressed in HEK293 cells and chromatographically purified. Plasma ADAMTS13 was from pooled normal plasma. Monoclonal antibody 14D2 recognizes ADAMTS13 domain T8. Plasma samples from 65 patients with TTP and ADAMTS13 activity < 20% were obtained through approved human studies protocols.

Results: At pH 6, ADAMTS13 and MDTCS had equal and maximal specific activity. As pH was increased toward pH 7.4, MDTCS activity remained roughly constant but full-length plasma ADAMTS13 activity decreased progressively to one-fourth of the activity observed at pH 6, suggesting that distal ADAMTS13 T-CUB domains inhibit proteolytic activity under physiological conditions. Recombinant ADAMTS13 behaved similarly. When plasma samples from patients with TTP were assayed for inhibitors, one contained an antibody that increased ADAMTS13 activity three-fold to almost equal the activity of MDTCS, with an activation titer of 9 U at pH 7.4. This activating antibody had no effect on ADAMTS13 activity at pH 6, or on

MDTCS activity at either pH 6 or pH 7.4. We screened 18 anti-ADAMTS13 monoclonal antibodies and found that 0.8 μg/mL MAb 14D2, with an epitope in T8, activated ADAMTS13 2.2-fold at pH 7.4 but did not further increase the activity of ADAMTS13 at pH 6. Increasing concentrations of VWF (up to 125 μg/mL, or 500 nM) progressively activated ADAMTS13 1.8-fold at pH 7.4 but not at pH 6, and had no significant effect on MDTCS activity.

Summary/Conclusion: ADAMTS13 is regulated by substrate-induced conformational changes. Full-length ADAMTS13 is autoinhibited by distal T-CUB domains and is activated allosterically by VWF, probably by binding to VWF domain D4. Activation by VWF is mimicked by low pH or by antibodies that bind ADAMTS13 domain T8. ADAMTS13 bound to native VWF has increased proteolytic activity and may contribute disproportionately to the cleavage of VWF multimers under shear stress *in vivo*.

OC 15.4

A comprehensive mutagenesis screen defines the substrate recognition landscape within VWF for ADAMTS13

Kretz CA[1], Desch KC[2], Yee A[1], Siemieniak D[1], Meng F[2] and Ginsburg D[1]

[1]*Life Sciences Institute, Ann Arbor, MI;* [2]*University of Michigan, Ann Arbor, MI, USA*

Background: The metalloprotease ADAMTS13 regulates the multimeric structure and adhesiveness of von Willebrand Factor (VWF). Deficiency in ADAMTS13 activity can lead to thrombotic thrombocytopenic purpura (TTP), a devastating microvascular thrombopathy.

Aims: The aim of this study was to comprehensively investigate the interaction of ADAMTS13 with its substrate VWF73, a fragment of the VWF A2 domain, to gain insights into ADAMTS13 specificity.

Methods: A mutant VWF73 substrate phage display library was developed consisting of 30 million independent clones with an average mutation frequency of 3% at each position. This library should contain VWF73 variants corresponding to every possible single amino acid substitution at every position as well as most combinations of double amino acid substitutions. This library exhibited proper substrate consumption kinetics when reacted with ADAMTS13, although accumulation of uncleaveable phage at later time points caused variation to predicted pseudo first order kinetics.

High throughput deep sequencing using the Illumina platform was used to provide unprecedented information of how each mutation influenced VWF73 proteolysis by ADAMTS13. Maximal enrichment of uncleavable phage was achieved by reacting 25 nM ADAMTS13 with the mutant VWF73 phage library for 10 hr and isolating uncleaved phage by immunoprecipitation. Thirty-five million sequences were obtained for both the selected uncleaved phage and the starting phage population and enrichment was analyzed using the ENRICH software package.

Results: Overall, the uncleaved phage exhibited enrichment for mutations compared to the unselected library at the majority of VWF73 positions. However, mutation frequencies remained unchanged at R1597, A1600, A1612, Q1667, and R1668, indicating that mutations at these positions did not inhibit proteolysis by ADAMTS13. Also, the interval between T1608-S1613 exhibited only modest increases in mutation frequency, indicating that these positions were also tolerant to mutations.

Mutations surrounding the Y1605-M6066 scissile bond tended to inhibit proteolysis compared to mutations at other positions on the substrate. Positions such as L1603, V1604, Y1605 exhibited an increase mutation frequency, indicating mutations at these positions inhibited proteolysis by ADAMTS13. Position V1607 exhibited the greatest increase in mutation frequency following selection, suggesting that this is an important amino acid in VWF substrate recognition. However, the P1' residue, M1606, was comparably permissive to mutations, indicating a less-critical role in substrate recognition. Positions I1616 and P1620 also exhibited increased mutation frequency after selection, indicating potential exosite interactions.

Focusing on single amino acid substitutions, L1619G exhibited a log2 enrichment ratio (L2ER) of 3.9, among the most deleterious mutations we discovered, indicating a potentially important role for this amino acid in regulating VWF73 recognition by ADAMTS13. However, L1619A had a L2ER of 1.8, suggesting that ala-scanning mutagenesis does not serve as a proxy for other substitutions.

Summary and Conclusions: Coupling comprehensive mutagenesis with high throughput deep sequencing revealed a detailed substrate recognition landscape for VWF73 that could not previously be assessed with standard technology. These data will be useful in defining important substrate recognition domains on VWF that may lead to the development of more sensitive ADAMTS13 activity assays and improved understanding of ADAMTS13 protease function and TTP pathogenesis.

OC 16 – Anticoagulants – Basic

OC 16.1

Effect of rivaroxaban with or without acetylsalicylic acid on thrombus formation in an *ex vivo* perfusion chamber – an open-label, randomized study in healthy subjects

Wolzt M[1], Gouya G[2], Kapiotis S[2], Becka M[3], Mueck W[3] and Kubitza D[3]

[1]*Medical University of Vienna;* [2]*Department of Clinical Pharmacology, Medical University of Vienna, Vienna, Austria;* [3]*Bayer HealthCare Pharmaceuticals, Wuppertal, Germany*

Background: Antiplatelet agents are effective for the secondary prevention of cardiovascular events in patients with acute coronary syndrome, but there is still a substantial residual risk of recurrence. Previous evidence has shown that co-administration of antiplatelet and anticoagulant therapies can further reduce the risk of cardiovascular events, although the risk of bleeding was increased with these combinations. Rivaroxaban, an oral, direct Factor Xa inhibitor, has been shown to be effective in the prevention and treatment of several thromboembolic disorders.

Aims: To investigate the effect of single doses of rivaroxaban (5–20 mg), with or without acetylsalicylic acid (ASA), on thrombus formation in an *ex vivo* perfusion chamber at low and high shear rates, representing conditions in the venous system and stenosed arteries, respectively.

Methods: Fifty-one healthy subjects were enrolled in this randomized, two-way crossover (for treatment with rivaroxaban with and without ASA) and parallel-group study for comparison between the different dosing regimens of rivaroxaban and ASA plus clopidogrel (EudraCT number: 2007-002345-21). The treatment groups were: (A) rivaroxaban plus ASA: rivaroxaban 5, 10 or 20 mg on day 0 and ASA once daily (od) on 4 consecutive days (day −3 to day 0; 300 mg loading dose followed by 100 mg); (B) rivaroxaban alone at 5, 10 or 20 mg on day 0; and (C) clopidogrel plus ASA: clopidogrel od on 4 consecutive days (day −3 to day 0; clopidogrel 300 mg loading dose followed by 75 mg) and ASA od on 4 consecutive days (as in group A). Thrombus formed in the perfusion chamber was measured as D-dimer levels (for fibrin deposition) and P-selectin content (for platelet deposition), performed at the time of maximum plasma concentration of rivaroxaban and at the maximum effect of ASA or clopidogrel. Pharmacodynamic parameters measured from plasma included inhibition of Factor Xa activity and measurement of prothrombin time, activated partial thromboplastin time and endogenous thrombin potential.

Results: Rivaroxaban reduced fibrin deposition in the perfusion chamber thrombus as measured by D-dimer levels, which were decreased by 9%, 84% and 65% at low shear rate and 37%, 73% and 74% at high

shear rate after rivaroxaban doses of 5, 10 and 20 mg, respectively. Steady-state ASA with rivaroxaban 5 mg caused a greater reduction in D-dimer levels (63%) at low shear rate. Co-administration of ASA and clopidogrel was associated with a 30% decrease in D-dimer levels at low shear rate and a 14% decrease at high shear rate. No conclusive effect was observed for thrombus P-selectin content across the treatment groups owing to large variations in the results. The other pharmacodynamic parameters measured in plasma were similar to previous studies, and co-administration of ASA and rivaroxaban had no additional influence.

Summary/Conclusions: Rivaroxaban dose dependently inhibited *ex vivo* thrombus formation under low and high shear rates. Co-administration of ASA had a significantly additive effect on the antithrombotic action of low-dose rivaroxaban, which further supports clinical findings in patients with acute coronary syndrome.

OC 16.2

Analysis of the interaction of anticoagulants on points of care (POC) tests for urine from patients on therapy with dabigatran and rivaroxaban

Krämer S[1], Giese C[1], Du S[1], Weiss C[2] and Harenberg J[1]
[1]*Clinical Pharmacology;* [2]*Biometry and Statistics, Mannheim, Germany*

Backgroud: The amount of new oral anticoagulants (NOACs) such as dabigatran and rivaroxaban may be necessary to determine in specific patient populations. Point of care (POC) methods were currently developed to analyse direct thrombin (international patent application No. PCT/EP2012/002540) and direct factor Xa inhibitors (international patent PCT/WO2012/069139A1) in urine. NOACs as well as conventional anticoagulants (except vitamin K antagonists) are excreted into the urine. Interactions of the anticoagulants may occur on the POC tests for dabigatran and rivaroxaban. POC test have the advantage over tests from plasma to be non-invasive, repetitive and rapid. They show when the NOAC is not any more on board and help to decide when to start or when to increase the dose the conventional anticoagulant.

Aim: We aimed to quantify the interaction of heparin, low-molecular-weight heparin (nadroparin), hirudin, and argatroban of the thrombin and factor Xa specific POC tests using urine samples on treatment with dabigatran or rivaroxaban.

Background: Urine samples were obtained from patients on treatment with 2 × 110 mg or 2 × 150 mg dabigatran (all $n = 15$) daily, 10 mg od rivaroxaban ($n = 15$), from 30 patients on treatment with low-molecular-weight heparin nadroparin (LMWH), and from five controls. All studies were accepted by the local university ethical board and patients gave written informed consent prior to participation. Urine samples of patients with dabigatran and controls were spiked with 0.0, 0.1–1.0 units of unfractionated heparin (UFH), 0.0 0.1–1 mg/mL hirudin and up to 6 mg/mL argatroban. From these samples the POC test for dabigatran was performed. Urine samples of patients with rivaroxaban or controls were spiked with similar concentrations of nadroparin and fondaparinux. Samples with UFH, nadroparin and fondaparinux were analysed without and with addition of 1 IU antithrombin/mL (AT) per mL urine. The POC test for rivaroxaban was performed from all these samples and from urine samples of patients under therapy with LMWH. The urine samples were incubated for 15 min in the POC device and the colour of the samples were judged as positive or negative.

Results: The POC tests for dabigatran and rivaroxaban were positive in all patients on therapy and negative in controls. UFH, LMWH, and fondaparinux did not indicate any interaction in all experimental settings. The POC test for rivaroxaban was negative in all patients on treatment with LMWH without addition of AT and was positive in some patients after addition of AT. High concentrations of hirudin and argatroban showed some interaction with the POC test for dabigatran.

Conclusion: The specificity of the POC assays for dabigatran and rivaroxaban in urine is high and no interactions occur in the absence or presence of AT for all heparins and heparin derived anticoagulants in patients on treatment with LMWH. Only for patients receiving hirudins and argatroban the POC test for dabigatran should not be used.

OC 16.3

Human clinical trials evaluating protein disulfide isomerase as an antithrombotic arget: pharmacodynamic and pharmacokinetic studies of oral quercetin and isoquercetin

Stopa JD, Furie B, Flaumenhaft R and Zwicker J
Beth Israel Deaconess Medical Center, Boston, MA, USA

Background: Protein disulfide isomerase (PDI) regulates both platelet accumulation and fibrin generation during thrombus formation following vascular injury in animal models. A high-throughput drug screen previously identified the flavonoid quercetin-3-rutinoside (and related analogs) as potent inhibitors of PDI activity *in vitro* and *in vivo*.

Aims: In anticipation of clinical trials to evaluate PDI as a novel antithrombotic target, we performed a pharmacokinetic study to assess whether oral quercetin or isoquercetin achieves therapeutic concentrations and pharmacodynamic studies to measure PDI inhibitory activity.

Methods: A total of 10 healthy volunteers were enrolled and received either quercetin 500 mg or isoquercetin 500 mg as a single dose. Serial phlebotomies were performed at 0 min, 30 min, 1 h, 2 h, 4 h, 6 h, 8 h, and 24 h. Total quercetin (aglycone) in plasma was measured by HPLC following enzymatic hydrolysis. In order to assess the pharmacodynamic inhibition of PDI following oral administration of the flavonoids, we developed a plasma-based assay utilizing a fluorescence-based eosin probe coupled to glutathione, with relative fluorescence measured in the presence of PDI.

Results: Isoquercetin demonstrated improved bioavailability (maximal concentration was 3.45 mM 95% CI 0.52–6.39 mM, Tmax 2.6 h, half-life 9.14 h, AUC 17.54) compared with quercetin aglycone (Cmax 0.77 mM 95% CI 0.4–1.12 mM, Tmax 3.8 h, half-life 10.79 h, AUC 5.14). The formulation of isoquercetin or quercetin with ascorbic acid (500 mg) to prevent oxidation did not alter pharmacokinetic profiles. Significant PDI inhibitory activity in plasma was detected following the ingestion of isoquercetin but not quercetin. The PDI inhibitory activity in plasma increased significantly by 4 h following the oral administration of isoquercetin ($P = 0.001$) with a mean difference of 59% relative to baseline. By 6 h, the mean PDI inhibitory activity neared baseline values (mean difference of 16% compared to baseline).

Conclusions: These studies provide proof-of-principle for the use of quercetins to inhibit extracellular PDI in humans and represent an important first step in the development of a novel class of antithrombotic agents. We conclude that oral isoquercetin has improved bioavailability compared with quercetin in healthy adults and results in detectable PDI inhibition as measured by a novel plasma based PDI assay. The antithrombotic efficacy of isoquercetin will be evaluated in cancer-associated thrombosis for high risk cancer populations and in individuals with antiphospholipid syndrome.

OC 16.4

Aptamer inhibition of an exosite of Factor (F)Xa or thrombin synergizes with non-aptamer inhibition of the catalytic site of FXa or thrombin, respectively

Frederiksen JW[1], Lohrmann J[2], Bompiani KM[3], Smock-Woodruff RBS[1], Gunaratne RBA[1] and Sullenger BA[1]
[1]*Duke University, Durham, NC, USA;* [2]*University of Freiburg, Freiburg, Germany;* [3]*Scripps Institute, San Diego, CA, USA*

Background: Aptamers that inhibit factor (F)Xa and thrombin function as reversible anticoagulants but achieve less intense anticoagula-

tion than recombinant (r)-tick anticoagulant peptide (TAP), r-hirudin, or heparin. 11F7t, an RNA FXa aptamer, binds a FXa exosite in a manner that inhibits FXa-FVa binding. ARC 183, a DNA thrombin aptamer, and R9D-14T, an RNA thrombin aptamer, each bind thrombin's substrate binding exosite, thereby inhibiting thrombin-substrate binding. In contrast, r-TAP and r-hirudin inhibit FXa and thrombin, respectively, by binding both an exosite and the catalytic site of FXa or thrombin, respectively. Those findings suggest that a univalent catalytic site inhibitor of FXa or thrombin might augment the anticoagulant intensity of an exosite-binding aptamer.

Aims: To test two hypotheses: (1) 11F7t plus a FXa catalytic site inhibitor will synergize; and (2) ARC183 or R9D-14T plus a thrombin catalytic site inhibitor will synergize.

Methods: One hundred and eighty-minute (min) whole blood thromboelastography (TEG) assays.

Results: r-TAP (2.0 μM), r-hirudin (3.67 μM), or heparin (5 U/mL) prevented clot initiation for > 180 min in whole blood TEG assays. The aptamers 11F7t (4.0 μM), ARC 183 (7.5 μM), and R9D-14T (10.0 μM), the small molecule FXa direct catalytic site inhibitors PRT54004 (10.0 μM), rivaroxaban (7.5 μM), and edoxaban (7.5 μM), the FXa indirect catalytic site inhibitor fondaparinux (4.63 μM), or the small molecule thrombin direct catalytic site inhibitor argatroban (98.3 μM) only prolonged clot initiation time to between 14 and 147 min (~2 to ~20 times control). In contrast, the combinations 11F7t (0.5 μM) plus PRT54004 (2.0 μM), 11F7t (2.0 μM) plus rivaroxaban (5.0 μM), 11F7t (2.0 μM) plus edoxaban (2.0 μM), 11F7t (0.5 μM) plus fondaparinux (1.16 μM), ARC 183 (5.0 μM) plus argatroban (5.0 μM), and R9D-14T (10.0 μM) plus argatroban (10.0 μM) each prevented clot initiation for > 180 min.

Summary/Conclusion: A FXa or thrombin aptamer plus a FXa or thrombin catalytic site inhibitor, respectively, synergize to anticoagulate whole blood. A FXa or thrombin catalytic site inhibitor may intensify the reversible anticoagulant effect of a FXa or thrombin aptamer in a clinical setting, such as cardiopulmonary bypass, that requires a high level of anticoagulation.

OC 17 – Clinical Relevance of Microparticles

OC 17.1

Circulating microparticles and thrombin generation phenotypes in the Prospective Observational Multicenter Major Trauma Transfusion (PROMMTT) study: correlation with coagulopathy and survival

Matijevic N[1], Wang YW[1], Holcomb JB[1], Cotton BA[1], Wade CE[1], Schreiber MA[2], Muscat P[3], Myers JG[4] and Cohen MJ[5]

[1]The University of Texas Health Science Center at Houston, Houston, TX; [2]Oregon Health and Science University, Portland, OR; [3]University of Cincinnati, Cincinnati, OH; [4]UTHSC, San Antonio, TX; [5]University of California, San Francisco, CA, USA

Background: Trauma-induced coagulopathy (TIC) following severe injury and shock is associated with increased bleeding, morbidity, and mortality. Severe injury may result in alteration of cellular phenotypes and release of cell-derived, procoagulant microparticles (MP). Circulating MPs are predominantly of platelet origin and support thrombin generation (TG) and clotting.

Aims: We hypothesized that trauma patients requiring transfusion would have different MP and TG phenotypes than controls, and these differences would be attenuated in TIC and non-survivors.

Methods: The PROMMTT study enrolled 1245 acute trauma patients at ten major level 1 USA trauma centers, of which 196 had blood samples collected for cellular and TG studies. The study was approved by the Institutional Review Boards and by the United States Army Human Research Protection Office. Blood samples were collected at hospital admission. Twenty normal subjects were analyzed for comparisons. Samples were analyzed by the Calibrated Automated Thrombogram to assess TG, and by flow cytometry for MP counts and cellular origin using marker-specific antibodies for platelets (PMP, CD41, CD62P), leukocytes (LMP, CD45), erythrocytes (RMP, CD235a), endothelial cells (EMP, CD51, CD146), tissue factor (TFMP, CD142), and Annexin V (AVMP). These data were analyzed with comprehensive demographic, injury, outcome, and other PROMMTT clinical data. Coagulopathy was defined as either INR ≥ 1.3 or APTT ≥ 35 s.

Results: The median cohort age was 41 (±18.7), 74% were male, Injury Severity Score was 26 (IQR 17, 34). Coagulopathy was noted in 41.6% by INR and 20.5% by APTT criteria. Admission endogenous thrombin potential (nM thrombin*min), thrombin peak (nM) and TG rate (nM/min) were significantly higher in study patients compared to controls (1539, 358, 247 vs. 1184, 208, 61, respectively; all $P < 0.001$). Flow cytometry revealed significant differences in both the MP counts/μL and their relative phenotypic distributions between patients and controls. Study patient EMP levels were 20-fold higher compared to controls (473 vs. 23, $P < 0.001$). RMP, LMP, and TFMP were also higher (407, 362, 181 vs. 197, 185, 67, respectively; $P < 0.001$).

INR-defined coagulopathic patients had significantly lower thrombin peak, TG rate, AVMP and PMP levels (314, 201, 1900, 1762 vs. 384, 272, 2616, 2326, respectively; all $P < 0.01$) compared to non-coagulopathic patients. APTT-defined coagulopathic patients additionally had significantly longer TG lag time, and a lower TFMP (57 vs. 206, $P < 0.001$).

When analyzed by the outcome, patients who died within 24 h of admission had significantly lower thrombin peak (321 vs. 364, $P < 0.01$), TG rate (199 vs. 256; $P < 0.02$), and AVMP, PMP, RMP, and TFMP compared to survivors (1962, 1732, 234, 112 vs. 2432, 2196, 434, 197, all $P < 0.01$). Patients who died within 12 h had the lowest thrombin peak (304) and PMP (1613).

Conclusion: Severe injury results in a significant endothelial activation and increased circulating cell-derived microparticles and thrombin generation. However, a combination of elevated EMP, lower PMP, RMP and TFMP, and lower TG correlates with coagulopathy and poor outcome at 24 h, offering the possibility of indices for interventions.

OC 17.2

Microparticle-dependent plasmin generation predicts the outcome of septic shock patients

Lacroix R[1], Harti Souab K[2], Cointe S[1], Bouriche T[3], Judicone C[3], Frankel D[1], Poncelet PH[3], Albanese J[2] and Dignat-George F[2]

[1]Aix-Marseille University/ INSERM; [2]CHU La Conception, APHM; [3]BioCytex, Marseille, France

Background: Septic shock (SS) occurs in 10 to 20% of patients in intensive care unit with a high mortality rate (30–50%). It is a systemic response to an infection associated with an hypotension resistant to vasoactive molecules and organ failures. The mechanisms imply a leucocytes and vascular inflammatory response associated with activation of the coagulation and abnormal fibrinolysis. Cellular activation is closely related to the vesiculation process which results in the release of microparticles (MP) from membranes. Over the past decades the role of these small vesicles in activation of the clotting cascade has been well recognized. High level of circulating leukocyte-derived MP (LeuMP) have been reported in SS. Moreover, we recently demonstrated that LeuMP support a plasmin generation capacity (MP-PGC) sustaining a fibrinolytic activity in the circulation.

Aims: Therefore, we hypothesized that MP-PGC is vectorized by MP in SS patients and counterbalances the risk of micro-thrombosis in those with a favorable outcome.

Methods: Thirty-two patients with proved SS were included in the study. All informed consents were obtained and the study was

approved by a local medical ethics committee. Patients outcome was recorded at 30 days. Consistent with the literature the mortality was 37%. MP were purified from SS plasma samples and characterized for plasminogen activators content, activity and cellular origin using chromogenic test, zymography, ELISA, flow cytometry and selective depletions. A new immuno-magnetic separation (IMS)-based bioassay was developed and validated to reproducibly measure the MP-PGC in plasma samples. MP-PGC was measured within the first 24 h after diagnosis on platelet free plasma of SS patients.

Results: Plasmin generation was found on MP purified from SS plasma. This MP-PGC was dependent on a C-terminal lysine binding of plasminogen and the expression of the uPA-uPAR system on the MP surface. LeuMP from granulocyte origin (CD15+) were the major MP subpopulation supporting this activity. Using a new and sensitive IMS-based method, we found that MP-PGC of healthy donors was 4.5 ± 2.8 mDO/min, $n = 20$. In contrast, SS patients showed heterogeneous profile of MP-PGC varying from 0.3 to 600 mDO/min. Interestingly, we observed significant lower MP-PGC values in the patients who died compared to those who survived (median [25–75% interquartile range] = 1.41 [0.89–2.33] mDO/min vs 3.82 [1.84–8.53] mDO/min, respectively, $P = 0.0017$). Thus, among patients with MP-PGC values above 1.65 mDO/min, 85% survived while 75% of patients with MP-PGC below this cut-off value died.

Summary/Conclusion: We demonstrated that MP-PGC is supported by circulating LeuMP in SS patients and predicts the outcome of SS patients. High MP-PGC was associated with survival suggesting that MP dependent fibrinolytic activity may counterbalances the systemic pro-coagulant state found in SS. Thus, MP-PGC not only provides clues for a more comprehensive view on the role of MP in the haemostatic equilibrium but also puts forward the basis for a potential new biomarker that needs to be evaluated on a larger scale.

OC 17.3

Characterization of microparticle numbers and cellular origin in human endotoxemia using high-sensitivity flow cytometry

Mooberry MJ[1], Bradford RL[1], Lin FC[1], Jilma B[2] and Key NS[1]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; [2]Medical University of Vienna, Vienna, Austria

The processes of inflammation and coagulation are intimately linked. The interplay of these two systems may be pertinent to a variety of disease states, such as sepsis and sickle cell disease. Endotoxemia causes an acute systemic inflammatory response with concurrent activation of coagulation. Circulating microparticles (MPs), particularly those bearing tissue factor (TF^+-MPs), have been studied using this model, where it has been shown that MP-TF activity increases acutely after intravenous endotoxin administration. To date, however, there are no comprehensive data documenting changes in total MP numbers and sub-sets according to cellular origin. We hypothesized that total MP numbers detected by flow cytometry would increase in parallel with MP-TF activity in the endotoxemia model, and that the magnitude of this increase would vary by cellular origin. To test this hypothesis, 16 healthy individuals were infused with LPS (4 ng/kg body weight) and blood samples were collected in 3.2% sodium citrate at four time points (pre-, 3-, 6- and 24 h post- infusion). Platelet free plasma (PFP) was obtained by two sequential centrifugations at 2500 $\boldsymbol{g} \times 15$ min, and aliquots were frozen at −80°C until analysis. MP-TF activity was determined using an in-house chromogenic assay detecting TF-dependent Xa generation on the MP fraction of plasma as previously described. MP enumeration and characterization was performed on a high-sensitivity flow cytometer (Stratedigm S1000Ex) using an MP size gate of 0.2–0.9 μm by polystyrene bead equivalents. Within the MP gate, total MPs were defined as Annexin+, platelet MPs (PMPs) as CD41+/Annexin+, monocyte MPs (MMPs) as CD14+/Annexin+, RBC MPs (RMPs) as CD235+/Annexin+, and endothelial MPs (EMPs) as CD31+/CD41- events. Circulating nucleosomes (DNA-histone complexes) were also measured using a commercial ELISA kit (Roche). As previously reported, MP-TF activity increased from baseline with a peak at 3 h (baseline: 0.06 ± 0.01 pg/mL; 3 h: 0.51 ± 0.05, $P < 0.001$; 6 h: 0.47 ± 0.06, $P < 0.001$; mean ± SEM). Increases in circulating nucleosomes paralleled that observed with MP-TF activity, peaking at 3 h and returning to baseline by 24 h (3 h: 1.4 ± 0.12-fold increase, $P = 0.001$; 6 h: 1.4 ± 0.12-fold increase, $P = 0.004$; mean ± SEM). The number of MPs generally peaked later at 6 h and was significant for total MPs (baseline: 677 [317, 1432]; 6 h: 1287 [694, 2952], $P = 0.046$; median [IQR]), RMPs (3 h: 155 [85, 377]; 6 h: 275 [157, 611], $P = 0.046$) and PMPs (baseline: 94 [77, 176]; 6 h: 232 [137, 966], $P = 0.046$). Similar increases were noted for MMPs (baseline: 78 [44, 245]; 6 h: 121 [72, 243], $P = 0.317$) but did not reach significance. No significant changes were noted for EMP numbers. Together these data further characterize the pathophysiologic processes observed in the human endotoxemia model and are the first comprehensive analysis of MPs utilizing high-sensitivity flow cytometry. This is also the first description of an acute increase in nucleosomes following endotoxin exposure to our knowledge, which may be clinically relevant in inflammatory disorders with thrombotic risk given their recently discovered association with activation of coagulation and thrombus formation.

OC 17.4

Microparticle-associated tissue factor activity is associated with disease severity in patients with E. coli urosepsis

Woei-A-Jin FJSH[1], Van der Starre E[2], Tesselaar ET[3], Garcia Rodriguez P[4], Van Nieuwkoop C[2], Bertina RM[5], Van Dissel T[2] and Osanto S[4]

[1]Leiden University Medical Center; [2]Department of Infectious Diseases, Leiden University Medical Center, Leiden; [3]Department of Medical Oncology, the Netherlands Cancer Institute, Amsterdam; [4]Department of Clinical Oncology, Leiden University Medical Center; [5]Einthoven Laboratory for Experimental Vascular Medicine, LUMC, Leiden, the Netherlands

Background: Blood microparticles may serve as highly mobile carriers of pro-inflammatory mediators and procoagulant proteins. Microparticles expressing tissue factor (MP-TF) are of special interest. Tissue factor (TF) is thought to play an important role in sepsis and inhibition of TF in primates attenuates disease morbidity and mortality. In a kinetic study of healthy volunteers challenged with purified *E. coli* lipopolysaccharide, we demonstrated that microparticles bearing active TF are concurrently released with markers of inflammation. Interestingly, the subject with the most prominent clinical response to endotoxin also had the highest MP-TF activity. We hypothesized that inflammatory conditions caused by an intact pathogen similarly induces shedding of MP-TF.

Aim: We investigated whether MP-TF activity correlated with disease severity and bacteraemia in a large patient cohort with *E. coli* urosepsis. In addition, we examined whether MP-TF activity decreased upon improvement of the infection and explored the relation of MP-TF activity with blood monocyte count, procalcitonin (a marker for bacterial infection) and markers of endothelial activation.

Methods: During a five-year period, we enrolled 215 consecutive patients without relevant comorbidity presenting with culture proven community-acquired *E. coli* urosepsis at the emergency departments of seven hospitals and affiliated primary healthcare centers. Patients provided informed consent and the study was approved by the medical ethics committees of all participating centers. Cultures of blood and urine were available for all patients. We measured MP-TF activity, sE-selectin, sVCAM-1, monocyte count and procalcitonin in blood collected immediately upon admission, and determined APACHE II disease severity scores. All patients received antibiotic treatment and MP-TF activity was again measured on day 3.

Results: Median MP-TF activity in the 215 septic patients (mean age 51 years, 73% female) was higher than in healthy controls (125 vs. 50 fM Xa/min; $P < 0.0001$), and was the highest in the 48 bacteraemic patients (206 fM Xa/min). Median MP-TF activity was significantly higher in all APACHE II disease severity score categories > 4 compared to the lowest category (299 fM Xa/min for 15–17, 164 fM Xa/min for 10–14, 144 fM Xa/min for 5–9, and 97 fM Xa/min for 0–4 scores; all P-values < 0.01). Furthermore, MP-TF activity decreased during antibiotic treatment from a median value of 116 at admission to 82 fM Xa/min on day 3. MP-TF activity upon inclusion correlated significantly, but weakly with markers of endothelial activation ($r = 0.28$ and 0.30 for sE-selectin and sVCAM-1, respectively; $P < 0.0001$) and showed an inverse correlation with monocyte count ($r = 0.23$; $P = 0.0142$). Moreover, MP-TF activity correlated with procalcitonin levels ($r = 0.35$; $P < 0.0001$).
Conclusion: In this large cohort of urosepsis patients reflecting daily clinical practice, we showed that MP-TF activity is related to disease severity and bacteraemia in patients with *E. coli* urosepsis. MP-TF activity correlated to procalcitonin, and decreased upon resolution of the infection (day 3). We speculate that monocytes are the source of MP-TF and that sE-selectin and sVCAM-1 reflect disease severity rather than an endothelial origin of MP-TF.

OC 18 – Coagulation Factors XI and XII

OC 18.1

APC-resistant factor V restores impaired coagulation resulting from deficient factor XI-mediated feedback activation

Rietveld IM[1], Camire RM[2], Reitsma PH[1] and Bos MHA[1]
[1]*Leiden University Medical Center, Leiden, the Netherlands*
[2]*The Children's Hospital of Philadelphia, Philadelphia, PA, USA*

Background: The positive factor Va/VIIIa/IXa feedback reactions by which thrombin propagates its own production are essential to robust clot formation, which is underscored by the fact that defects or deficiencies therein lead to hemophilia. We have previously demonstrated that these feedback loops are regulated in a highly interdependent manner, as absence of the factor VIII/IX-dependent feedback results in premature inactivation of factor V (FV) by activated protein C (APC). Interestingly, APC-resistant FV was shown to have the potential of counterbalancing this secondary defect by impairing the APC system and correcting thrombin generation.
Aim: Here we examined whether the factor XI (FXI)-mediated feedback loop is also tightly linked to FV regulation by assessing if APC-resistant FV can overcome the attenuated coagulation in FXI deficiency.
Methods: Constitutively active FV-810 (Pro811-Gy1491 deleted) and FV-810-QQ, in which the main APC cleavage sites Arg306 and Arg506 are substituted by Gln, were expressed and purified. Coagulation was initiated by low tissue factor, and thrombin activity and tPA-induced fibrinolysis were assessed.
Results: Consistent with its bleeding phenotype, thrombin generation was reduced in FXI deficiency. Surprisingly, whereas triggering the protein C pathway by adding thrombomodulin (TM, 10 nM) or APC (2 nM) partially reduced thrombin formation in normal plasma, thrombin production became fully abolished in FXI-deficient plasma. This suggests that, similar to deficiencies in the FVIII/FIX-dependent feedback loops, a lack of FXI activity renders the plasma more sensitive to the APC system. APC-resistant FV could counterbalance this defect, as addition of FV-810-QQ (1 U/mL) increased thrombin formation substantially in FXI-deficient plasma, whereas FV-810 had no effect. In a clot lysis assay, addition of increasing TM concentrations (0–10 nM) confirmed enhanced sensitivity to the APC system as clot formation was severely prolonged in FXI-deficient plasma (40 min. vs. 5–6 min. in normal plasma). Even though fibrinolysis was inhibited by TM-mediated thrombin-activatable fibrinolysis inhibitor (TAFI) activation in both plasmas, the maximum inhibition attained in FXI deficiency was much lower as compared to normal, concurring with previous observations. Subsequent supplementation with FV showed that, being constitutively active, both variants normalized the clot time in FXI-deficient plasma. Clot lysis times, on the other hand, were fully restored upon adding FV-810-QQ to plasma lacking FXI activity; addition of FV-810 showed no effect in both plasmas. This implies that APC-resistant FV may contribute to enhanced TAFI activation, thereby bypassing the need for upstream feedback activation reactions. This was supported by assessing the clot lysis time using varying concentrations of a TAFI inhibitor (carboxypeptidase inhibitor), which demonstrated that supplementation of FXI-deficient plasma with FV-810-QQ increased activated TAFI to the level of normal plasma.
Conclusions: These data show that similar to deficiencies in the FVIII/FIX-dependent feedback loop, a defect in the thrombin-mediated FXI activation pathway leads to a dramatic reduction in thrombin formation due to action of the protein C pathway. Whereas constitutively active normal FV can partially restore impaired coagulation, its APC-resistant counterpart has the potential of rescuing both clot formation and stability, thereby providing a potential alternative for hemophilia treatment.

OC 18.2

Two novel inhibiting factor XI antibodies prevent cessation of blood flow in a murine venous thrombosis model

Van Montfoort ML[1], Knaup VL[1], Marquart A[1], Bakhtiari K[1], Castellino FJ[2], Hack E[3] and Meijers JC[4]
[1]*Academic Medical Center, Amsterdam, the Netherlands;* [2]*W.M. Keck center for Transgene Research, Notre Dame, IN, USA;* [3]*UMCU, Utrecht;* [4]*Academic Medical Center Amsterdam, Amsterdam, the Netherlands*

Background: Coagulation factor XI is a potential target for anticoagulation. Factor XI seems promising because of its major role in thrombosis and relatively minor role in hemostasis. This might imply that inhibition of factor XI can prevent thrombosis without causing bleeding.
Aim: To investigate the antithrombotic properties of two novel inhibiting factor XI antibodies (αFXI-175 and αFXI-203).
Methods: The *in vitro* properties of both antibodies were analyzed using standard clotting assays (PT/aPTT) and calibrated automated thrombography. For the *in vivo* model we used factor XI knock out mice on a C57BL/6 background, in which factor XI plasma levels were restored with purified human factor XI. Thrombosis was induced by applying a 10% ferric chloride solution to the vena cava inferior for 3 min. Time to occlusion was analyzed with a tissue perfusion monitor. A tail bleeding assay was used to investigate the safety of both antibodies.
Results: Both antibodies dose-dependently prolonged coagulation in normal plasma in the aPTT. Using calibrated automated thrombography, both antibodies inhibited thrombin generation initiated via the intrinsic pathway. In contrast, upon tissue factor (TF)-initiated thrombin generation, αFXI-203 did not inhibit thrombin generation, while αFXI-175 was only able to inhibit thrombin generation at low concentrations of TF (up to 1 pM). The vena cava inferior remained patent for 25 min in mice treated with αFXI-175 and for 12.5 min in αFXI-203 treated animals, which was significantly longer than in placebo treated animals (5 min, $P < 0.05$). Both antibodies did not prolong the bleeding time or caused severe blood loss in a tail bleeding assay.
Conclusions: Two inhibitory antibodies against factor XI were generated with different specificities. Both antibodies prevented cessation of blood flow in a murine thrombosis model without inducing a bleeding tendency.

OC 18.3

Factor XI acts by mechanisms at least partially independent of thrombin-induced platelet activation in a mouse model of arterial thrombosis

David T[1], Concengo C[1], Wang L[1], Ha D[1], Cornelissen I[1], Flick MJ[2], Degen JL[2] and Coughlin SR[1]

[1]UCSF, San Francisco, CA; [2]Cincinnati Children's Hospital – Cancer and Blood Diseases Institute, Cincinnati, OH, USA

Background: Factor XI (FXI) is a coagulation factor that can be activated by Factor XIIa (contact pathway) to trigger coagulation and thrombin generation. FXI can also be activated by thrombin as part of a positive feedback loop. Once generated, thrombin cleaves fibrinogen and protease-activated receptors (PARs) to form fibrin and activate platelets, respectively. Fibrin and activated platelets together form a thrombus. FXI-deficient patients and mice exhibit little or no spontaneous bleeding, but appear to be protected against some forms of thrombosis.

Aims/Methods: The primary objective of these studies was to understand the mechanism(s) by which Factor XI deficiency is protective against thrombosis without significantly impairing hemostasis. More specifically, we employed mouse genetics to explore whether there are differential actions of FXI on platelet activation and fibrin formation in the settings of hemostasis and thrombosis.

Results: FXI knockout mice showed no spontaneously bleeding or increased blood loss in a tail bleeding assay, but exhibited remarkable protection in an arterial thrombosis model (2.8 M $FeCl_3$-induced carotid injury). Par4 knockout mice, which have platelets that show no responses to thrombin, showed increased tail blood loss but only modest protection against thrombosis under the same conditions. Mice lacking both Par4 and Factor XI were indistinguishable from mice lacking only Factor XI in our arterial thrombosis model and indistinguishable from Par4 knockouts in the tail blood loss assay. Thus, Factor XI contributes to arterial thrombosis in a manner that is at least partially independent of Par4 and platelet activation by thrombin. Furthermore, Factor XI function appears to be unnecessary in a mouse model of hemostasis even in a sensitized setting in which thrombin-mediated platelet activation has been eliminated.

Thrombin-dependent fibrin formation is an obvious candidate for the platelet-independent role of Factors XI in the thrombosis model. FibAαEK mice carry a mutant form of fibrinogen that cannot be converted to fibrin but fully support platelet aggregation. Preliminary data suggest that the fibrinogen-AαEK variant can support hemostasis and that the FibAαEK mice are comparable to control littermates in the carotid thrombosis under the conditions employed above. While fibrin formation may not be strictly required for hemostasis or arterial thrombosis, it is possible that fibrin formation will be required in the setting of Par4 deficiency and defective platelet activation, and that loss of both fibrin formation and platelet activation due to decreased thrombin generation will account for the dramatic protection seen in FXI-deficient mice. Alternatively, FXI may contribute to hemostasis and thrombosis by mechanisms independent of thrombin generation and thrombin-dependent fibrin formation and platelet activation.

Conclusion: Protection of Factor XI-deficient mice in a model of arterial thrombosis is at least partially independent of thrombin-induced platelet activation. To assess the possibility that fibrin formation accounts for this activity, a comparison of FXI deficient mice to *Par4*:*FibAαEK* and *FXI:FibAαEK* double mutant mice and to mice treated with inhibitors of thrombin generation is in progress.

OC 18.4

A model for binding of factor IX to the factor XIa apple 3 domain

Gailani D[1], Geng Y[1], Verhamme IM[1], Sun MF[1], Bajaj P[2] and Emsley J[3]

[1]Vanderbilt University, Nashville, TN; [2]University of California – Los Angeles, Los Angeles, CA, USA; [3]University of Nottingham, Nottingham, UK

Background: Factor XIa (fXIa) cleaves factor IX (fIX) at the Arg^{145}-Ala^{146} bond to form the intermediate factor IXα (fIXα), and then at the Arg^{180}-Val^{181} bond, to form the protease factor IXaβ (fIXaβ). As catalytic efficiency for Arg^{180}-Val^{181} cleavage is seven-fold greater than Arg^{145}-Ala^{146} cleavage, fIXα does not accumulate. A fIX binding exosite on the fXIa A3 domain is central to this mechanism. The fIX Gla-domain is also required for fIX activation by fXIa, and may be the structural element that binds to fXIa.

Aims: To identify structures on the fXIa A3 domain and fIX Gla-domain involved in fIX activation by fXIa.

Methods: Wild type fXIa ($fXIa^{WT}$), fXIa with the A3 domain (amino acids 182–265) replaced with the prekallikrein A3 domain (fXIa-PKA3), and fXIa with alanine substitutions for amino acids 183–185 ($fXIa\text{-}Ala^{183\text{-}185}$) were expressed in HEK293 fibroblasts. FXIa-PKA3 was used as a scaffold to reintroduce fXI sequence into PKA3 to determine the minimal number of fXIa residues needed for restoration of fIX activation. FIX molecules with segments of the Gla-domain replaced with factor VII sequence were also expressed. The fXIa proteases were tested for their ability to activate recombinant and plasma fIX.

Results: FXIa-PKA3 cleaves the fIX Arg^{145}-Ala^{146} and Arg^{180}-Val^{181} bonds with 60- and 4500-fold lower catalytic efficiency, respectively, than $fXIa^{WT}$, due to loss of the fIX/fIXα binding site on the A3 domain. $FXIa\text{-}Ala^{183\text{-}185}$ displayed a comparable defect, indicating residues 183–185 are required for exosite function. Residues 183–185 are at the N-terminus of the A3 domain, and contribute to formation of a charged patch and hydrophobic pocket on the A3 surface. Replacing PK residues at positions 183–185 in fXIa-PKA3 with the corresponding fXIa residues partially restored fIX activation (~5% activity of fXIaWT). The N- and C-termini of A3 are in proximity due to the Cys^{182}-Cys^{265} bond at the ends of the domain. Introducing fXI residues at the C-terminus of fXIa-PKA3 (residues 260–264), in addition to fXI sequence at 183–185, completely restored fIX activation. Replacement of fIX Gla-domain residues 4–11 (the Ω-loop) with the corresponding sequence from factor VII resulted in a defect in activation by $fXIa^{WT}$ similar to the one observed when fXIa-PKA3 activates fIX.

Summary/Conclusion: Amino acids 183–185, and 260–264 are closely associated in fXIa, and contribute to formation of charged and hydrophobic regions on the A3 domain surface that are not predicted to be present in the prekallikrein A3 domain. These structures likely form a fIX binding site on fXIa. The protease domain in zymogen fXI covers this region of A3, consistent with the observation that fIX does not bind to the zymogen. Conformational changes that occur during fXI conversion to fXIa must expose this area to permit fIX binding. Binding of the fIX Gla-domain through its Ω-loop to phosphatidylserine-rich surfaces contributes to K_m for fIX activation by factor VIIa-tissue factor. The fIX Ω-loop may mediate a similar interaction with the fXIa A3 domain that is required for initial recognition of fIX by fXIa.

Circulating histone-induced thrombosis leads to circulatory and respiratory failure

Abrams ST[1], Manson J[2], Liu T[1], Alhamdi Y[1], Brohi K[2], Wang G[1] and Toh CH[1]

[1]*University of Liverpool, Liverpool;* [2]*Queen Mary University of London, London, UK*

Background: Extensive cell damage associated with coagulation activation and the development of circulatory and respiratory failure are common features in critically illness but the underlying pathophysiological mechanisms remain unclear. During cell death, nuclear proteins and histones in particular, are released into the circulation and cause toxicity through thrombin generation, platelet aggregation, endothelial damage and cytokine release. This recent discovery may increase the understanding of the fundamental pathologies of critical illness and deliver improved patient management approaches for these unmet health challenges.
Aim: Investigate the hypothesis that extracellular histones serve as mediators of distant organ damage after extensive cell death.
Methods: To investigate this further, we used *in vivo* experimental models and clinical samples from patients with severe non-thoracic trauma.
Results: Cytokines and markers for endothelial damage (sTM) and coagulation activation (TAT) significantly increased immediately after trauma or histone-infusion in mice. Cardiac function was impaired in histone-infused mice with increased pulmonary pressure and right ventricular size. Pathological examination showed that lungs were the predominantly affected organ with severe edema, multicocal alveolar hemorrhage, microvascular thrombosis and neutrophil congestion. Histone treated mice developed dyspnea and cyanosis as a manifestation of pulmonary and cardiac failure and died within 2 h. Pathological changes and mortality could be prevented by anti-histone antibodies. Clinically, circulating histone levels surged significantly immediately after injury to levels that were toxic to cultured endothelial cells ($\geq$ 50 μg/mL). The high levels were significantly associated with the incidence of acute respiratory failure and SOFA scores, as well as sTM (median: 4.6, quartile: 3.6, 5.5 ng/mL) and TAT levels (median: 81.2, quartile: 33.7, 110.3 ng/mL).
Conclusions: This work has elucidated a new mechanism for multiple organ failure in critically ill patients and proposes future translational intervention with rapid assays to monitor circulating histone levels and anti-histone therapies to reduce thrombosis and improve the pulmonary microcirculation. Overall, anti-histone therapy could potentially protect against the development of multi-organ failure and improve overall outcome in many critical illnesses.

OC 19.2

An essential role of factor XI-feedback activation for hemostasis in embryonic development

Jämsä A[1], Spronk HMH[2], Govers-Riemslag JWP[2], Knetsch ML[3], Gailani D[4], Mackman N[5] and Renné T[1]

[1]*Karolinska Institutet, Stockholm, Sweden;* [2]*Maastricht University Medical Center, Maastricht;* [3]*Maastricht University, Maastricht, the Netherlands;* [4]*Vanderbilt University, Nashville, TN;* [5]*University of North Carolina at Chapel Hill, Chapell Hill, NC, USA*

Background: The classical cascade model of plasma coagulation proposes that activated factor XII initiates thrombin formation via activation of its substrate factor XI (FXI). Recent studies have shown that factor XII-mediated FXI activation has a crucial role for thrombosis in mouse models. In contrast, the revised model of coagulation proposes that FXI is predominantly activated by thrombin, which is generated upon activation of the tissue factor pathway (feedback activation). This concept, however, has poorly been tested *in vivo*.
Aims: Our studies analyze the concept of FXI-feedback activation in plasma and in genetically altered mice.
Methods and Results: Minute amounts of particle-bound thrombin triggered thrombin production in plasma both in the absence of tissue factor and in the presence of active site inhibited factor VIIa. Thrombin did not activate factor XII and thrombin generation was nearly abolished by an anti-FXIa antibody and in FXI-deficient plasma. Surface bound thrombin induced complex formation of FXI, with its major inhibitor C1 inhibitor, even in factor XII-deficient plasma. To analyze functions of FXI-feedback activation *in vivo* we crossed tissue factor-deficient mice (low tissue factor) with mice deficient in the intrinsic pathway proteases factors IX, XI and XII, respectively. Factor IX null mice have a bleeding phenotype (hemophilia B), whereas FXI and factor XII deficient mice have a normal hemostatic capacity. Combined deficiency in tissue factor and factor IX resulted in the intrauterine death of embryos due to hemorrhage. In contrast, factor XII/tissue factor-deficient mice were viable and their bleeding phenotype was unchanged as compared to deficiency in tissue factor alone. Unexpectedly and in contrast to factor XII/tissue factor-deficiency phenotype, combined deficiency in FXI/tissue factor was lethal. Less than 5% of expected offspring with deficiency in both factors were born alive. At late developmental stages FXI/tissue factor-deficient embryos were found in the Mendelian distribution range, indicating that most embryos died during delivery. Morphological and histological analysis of these embryos revealed normal growth but hyperemia in livers, edema and fibrin deposition in hearts and frequent hemorrhages in abdominal or thoracic cavities and in placentas.
Conclusions: Our studies show that FXI-feedback activation exists *in vivo* and support a crucial role of this pathway for hemostasis in neonatal development.

Whole blood minimal tissue factor triggered thrombelastometry and calibrated automated thrombogramme are useful tools for the evaluation of the global effect of antithrombotic treatment

Gerotziafas T[1], Benziane O[1], Hatmi N[1], Ketatni K[1], Galea V[1], Samama C[2] and Elalamy I[1]

[1]*Tenon University Hospital;* [2]*Service d'Hématologie Biologique Hôpital Hôtel Dieu, Paris, France*

Background: Routine blood coagulation tests (PT and aPTT) and the anti-Xa activity evaluate a partial aspect of the global antithrombotic activity of the anticoagulant drugs and are used for the monitoring of treatment with VKA, UFH and LMWHs. Thromboelastometry and thrombogramme are performed in more physiologically relevant conditions in the presence of low TF concentration and might offer additional information for the global anticoagulant effect of the anticoagulant agents.
Aim of the Study: We investigated the sensitivity of whole blood thromboelastometry and thrombin generation (TG) assay to detect the effect of LMWH or VKA treatment.
Materials and Methods: Patients receiving prophylaxis (n = 100) or treatment (n = 50) with enoxaparin or VKA (n = 100) were studied. Minimal TF-TEM in whole blood (WBminTF-TEM) was performed according to previously published method. TG was done in PPP prepared from the same WB samples and assessed with Thrombinoscope assay. For patients receiving enoxaparin the dose, time of injection and blood collection were recorded. The anti-Xa activity in PPP and the INR were also measured. The control group (n = 40) consisted of healthy individuals with normal PT and aPTT. The upper and lower normal limit (in the control group – UNL/LNL) and upper and lower

therapeutic limit for each group of treated patients and the inter-individual variability of the response (iCV) was calculated for each assay.
Results: Table 1 shows the values of WBminTF-TEM and TG parameters in the control group and in the patients' groups. Both tests were sensitive to the anticoagulant effect of the studied drugs. Enoxaparin induced dose-dependent alterations on both assays. Treatment with LMWH or VKA induced similar modifications on both assays. For each assay the iCV range was 6–30% in the control group, 11–45% in LMWHprophylaxis group, 25–80% in LMWHtreatment group and 9–79% in VKA group. In 10% of patients no modification of thromboelastogram or thrombogram was observed although the anti-Xa activity or INR were within the expected range.
Conclusion: WBminTG-TEM and TG are global coagulation assay sensitive to detect the anticoagulant effect of prophylactic and therapeutic doses of LMWH and that of treatment with VKA. Both assays demonstrate the presence of a variable biological response to the treatment which is not predicted by the levels of the anti-Xa activity and the INR.

OC 19.4

Human VKORC1 mutations (His28Gln, Trp59Leu, Val66Met) investigated by the new cell-based assay exhibit warfarin resistance phenotypes not detected by the 'classical' DTT-driven VKOR assay

Czogalla KJ, Watzka M, Wendeln AC, Bevans C, Liphardt K, Westhofen P and Oldenburg J

Instiute for Experimental Haematology and Transfusionmedicine, Bonn, Germany

Background: Coumarins are globally used as oral anticoagulants for prevention and therapy of thrombosis and embolism since the early 1950s. However, clinical use of coumarins is difficult due to risk of bleeding and high interindividual dose variation including coumarin resistance. In most cases, oral anticoagulant resistance (OACR) originates from mutations in the enzyme vitamin K 2,3-epoxide reductase complex subunit 1 (VKORC1), that is the molecular target of coumarins.
Aim: Because investigation of VKORC1 variants by the 'classical' dithiothreitol (DTT)-driven VKOR assay does not reflect patient phenotype well, we used the cell-based assay to study human VKORC1 (hVKORC1) mutations (His28Gln, Trp59Leu, Val66Met). This assay implements coexpression of human coagulation factor IX (hFIX) together with hVKORC1 in HEK293T cells and uses secreted hFIX activity as surrogate marker to report wild-type and variant hVKORC1 inhibition by warfarin.
Methods: hVKORC1 and hFIX cDNA were cloned into a bicistronic vector. Afterwards, OACR-associated hVKORC1 mutations (His28Gln, Trp59Leu, Val66Met) were introduced by site-directed mutagenesis and the respective constructs were transfected into HEK293T cells. The expression medium was supplemented with vitamin K (5 ng/μL) and different concentrations of warfarin (0.01–1 μM). Seventy-two hour after transfection FIX activity was measured.
Results: In the absence of warfarin, basal FIX activities for the coexpressed hVKORC1 variants were similar to that of wild-type hVKORC1 and decreased according to the warfarin concentration. Dose response curves were fitted and half maximal inhibitory concentrations (IC_{50}) for warfarin were calculated for wild-type hVKORC1 as well as for His28Gln, Trp59Leu, and Val66Met hVKORC1 variant (24.7 nM, 71.6 nM, 1857.9 nM, 133.6 nM, respectively).
Conclusion: In contrast to the 'classical' DTT-driven VKOR assay, mutation His28Gln, Trp59Leu, and Val66Met exhibit a warfarin resistance in our cell-based system. Furthermore, calculated IC_{50} values for hVKORC1 variants allow us to rank the severity of the respective mutation. Thus, His28Gln exhibit a mild resistance, Val66Met a moderate resistance and Trp59Leu a total resistance phenotype. Additionally, IC_{50} values for the OACR-associated variants divided by that for wild-type VKORC1 might be a first approximation for increased warfarin dose requirements for patients carrying the mutation *in vivo*. Based on our *in vitro* results, patients bearing His28Gln, Trp59Leu, and Val66Met are expected to require 2.9-, 5.4-, and 75-fold greater mean warfarin dosage in order to achieve the same VKORC1 inhibition levels as patients with wild-type VKORC1. These data correspond well to the clinical phenotype reported for the respective patients.
In conclusion, our results from the cell-based assay accurately reflect *in vivo* OACR patient phenotype. In addition, this assay is a good tool for further studies on VKORC1 function.

OC 20 – Diagnosis of Primary Venous Thrombosis

OC 20.1

Is it useful to image both legs in patients with suspected deep vein thrombosis? A retrospective chart review

Le Gal G[1], Robert-Ebadi H[2], Carrier M[3], Kearon C[4], Bounameaux H[2] and Righini M[2]

[1]Ottawa Health Research Institute, Ottawa, ON, Canada; [2]Geneva University Hospital, Geneva, Switzerland; [3]Ottawa Hospital Research Institute, Ottawa; [4]McMaster University, Hamilton, ON, Canada

Background: Compression ultrasonography (CUS) is the cornerstone of the diagnostic workup in patients with suspected deep vein thrombosis (DVT). However, significant variations exist in clinical practice between centers and/or countries, as highlighted by recent studies comparing single whole-leg to serial proximal ultrasonography. Much less data exist on the need for bilateral leg imaging. Many centers systematically perform a bilateral leg ultrasonography, while imaging is restricted to the symptomatic leg(s) in other centers.
Aims: To assess the yield of bilateral leg ultrasonography in patients with suspected DVT.
Methods: We retrieved the charts of all patients who underwent venous ultrasonography inGeneva University Hospital, Switzerland, between Jan 1, 2009 and Dec 31, 2012. Patients undergoing CUS for another reason than a clinical suspicion of DVT were excluded. For each patient, we extracted information on general demographic information, main risk factors for DVT, clinical probability as assessed by the Wells' score for DVT, side of clinical suspicion, and CUS results. All patients were investigated using bilateral whole-leg CUS.
Results: Out of > 3000 patients referred with suspected DVT, 467 patients (mean age 64 (SD 20) years, female 52%) had proximal or distal DVT confirmed by CUS. Main risk factors were immobilization (32%), cancer (23%), personal history of venous thromboembolism (22%), estrogen use (8%) and family history of venous thromboembolism (8%). DVT was suspected on the left side in 255 (55%), on the right side in 187 (40%), and on both sides in 23 (5%) patients; this information was missing in two patients. A DVT was found only in the symptomatic leg(s) or in one of the two symptomatic legs in 442 patients (95%). In 19 patients (4%), a DVT was found in the asymptomatic leg as well as in the symptomatic leg. Of note, 15 of these 19 patients had cancer, and they represented 14% of cancer patients with DVT. Finally, in four patients (0.9%), CUS was negative on the side of the suspected DVT but positive on the opposite side. All four were below-knee muscular thromboses (three soleal and one gastrocnemial).
Summary/Conclusions: Systematic imaging of both legs in patients with suspected DVT is unnecessary. An examination of the contralateral leg may be worthwhile in cancer patients found to have DVT as this test could be used as a baseline imaging test in case of future suspected DVT in this population with a high risk of recurrent thrombosis.

OC 20.2

Safety of ruling out pulmonary embolism (PE) in pregnancy by computed tomography pulmonary angiography (CTPA)

Nijkeuter M[1], Tan M[2], Middeldorp S[1], Kroft LJM[2], Beenen L[1] and Huisman MV[2]

[1]Academic Medical Center Amsterdam, Amsterdam; [2]Leiden University Medical Center, Leiden, the Netherlands

Background: Pulmonary embolism (PE) is one of the leading causes of maternal mortality. An accurate diagnosis of PE is of critical importance in order to adequately treat diagnosed PE on one hand, and to prevent morbidity and mortality by starting anticoagulant treatment without indication on the other hand. Numerous studies have investigated clinical decision rules, D-dimer and imaging tests in order to establish the most efficient diagnostic algorithm. However, pregnant patients have been systematically excluded from these studies. Clinical decision rules established in non-pregnant patients cannot be applied to pregnant patients since items in these scores are either physiologically more common, e.g. tachycardia, or seldomly present, e.g. malignancy. D-dimer tests as a single-test is advised against in non-pregnant patients and furthermore D-dimer levels rise physiologically during pregnancy accounting for a lower specificity. Objective imaging tests are therefore the cornerstone of diagnosing PE in pregnancy. Prospective studies on the performance of these tests to exclude the diagnosis in pregnancy are lacking.

Aim: To investigate the performance of ruling out PE by CTPA in pregnant patients with a clinical suspicion of PE.

Methods: We performed a prospective study of consecutive pregnant patients with a clinical suspicion of PE, conducted in three centers in the Netherlands from February 2004 through December 2012. We excluded women who used anticoagulant treatment. A CTPA was performed and in case of an intravascular filling defect, the diagnosis of pulmonary embolism was established and anticoagulant treatment was started. In case of a normal result or an alternative diagnosis, pulmonary embolism was ruled out and anticoagulant treatment was withheld. In case of an inconclusive result, management was left to the discretion of the treating physician. All patients were followed for 3 months to assess the occurrence of symptomatic or fatal venous thromboembolism (VTE). Consent and ethical approval was obtained.

Results: A total of 149 pregnant patients were enrolled and six patients were excluded because of use of therapeutic Low-Molecular-Weight-Heparin (LMWH) for more than 24 h. The median age of the 143 included patients was 30.7 years (IQR 27.3–35.2) and 10 patients (7.0%) had a history of previous VTE. PE was diagnosed in six patients (4.2%). CTPA excluded PE in 129 patients (90.2%) and was inconclusive in eight patients (5.6%), of whom one was treated with anticoagulation therapy. None of the 136 patients in whom PE had been ruled out and who were not treated with anticoagulants experienced VTE in the 3-month follow-up (incidence 0.0%, 95% upper confidence interval 2.7%).

At time of submitting this abstract, a few patients had not completed the 3-month follow-up because this date is behind the abstract submission date.

Summary/Conclusions: A negative CTPA safely rules out pulmonary embolism in pregnant women with a clinical suspicion and can be used as a first-line test.

OC 20.3

Cost-effectiveness of ruling out pulmonary embolism in primary care using the Wells rule and D-dimer testing

Erkens PGM[1], Ten Cate-Hoek AJ[1], Geersing GJ[2], Lucassen W[3], Moons C[2], Prins MH[1], Van Weert H[3], Stoffers JI[1] and Joore M[1]

[1]Maastricht University, Maastricht; [2]Julius Centrum, Utrecht; [3]AMC, Amsterdam, the Netherlands

Background: Referral of all patients suspected with PE presenting in primary care for diagnosis is inefficient since the prevalence of the disease is only 10–15%. The Amsterdam Maastricht Utrecht Study on ThromboEmbolism (AMUSE-2) recently showed that a diagnostic strategy that combines the Wells rule for pulmonary embolism (PE) with a negative D-dimer test result can safely and efficiently exclude PE in primary care. This abstract presents the results of a cost-effectiveness study that evaluates whether the AMUSE-2 strategy will reduce health care costs without considerable loss of quality adjusted life years (QALY).

Aims: To assess the cost-effectiveness of a diagnostic strategy that combines the use of the Wells rule with qualitative point-of-care D-dimer testing to select primary care patients with suspected PE for referral to secondary care, compared to referral of all patients with suspected PE.

Methods: A Markov-type cost-effectiveness model with a 5-year time horizon and a 6-month cycle time was used to compare the AMUSE-2 strategy to referral of all patients with suspected PE to secondary care. Transition probabilities were derived from the AMUSE-2 study (2007–2010) and the literature. Societal costs and health state utilities were obtained from literature. The Markov model consisted of six mutually exclusive health states: no PE, post 1st PE, post recurrent PE, chronic thromboembolic pulmonary hypertension, post central nervous system bleed, and death. The AMUSE-2 strategy consisted of two sub-strategies: the Wells rule with a cut-off point of < 2 combined with qualitative point-of-care D-dimer testing and the Wells rule with a cut-off point of ≤ 4 combined with qualitative point-of-care D-dimer testing. The model was evaluated using cohort simulation. Uncertainty was assessed in a probabilistic sensitivity analysis. Cost effectiveness acceptability curves (CEAC) were constructed.

Results: Compared to referral of all patients both AMUSE-2 strategies resulted in lower costs and less QALYs. The AMUSE-2 strategy with a cut-off point of < 2 resulted on average in a saving of €903 82 and a QALY loss of 0.03 as compared to referral of all. The strategy with a cut-off point of ≤ 4 showed on average a saving of €1198 76 with a QALY loss of 0.10 compared to referral of all. The ICER is €32747 for cut-off point < 2 compared to referral of all patients. For cut-off point ≤ 4 compared to cut-off point < 2 the ICER is €4318. The CEAC curves show that the AMUSE-2 strategy with Wells-score cut-off point < 2 has the highest probability of being cost-effective even for ceiling ratios over €100.000

Conclusions: The Amuse-2 strategy based on the Wells rule for PE and a qualitative point-of-care D-dimer test to exclude PE in primary care is cost-effective compared to referral of all patients suspected of PE in primary care when using a cut-off point of < 2 for the Wells rule.

OC 20.4

D-dimer relevance score

Penaloza A[1], Kabrhel C[2], Verschuren F[1], Vielle B[3], Kline J[4], Le Gal G[5], Thys F[1] and Roy P-M[3]

[1]Cliniques Universitaires St-Luc, Brussels, Belgium; [2]Massachusetts General Hospital, Boston, MA, USA; [3]CHU Angers, Université d'Angers, Angers, France; [4]Indiana University School of Medicine, Indianapolis, IN, USA; [5]Ottawa Health Research Institute, Ottawa, ON, Canada

Background: Some clinical conditions (age, cancer…) increase the risk of false positive D-dimer results, decreasing test utility. In these conditions some clinicians elect not to measure D-dimer and proceed directly to computed tomography pulmonary angiography (CTPA).

Aims: To help physicians to determine the utility of D-dimer measurement, we derived and internally validated a score for risk of false positive D-dimer. We analyzed an arbitrary D-dimer relevance threshold of at least 10% probability of negative D-dimer.

Methods: Secondary analysis of three prospectively collected databases of PE suspected patients (2 European, 1 American). Only patients with highly sensitive quantitative D-dimer measurement were included. The study population (n = 4537) was randomly divided into two groups. Patients with PE were excluded to derive a score of risk of false positive D-dimer. In the derivation group, variables statistically significantly associated with PE in univariate analyses were included in a multivariable logistic model. Points were assigned according to regression coefficients. The score was applied to the validation group. Its clinical applicability was evaluated in patients with low or moderate clinical probability (i) assessed by three methods (Wells score, revised Geneva score and gestalt) (ii) in our European and American populations. Receiver operating characteristic curve analysis was performed and the area under the curve (AUC) assessed.

Results and Discussion: The final score contained ten variables: Female sex (1 point), Age 65–84 years (4 points), Age ≥ 85 years (8 points), Personal history of venous thromboembolism (1 point), Surgery within 4 weeks (2 points), Active malignancy (3 points), Pregnancy or Postpartum within 4 weeks (4 points), Heart rate ≥ 95/' (1 point), O2 saturation < 95% (2 points), Temperature ≥ 38.5 °C (3 points). AUC was 0.76 (CI: 0.73–0.78). There was a regular decrease in the proportion of negative D-dimers with increasing score values. Scores ≤ 8 were associated with at least 10% probability of a negative D-dimer. In clinical application (patients with low or moderate clinical probability), results were similar regardless of how clinical probability was assessed, and in both continents. The proportion of patients with a score above 8 was 5% in the overall population and 10.2% vs. 3.1% respectively in the European and American populations ($P < 0.001$). This difference appears to be mainly explained by the difference in PE prevalence (13.3% vs. 3.2%) and by differences in patient characteristics between these two populations.

The score might lead physicians who always measure D-dimer to think about alternative strategies when the probability of a negative D-dimer result is low (score > 8). On the other hand, this was the case in only 5% of patients; thus the score should also and mainly lead sceptical physicians to measure D-dimer more frequently, instead of directly performing CTPA in patients with one criterion thought to be associated with a high risk of false positive test.

Conclusion: The score gives information about the expected proportion of negative D-dimer and enables clinicians to make better informed decisions about whether to measure D-dimer or not in PE suspected patients.

OC 21.1

Bimolecular interactions of platelet factor 4 (PF4) with HIT-pathogenic versus non-pathogenic anti-PF4/heparin antibodies

Litvinov RI[1], Sachais BS[1], Yarovoi S[1], Rauova L[2], Rux AH[1], Arepally GMG[3], Cines DB[1] and Weisel JW[1]

[1]University of Pennsylvania, Philadelphia; [2]Chidren's Hospital of Philadellphia, Philadelphia, PA; [3]Duke University, Durham, NC, USA

Background: Heparin induced thrombocytopenia (HIT) is a thrombotic complication of heparin therapy mediated by antibodies to complexes between platelet factor 4 (PF4) and heparin or cellular glycosaminoglycans. However, only a fraction of patients with these antibodies develop HIT, implying that only a subset of anti-PF4/heparin antibodies is pathogenic. The basis for the difference in the capacity of anti-PF4/heparin antibodies to activate platelets/monocytes and induce thrombosis *in vivo* are not revealed by conventional bulk techniques, such as ELISA, and remains unclear.

Aims: To elucidate the intrinsic PF4-binding properties of HIT-like monoclonal antibodies (KKO) vs. non-pathogenic antibodies (RTO) at the single-molecule level to avoid effects of avidity and other auxiliary intermolecular interactions.

Methods: We measured the strength of binding of surface-attached bivalent intact KKO and RTO with PF4 utilizing optical trap-based force spectroscopy. Briefly, a KKO- or RTO-coated latex bead was trapped by the laser beam and brought into intermittent contact with the PF4-coated pedestal. Rupture force signals following repeated contacts between the protein-coated surfaces were collected and displayed histograms. The binding probability reflected the association rate, while the peak of forces (binding strength) reflected the forced dissociation rate.

Results: In control experiments with tetrameric WT PF4 and either KKO or RTO, we identified weak interactions arising from PF4-PF4 bonds, which were difficult to separate from antibody-PF4 interactions. To study antibody-PF4 binding specifically, we prevented rupture of PF4-PF4 bonds by chemical cross-linking of the PF4 tetramers. The specificity of rupture forces generated by the surface-bound cross-linked PF4 and KKO or RTO was confirmed by competitive inhibition experiments in the presence of the free Fab fragments or PF4. Single-molecule binding was confirmed by the dependence of binding probability on surface density. Modeling of the force histogram revealed that KKO-PF4 interactions were about 10-fold faster than RTO-PF4 (kon' = 4.36 vs. kon' = 0.45/s, respectively) and the apparent equilibrium dissociation constants differed ~10-fold (Kd' = 7.1 × 10^{-4} and Kd' = 6.4 × 10^{-3}, respectively) with similar force-free off-rates ($koff$ = 0.0031 and $koff$ = 0.0029/s). The KKO-PF4 interactions were somewhat stronger, as reflected by the position of the force peak (84 ± 5 vs. 78 ± 4 pN, $P < 0.05$). In contrast to the WT PF4, KKO and RTO showed lower and similar binding probabilities to cross-linked $PF4^{K50E}$, which forms few oligomers, although the binding strength was again slightly higher for KKO vs. RTO.

Summary/Conclusions: The data indicate that KKO has significantly higher affinity for PF4 oligomers than RTO. In combination with the ability of KKO to promote super-oligomerization of the PF4 tetramers, these data suggest an amplification reaction, in which KKO, unlike RTO, binds preferentially to PF4 tetramers (with or without heparin), enhances their further polymerization and becomes more and more avid as the antigenic complexes grow in size. The results of the single-molecule rupture force measurements indicate that there is a fundamental difference in the antigen binding mechanisms between pathogenic and non-pathogenic anti-PF4 antibodies that underlie their distinct pathophysiological behaviors/profiles. These studies suggest that epitope specificity may contribute to the pathogenic potential of some anti-PF4 antibodies.

OC 21.2

Serological investigation of 20 patients re-exposed to heparin with a previous history of heparin-induced thrombocytopenia (HIT)

Warkentin TE and Sheppard JI
McMaster University, Hamilton, ON, Canada

Background: Sparse data exist regarding the frequency, timing and magnitude of the anti-platelet factor 4/heparin (PF4/H) immune response 'and associated risk of recurrent heparin-induced thrombocytopenia (HIT)' 'among patients who have recovered from HIT but who are subsequently re-exposed to heparin. One report (Poetzsch et al. N Engl J Med 2000;343:509:515) found that among 10 patients with previous HIT who underwent cardiac surgery with unfractionated heparin (UFH), *none* developed antibody recurrence by anti-PF4/H enzyme-immunoassay (EIA), even though ~50% of post-cardiac surgery patients would be expected to form anti-PF4/H antibodies (and ~10% expected to form platelet-activating antibodies by serotonin-release assay [SRA]). The true risk of HIT recurrence' 'whether higher, about the same, or potentially even lower than in patients without previous HIT' 'remains uncertain.
Aims: To determine the frequency, timing, and magnitude of the anti-PF4/H immune response, and the frequency of recurrent HIT, among patients with well-documented previous HIT who were re-exposed to heparin.
Methods: We studied 20 patients with previous HIT (definite [4Ts $\geq$ 4, SRA+], n = 16; probable [4Ts $\geq$ 4, EIA+; SRA not done], n = 4) who underwent repeat heparin re-exposure (UFH, n = 19; LMWH, n = 1), occurring 4.4 year (mean [range, 8 week to 13.5 year]) post-HIT diagnosis. We examined serial platelet counts for HIT recurrence, and the SRA and isotype-specific anti-PF4/H EIAs for antibody recurrence, testing serial post-exposure blood samples (median, nine samples/patient to day 30 post-rechallenge [last sample, median 11 days after re-exposure]).
Results: One patient (5%) developed recurrent HIT, confirmed by seroconversion from negative baseline to strong-positive SRA (%serotonin-release = 95%/100%/100%/5% at 0/0.1/0.3/100 U/mL UFH) and strong-positive EIA-IgG (2.74 OD units; normal < 0.45) following cardiac surgery and while receiving postoperative thromboprophylaxis with fondaparinux (2.5 mg/day); this patient's clinical course was unusual (2009 HIT: onset day 7, platelet nadir = 20, platelet recovery by ~70 days, deep-vein thrombosis (DVT), generalized maculopapular rash, full recovery with therapeutic-dose fondaparinux 7.5 mg/day), virtually recapitulating his prior HIT episode 11 year earlier (1998 HIT: also post-cardiac surgery, onset day 7, platelet nadir = 26, recovery by ~50 days, DVT/pulmonary embolism, generalized maculopapular rash, full recovery with therapeutic-dose danaparoid). Despite no other patient developing recurrent HIT, 8/17 (47%) post-cardiac/vascular surgery re-exposed patients developed seroconversion to a positive SRA, and 10/17 (59%) demonstrated an anti-PF4/H immune response (IgG>IgA>IgM), even though none of these 17 patients continued to receive UFH or LMWH postoperatively. None of three patients who received a repeat course of UFH or LMWH for a medical indication developed recurrent antibodies. Interestingly, there was no evidence for speedier antibody formation among eight patients in whom timing of antibody detectability after re-exposure could be compared with the timing of onset of their prior HIT episode. Summary/Conclusions
Patients with a previous history of HIT who undergo repeat heparin exposure are at considerable risk of repeat formation of platelet-activating anti-PF4/H antibodies (positive SRA), although in the absence of continuing heparin administration the risk of HIT appears to be low. We also report the first case of recurrent HIT despite the strategy of limiting repeat UFH to a brief intraoperative re-exposure (this patient recovered fully with therapeutic-dose fondaparinux).

OC 21.3

Impact of polymorphisms affecting ACP1, which codes for a protein tyrosine phosphatase, on levels of antibodies to platelet factor 4/heparin complexes

Rollin J, Pouplard C, Leroux D, May MA and Gruel Y
University hospital of Tours, Tours, France

Background: Heparin-induced thrombocytopenia (HIT) results from an atypical immune response to platelet factor 4/heparin complexes (PF4/H), with rapid synthesis of platelet-activating IgG antibodies that activate platelets *via* FcgRIIa receptors. The reasons explaining why only a subset of patients treated with heparin develop IgG to PF4/H complexes, and why most patients with these antibodies do not develop HIT, have not been fully defined. The immune response in HIT involves both B and T cells, and protein tyrosine phosphatases (PTPs) are crucial for regulating antigen receptor-induced lymphocyte activation and FcgR-dependant pathways. Therefore, several studies have showed that functional polymorphisms affecting PTPs such as *PTPN22* and *ACP1* coding LYP and LMPTP respectively were associated with autoimmune diseases.
Aim: To investigate whether an association between polymorphisms in *PTPN22* (1858C/T) or *ACP1* (A, B, C alleles) and the development antibodies to PF4/H and HIT may exist.
Patients and Methods: Eighty nine patients with definite HIT (positive PF4-specific ELISA (HAT® GTI) and serotonin release assay) and two control groups were studied. The first control group (Ab^{neg}) consisted of 179 patients who had undergone cardiopulmonary bypass (CPB) with high doses of heparin, without Abs to PF4/H post-operatively. The second control group (Ab^{pos}) consisted of 160 patients who had also undergone CPB and developed significant levels of PF4-specific antibodies, but without HIT. Genotypes of *PTPN22* 1858C/T (rs2476601), *ACP1* 228C/T (rs11553742) and 254C/T (rs11553746) were defined by the PCR-HRM method. The *ACP1* A, B, C alleles were defined by combining the analysis of both SNP 228C/T and 254C/T.
Results: The frequency of *PTPN22* 1858T alleles was similar in HIT patients (11%) and controls (12% and 11%), whether they had developed antibodies to PF4 or not. In contrast, the *ACP1* A allele was less frequent in patients with antibodies to PF4, whether they had developed HIT (25%) or not (27.5% in Ab^{pos} controls), than in Ab^{neg} subjects (37%, P = 0.001). The A, B and C alleles *of ACP1* had previously been associated with the synthesis of distinct active LMPTP isoforms exhibiting different catalytic properties. In this regard, the genotypes known to exhibit the highest LMPTP enzyme activity i.e. AC, BB and BC, were more frequent (66.5%) in patients with high levels of antibodies to PF4/H complexes (A_{405} > 2) than in the others (52%, P = 0.03). Therefore, these genotypes appeared increase the risk of anti-PF4/H antibody formation in heparin-treated patients (OR 1.8; 95% CI 1.2–2.6, P = 0.005 after comparing Ab^{pos} + HIT vs. Ab^{neg}).
Conclusion: LMPTP regulates ZAP70 and lymphocyte activation by enhancing T-cell antigen receptor-dependant signaling and our study supports that *ACP1* genotypes associated with strong enzymatic activity of this PTP may increase the intensity of immune response to heparin-modified PF4.

OC 21.4

Endocytotic mechanisms contributing to the internalization of ADAMTS13 by macrophages

Verbij FC[1], Sorvillo N[1], Kaijen P[1], Ten Brinke A[2], Fijnheer R[3] and Voorberg J[1]
[1]Sanquin; [2]Sanquin-AMC Landsteiner Laboratory, Amsterdam; [3]University Medical Center Utrecht, Utrecht, the Netherlands

Background: Acquired thrombotic thrombocytopenic purpura (TTP) is a severe disorder characterized by the production of autoantibodies directed against ADAMTS13, a metalloproteinase that regulates plate-

let adhesion and aggregation through cleavage of ultra-large von Willebrand factor (UL-VWF) multimers. At present the cause of antibody formation is unknown. We have previously shown that ADAMTS13 is efficiently internalized and presented on MHC class II by dendritic cells (Sorvillo et al, Blood 2012, 2013), suggesting a possible role of CD4+ T cells in the initiation of the autoimmune reactivity towards ADAMTS13. Activation of T cells leads to production of autoantibodies directed against ADAMTS13. Macrophages may participate in the immune response to ADAMTS13 and may also accelerate the clearance of ADAMTS13.

Aim: Here we investigated endocytotic mechanisms contributing to the uptake of ADAMTS13 by macrophages.

Methods: Human monocyte-derived macrophages (MDMs) were used to monitor the uptake of fluorescently labelled recombinant ADAMTS13 by flow cytometry. Macrophages were treated with different pharmacological inhibitors such as mannan, EDTA, heparin and dextran sulphate. In addition, an established cell-permeable inhibitor of clathrin-mediated endocytosis was used for these studies. The involvement of cellular receptors was addressed using blocking antibodies or siRNA mediated gene silencing. Uptake of ADAMTS13 by macrophages was also monitored by confocal microscopy.

Results: A time- and concentration dependent endocytosis of ADAMTS13 was observed when MDMs were incubated with fluorescently labeled ADAMTS13. Confocal microscopy studies revealed partial colocalization of ADAMTS13 with early endosomes. Recognition and/or uptake of antigens by MDMs occurs through two main pathways: receptor-mediated endocytosis and macropinocytosis. In order to identify the mechamism that mediates ADAMTS13 endocytosis we evaluated uptake of fluorescently labeled ADAMTS13 after pre-incubation of the cells with dynasore. Significant reduction of endocytosis was observed suggesting that ADAMTS13 uptake proceeds via clathrin mediated endocytosis. Internalization of ADAMTS13 was blocked upon addition of mannan and EDTA suggesting a possible role of C-type lectins (CLRs). We have recently demonstrated that the macrophage mannose receptor (MR) is involved in endocytosis of ADAMTS13 by human monocyte derived dendritic cells (Sorvillo et al, Blood 2012). However, uptake of ADAMTS13 by MDMs was not affected by the addition of different sugars or by a monoclonal antibody directed towards the MR. Furthermore siRNA silencing of MR did not significantly reduce uptake suggesting the involvement of other type of receptors. Interestingly, we observed a robust inhibition of ADAMTS13 endocytosis upon incubation with heparin and dextran sulphate.

Summary/Conclusion: Taken together our data suggest that internalization of ADAMTS13 by macrophages proceeds via a mechanism that is dissimilar from that previously defined in dendritic cells. We anticipate that the endocytic uptake by macrophages promotes the clearance of ADAMTS13 from the circulation.

OC 22 – Inhibitors in Haemophilia A – I

Exploration of biomarkers for early recognition of FVIII inhibitor development in previously untreated severe hemophilia A patients: Hemophilia Inhibitor PUP Study and beyond

Hofbauer CJ[1], Male C[2], Brown D[3], Santagostino E[4], Oldenburg J[5], Scheiflinger F[1] and Reipert BM[1]

[1]Baxter BioScience; [2]Medical University Vienna, Vienna, Austria; [3]University of Texas, Houston, TX, USA; [4]University of Milan, Milan, Italy; [5]University Clinic Bonn, Bonn, Germany

Background: The development of neutralizing antibodies (FVIII inhibitors) is the major treatment complication of current care for patients with hemophilia A. Despite progress in understanding the regulation of immune responses against FVIII in preclinical animal models, no substantial improvement in the treatment of patients has resulted from animal studies.

There is a demand for biomarkers that allow early recognition of FVIII inhibitor development in previously untreated patients (PUPs) during first exposure days to FVIII. Likewise, suitable biomarkers are missing that facilitate early recognition of FVIII inhibitor eradication during Immune Tolerance Induction therapy (ITI).

Aim: Establish suitable technologies that facilitate the search for early biomarkers of inhibitor development and inhibitor eradication in patients. These technologies are to be optimized for small blood volumes and should be applicable to a multi-center setting of clinical studies.

Methods: A set of assays was established to extensively characterize antibodies against FVIII and to identify FVIII-specific CD4+ T cell signatures. Antibody assays not only include the differentiation of Ig isotypes and IgG subclasses but also allow for the assessment of apparent affinities of FVIII-specific antibodies to facilitate monitoring of affinity maturation of antibodies during the evolvement of FVIII inhibitors. Furthermore, DNA-based epigenetic marker analysis for different lymphocyte populations is included that should be suitable for monitoring the immune status of patients.

Results: We will present a set of proof of principle data that include the prevalence and in-depth characterization of FVIII-specific antibodies (Ig isotypes, IgG subclasses and apparent affinity) found in healthy individuals and in different cohorts of severe hemophilia A patients (with and without FVIII inhibitors as well as after successful ITI). High affinity FVIII-specific IgG1 and IgG4 occur to be the predominant antibodies in inhibitor patients, whereas low affinity FVIII-specific IgG1 and IgG3 can be found in selected healthy donors and in non-inhibitor patients. Interestingly enough, no FVIII-specific IgG4 was detected in healthy individuals (n = 600) from different geographies or in patients without FVIII inhibitors. Furthermore, CD4+ T-cell signatures indicate a FVIII-specific modulation of the expression of inflammatory genes such as *MYD88* in FVIII inhibitor patients in the course of successful ITI.

Conclusions: We developed and validated a set of technologies that will allow the identification of early biomarkers associated with FVIII inhibitor development and inhibitor eradication in patients with hemophilia A. Their application in the ongoing Hemophilia Inhibitor PUP Study (HIPS) has the potential to uncover new mechanisms of FVIII inhibitor development during early exposure days to FVIII.

OC 22.2

European monitoring of inhibitor development in haemophilia A and B

Fischer K[1], Makris M[2], Calizzani G[3], Hay CRM[4], Ludlam CA[5], Lambert T[6], Lassila R[7] and Mannucci PM[8]

[1]UMCU, Utrecht, the Netherlands; [2]Royal Hallamshire Hospital, Sheffield, UK; [3]Centro Nazionale Sangue, Rome, Italy; [4]Manchester Royal Infirmary, Manchester; [5]Royal Infirmary of Edinburgh, Edinburgh, UK; [6]Paris AP-HP Haemophilia Treatment Centre, Paris, France; [7]Helsinki University Central Hospital, Helsinki, Finland; [8]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico (CA'GRANDA), Milan, Italy

Introduction: Inherited bleeding disorders are rare and monitoring side effects of treatment with FVIII or IX concentrates in haemophilia A and B requires multicentre, preferably international collaboration.

Aim: The European Haemophilia Safety Surveillance (EUHASS) was set up as a prospective registry monitoring adverse events, including inhibitor formation.

Methods: The EUHASS project started on 1-10-2008, patient numbers according to diagnosis and treatment status were reported annually, specifying patients who completed 50 exposure days. Adverse events were reported every quarter using a web-based form. Inhibitors were defined as two positive inhibitor tests according to the local laboratory.

Results: During the first three years, the number of reporting centres increased from 45 to 69. 250 Previously Untreated Patients (PUPs) with haemophilia A, and 40 with haemophilia B reached 50 exposure days. In total, 12470 (haemophilia A) and 2206 (haemophilia B) patient years were monitored in Previously Treated Patients (PTPs). Inhibitor development in PUPs with severe haemophilia A occurred in 71/250 (26%; 95% confidence interval: 21–32%) patients and in 3/39 [8%; 95% CI (2–21)] patients with haemophilia B. Inhibitor development for FVIII concentrates was similar for recombinant (65/250 = 26%, 95% CI 21–32) and plasma derived (6/40 = 15%, 95% CI 6–30) FVIII products. For PTPs, 26 new inhibitors were recorded in the registry, the rate of inhibitor development was 0.2/100 patient years (95% CI 0.1–0.3) for severe haemophilia A, 0.05/100 patient years (95% CI 0–0.3) for severe haemophilia B. Statistically significant differences between concentrates were not observed during the first 3 years of EUHASS. Results from all first 4 years of data will be presented during the ISTH congress.
Conclusion: Results from the first 3 years of the EUHASS registry showed that inhibitor formation is the main side effect of haemophilia treatment, occurring in 26% of PUPs with severe haemophilia A and 8% with severe haemophilia B. The inhibitor rates for PTPs with severe haemophilia A and B were 0.2 and 0.05 per 100 patient years, respectively.

OC 22.3

The change of Treg cells and serum BAFF level in the development of anti-factor VIII antibiotics in hemophilia A mice model

Cheng S-N, Huang CP, Dai M-S and Chen YC
Tri-Service General Hospital, Taipei, Taiwan

Objectives: Hemophilia A is an X-linked bleeding disorder. The most serious complication of replacement therapy was production of antibodies. Regulatory T cells (Tregs) play a critical role in maintenance immune homeostasis and inhibitor formation. B cell-activating factor (BAFF) is involved in the survival and maturation of B cell and plays a critical role in most of immune responses. The purpose of this study was to investigate the relationship between the percentage of Treg and BAFF level in the emergence of anti-FVIII antibodies in animal model.
Methods: Hemophilia mice (C57BL/6 and 129 mix background, Exon 16 knockout), were intraperitoneally injected with 2 IU (~80 IU/Kg) of human recombinant FVIII (rFVIII) (Baxter) at 4 consecutive weeks. The mice serum and plasma were sampled before injection and after 4 consecutive weekly injections. Total anti-FVIII antibody titres and serum BAFF concentration were determined by ELISA. The functional activity of FVIII antibodies was measured using modified-Bethesda assay. The percentage of Treg cells were stained with specific antibodies conjugated with fluorochromes (CD4-FITC, CD25-APC, FoxP3-PE), and analysed with a FACSCalibur fluorescence activated cell sorter (FACS) using CELL QUEST software (BD Biosciences Pharmingen). The difference between those experimental groups was evaluated by one-way ANOVA using PRISM.
Results: Four subsequent weekly intraperitoneal injection of 2 IU rFVIII successfully induced high titer of anti-FVIII antibodies (216–309 μg/mL; 38–152 BU).We found in the rFVIII treated group, BAFF level and Treg cells increased before high-titer anti-FVIII antibodies formation, then the BAFF level decreased while the antibodies significant increased. High-titer anti-FVIII antibodies developed after Treg cells dropped.
Conclusions: In rFVIII treated group, high-titer anti-FVIII antibodies developed after brief BAFF and Treg cells surged. Our investigated results indicated that BAFF and Treg cells may play a role in early anti-FVIII inhibitor formation. Design of Treg positive cell-based therapy or anti-BAFF treated experiment, may characterize the mechanism between the Treg cells and BAFF in the inhibitor immune response. BAFF and Treg targeting strategy might prevent or reduce its occurrence.

OC 22.4

Restricted specificity of a recombinant anti-idiotypic antibody in protecting human factor VIII against anti-C2 inhibitory antibodies

Plantier J-L[1], Gilles J-G[2], De Romeuf C[1], Fontayne A[1], Gaucher C[1], Behrens C[1], Urbain R[1], Prost J-F[1] and Saint-Rémy J-M[2]
[1]LFB Biotechnologies, Lille, France; [2]Catholic University Leuven/Imcyse, Leuven, Belgium

Background: Anti-idiotypic antibodies (anti-id's) are generated against naturally circulating antibodies, mimicking somehow the structure of the protein initially targeted by the circulating antibodies. Natural anti-id's directed against anti-factor VIII (FVIII) antibodies can be retrieved in normal population but also in hemophilia A patients, in particular in those that generated inhibitors. Anti-id's were shown to participate in the success of immunotolerance protocols in hemophilia A patients with inhibitors.
Aim: In order to gain further insight in the mechanism governing this effect, we decided to assess the ability of recombinant anti-id's in protecting FVIII to inhibitors.
Methods: Four couples of FVIII inhibitors/anti-idiotypic antibodies were generated. Two inhibitors directed against the C1 domain (Le2E9 and RHD5) or the C2 domain (B02C11 and VDR2C5) were generated by immortalizing B-cells from hemophilia A patients using Epstein-Barr Virus. Antibodies from these cell lines were isolated and characterized. These antibodies were used to generate anti-id's in mice. Anti-id's against Le2E9, RHD5 and B02C11 were characterized and prepared as chimeric by fusing the variable regions with human IgG1/k constant regions. The recombinant chimeric anti-id antibody 14C12, raised against the anti-C2 inhibitor BO2C11, closely mimics the structure of the entire C2 domain. It was thus used as a model to evaluate an anti-id protective action with regard to the C2 domain.
Results: As evidenced by flow-cytometry, the anti-id antibodies specifically recognized the B-cell line expressing the inhibitors against which they were raised. In contrast, they were unable to cross-react with the B-cell line which expressed a non-related inhibitor directed against a different or the same FVIII domain. The potential of 14C12 in alleviating inhibitor actions was then assessed in a thrombin generation assay. The reaction was induced by tissue-factor (0.5 nM) in FVIII-deficient plasma reconstituted by 1 U/mL FVIII. Anti-id 14C12 (ratio varying up to 250:1) was able to significantly restore the amount of thrombin generated in the presence of BO2C11 inhibitor. An endogenous thrombin potential higher than 50% of a control without inhibitor was obtained. In contrast, 14C12 restored no more than 12%, 17% and 3% respectively of the thrombin generated in the presence of VDR2C5, or in the presence of the commercial ESH8 or ESH4 monoclonal anti-C2 antibodies. In the presence of a sheep polyclonal anti-FVIII antibody (adjusted at 20 BU/mL), or in two plasmas from hemophilia A patients with inhibitors (7 BU/mL and 20 BU/mL), 14C12 anti-id restored only 3%, 10% and 0% respectively of the endogenous thrombin potential.
Summary/Conclusions: This data showed that anti-id's seem to specifically and efficiently target the inhibitory antibody against which they were established. Despite mimicking a complete protein domain, such as 14C12, anti-id cannot efficiently inhibit other inhibitors directed against the same protein domain. These results therefore suggest the need for an extended anti-idiotypic network in down-modulating *in vivo* a pre-established complex inhibitory response against factor VIII.
Technical help: This data was obtained with the technical help of Carole Pirckher, Linda Baptista and Dominique Grenier

OC 23 – Intrinsic Pathway of Coagulation

OC 23.1

Two cleavage sites in factor XII direct its diverging activities

De Maat S[1], Beringer D[2], Kroon-Batenburg MJ[2], De Groot PG[1] and Maas C[1]

[1]University Medical Center Utrecht; [2]Utrecht University, Utrecht, the Netherlands

Introduction: When factor XII (FXII) binds to activating surfaces, it becomes catalytically active in an elusive event. Intriguingly, some surfaces trigger both coagulation and inflammation, whereas others only trigger inflammatory responses. FXII contains three closely positioned kallikrein cleavage sites; two of which reside within the catalytic domain and one within the heavy chain. During digestion of FXII by plasma kallikrein, the 80 kDa zymogen is first activated into α-FXIIa (80 kDa), where after its catalytic domain (β-FXIIa; 28 kDa) is released from its heavy chain. β-FXIIa is not procoagulant, but it does retain its inflammatory capacity. This suggests that a cleavage intermediate of FXIIa drives coagulation.

Aims: To investigate whether separate isoforms of FXIIa affect coagulation and inflammation with varying capacities.

Methods: The essential arginines within the three kallikrein cleavage sites (R334, R343, R353) and combinations thereof, were replaced with alanines (A) by site-directed mutagenesis. Subsequently, we studied the capacity of these mutants to directly cleave chromogenic substrates for kallikrein and thrombin. In plasma, we studied their capacity to trigger kaolin-induced prekallikrein activation, thrombin generation and coagulation.

Results: In line with earlier work, we found that cleavage at R353 is essential for induction of FXII activity, as none of the mutants containing R353A displayed any activity. Next, we identified that further proteolytic steps modulate the molecular functions of FXIIa. Upon activation, purified FXII mutant R343A is less capable of directly cleaving chromogenic kallikrein substrate and also has a reduced capacity to activate prekallikrein in plasma compared to WT FXII. This R343A mutant also converts less thrombin substrate and triggers a prolonged time to peak in a kaolin-driven thrombin generation assay in plasma (38 ± 2 min,: WT 26 ± 3 min). These findings suggest that a reduced thrombin-like activity of FXIIa may underlie a reduced capacity to activate factor XI and support thrombin generation.

In contrast, prevention of heavy-chain dissociation in FXII mutant R334A accelerates surface-induced coagulation and thrombin generation (21 ± 2 min; WT 26 ± 3 min), as well as prekallikrein activation and conversion of kallikrein substrate.

Finally, FXII R334A/R343A double mutant has a normal capacity (comparable to WT) to convert chromogenic kallikrein substrate and activate prekallikrein in plasma. Interestingly, this mutant shortens coagulation times in clotting assays (compared to WT), directly converts more thrombin substrate, and further accelerates thrombin generation (18 ± 1 min).

Conclusions: Together, our data indicate that cleavage intermediates of FXIIa have different enzymatic capacities. Where a primary cleavage at R353 yields a thrombin-like FXIIa, further cleavage at R343 modulates its function from a thrombin-like into a kallikrein-like enzyme. Subsequently, these activities can be amplified via the intrinsic pathway or the kallikrein-kinin system, respectively. A final cleavage at R334 dissociates the catalytic domain to restrict autoactivation.

OC 23.2

FXIIa enhances fibrinolysis in addition to plasminogen activators

Konings J[1], Hoving L[1], Ariëns R[2], Smith E[2], Ninivaggi M[3], Hardy L[2], De Laat B[3], Ten Cate H[1], Philippou H[2] and Govers-Riemslag JWP[1]

[1]CARIM, Maastricht University Medical Centre, Maastricht, the Netherlands; [2]Division of Cardiovascular and Diabetes Research, University of Leeds, Leeds, UK; [3]Synapse BV, CARIM, Maastricht University Medical Center, Maastricht, the Netherlands

Background: Previously we have shown that activated coagulation factor XII (α-FXIIa) is able to bind to both fibrinogen and fibrin, and alter the structure and properties of a fibrin clot. In the presence of α-FXIIa, a denser clot is formed with thinner fibers, lower maximal turbidity and increased clot stiffness (Blood 2011, PMID = 21828145), typical for clots which are difficult to lyse. Conversely, the proteins of the contact system and the fibrinolytic system show a high degree of homology and FXIIa can directly convert plasminogen into plasmin, contributing to increased fibrinolysis.

Aims: The aim of this study was to investigate the contribution of α-FXIIa to clot stability and fibrinolysis.

Methods: Under static conditions, fibrin formation and fibrinolysis were determined simultaneously by turbidity and plasmin generation tested with S-2251. Fibrin formation and fibrinolysis of clots formed under flow conditions in a Chandler loop were determined through plasmin generation and fluorescent measurements of incorporation and release of fibrinogen Alexa Fluor® 488. The influence of α-FXIIa on clot structure and on fibrinolysis was visualized via scanning electron microscopy (SEM) and the fiber thickness was analyzed using Fibermetrics.

Results: Fibrin clots formed in the presence of α-FXIIa had a lower maximal turbidity than clots formed in the absence of α-FXIIa independent of tPA concentration, indicating a denser fibrin structure with thinner fibers. Furthermore, we observed that α-FXIIa was able to directly convert plasminogen into plasmin and to reduce the clot lysis time at all tPA concentrations tested (0–1500 pM). Simultaneous assessment of plasmin generation (with the chromogenic substrate S-2251) alongside turbidity measurements, showed earlier onset of plasmin generation in the presence of α-FXIIa. Fibrinolysis of clots formed under flow conditions, revealed that incorporation of α-FXIIa, together with plasminogen, into the clot accelerated clot break-down and increased plasmin generation by tPA, compared to clots prepared in the absence of α-FXIIa. Electron microscopy revealed that fibrin fibers were thinner if α-FXIIa was present during clot formation: in the presence of α-FXIIa on average the fibers were between 120 and 140 nm, in the absence between 140 and 160 nm. When we initiated fibrinolysis by adding tPA (150 pM and 300 pM) during clot formation, the fiber thickness did not change in the absence of α-FXIIa. However, in the presence of α-FXIIa the average fiber thickness increased at 300 pM tPA.

Summary/Conclusion: We observed that α-FXIIa is able to convert plasminogen into plasmin and that the additional plasmin generated enhances fibrinolysis. This was the case irrespective of whether tPA was present during clot formation or added after to initiate fibrinolysis. Visualisation by SEM showed that in the presence of α-FXIIa, the fibrin clot consisted of thinner fibers, however, during fibrinolysis the fiber thickness of the remaining fibers increased. The fiber thickness did not change during fibrinolysis in the absence of α-FXIIa. We postulate that FXIIa first enhances the clot structure during clot formation and thereafter helps initiate fibrinolysis.

OC 23.3

Direct inhibition of FXa by TFPI independent of TF-FVIIa contributes to the down-regulation of coagulation

Thomassen LGD[1], Heinzmann CA[1], Herfs L[1], Hartmann R[2], Dockal M[2], Scheiflinger F[2], Hackeng TM[1] and Rosing J[1]
[1]Maastricht University, Maastricht, the Netherlands; [2]Baxter Innovations GmbH, Vienna, Austria

Background: Tissue factor pathway inhibitor (TFPI) is a Kunitz-type serine protease inhibitor that down-regulates the extrinsic coagulation pathway by inhibiting the tissue factor-factor VIIa complex (TF-FVIIa). In the process of TF-FVIIa inhibition TFPI first binds to and inhibits Factor Xa (FXa) forming a binary TFPI-FXa complex in a reaction that is stimulated by protein S. The TFPI-FXa complex subsequently forms a quaternary complex with TF-FVIIa and blocks the initiation of coagulation. Although TFPI can directly inhibit FXa, this inhibition is generally considered not to be physiologically relevant because the plasma concentrations of other FXa inhibitors e.g. antithrombin (AT = 2.5–5 μM) are several orders of magnitude higher than the TFPI concentration (0.25–0.5 nM).
Aims: To investigate whether direct inhibition of FXa by TFPI, independent of TF-FVIIa, contributes to the down-regulation of coagulation.
Methods: Inhibition of FXa by TFPI and AT in model systems was determined in the presence of calciumchloride, phospholipids and protein S, using a chromogenic substrate to monitor FXa. Inhibition of FXa by TFPI in plasma was determined by measuring thrombin generation curves triggered with FXa, RVV-X, FXIa or FIXa in plasma that contained a cocktail of anti TF/anti FVIIa antibodies to inhibit any contribution of traces of TF that might be present in plasma to the initiation of coagulation. The TF-independent contributions of TFPI and/or protein S to the down-regulation of thrombin generation were quantified after neutralisation of TFPI and protein S with an anti TFPI cocktail or anti protein S antibodies.
Results: Comparison of the inhibition of FXa by physiological concentrations of AT (2.5 μM) and TFPI (0.25 nM) shows that TFPI is a better FXa inhibitor ($t_{1/2}$ = 2.5 min) than AT ($t_{1/2}$ = 3.2 min). Both anti-TFPI and anti-protein S antibodies enhanced thrombin generation in plasma triggered with RVV-X, FXa, FIXa or FXIa. Depending on the trigger and trigger concentration used anti-TFPI and anti-protein S antibodies decreased the lag time and/or increased the peak height of thrombin generation. At high trigger concentrations neither anti-TFPI nor anti-protein S antibodies enhanced thrombin generation. TFPI and protein S titrations in TFPI- and protein S-depleted plasma in which thrombin formation was initiated with triggers other than TF confirmed that both TFPI and protein S express TF-independent anticoagulant activity.
Conclusions: Our observations indicate that TFPI, despite its low plasma concentration, expresses anticoagulant activity in the absence of TF. Kinetic experiments in model systems at plasma TFPI concentrations show that direct inhibition of FXa by TFPI can account for the TF-independent anticoagulant effect of TFPI on thrombin generation. Neutralisation of protein S with anti-protein S antibodies also enhances thrombin generation with triggers other than TF. This suggests that TFPI requires protein S for expression of TF-independent anticoagulant activity in plasma. Inhibition of thrombin generation by TFPI independent of the TF pathway is an important observation since coagulation on endothelial cells, which mainly proceeds via the intrinsic pathway, becomes susceptible to down-regulation by TFPI through direct inhibition of FXa.

OC 23.4

A microfluidic model of *in vitro* hemostasis that potentiates thrombin generation via the intrinsic pathway of coagulation

Colace TV[1], Fogarty P[2] and Diamond SL[1]
[1]University of Pennsylvania; [2]Hospital of the University of Pennsylvania, Philadelphia, PA, USA

Background: Microfluidic models of hemostasis rarely incorporate both platelet adhesion and coagulation, despite their strong connections. Traditionally, PPACK, a small molecule inhibitor of thrombin, is used to study platelet deposition to adhesive proteins under flow. Recently, we have demonstrated a model of platelet adhesion and coagulation functioning together under flow using a procoagulant surface of collagen type I with immobilized tissue factor-bearing vesicles (TF). Here we describe a model of hemostasis that does not rely on extrinsic coagulation to generate thrombin.
Aim: We sought to develop a microfluidic model of platelet adhesion and coagulation under flow utilizing the intrinsic pathway to trigger thrombin generation.
Methods: Whole blood (WB) was drawn from healthy or hemophiliac donors into 4 μg/mL Corn Trypsin Inhibitor (CTI), an inhibitor of activated factor XII (FXIIa). This quantity of CTI was chosen as it was below the saturating levels described by our lab earlier, but provided 30–45 min before clotting was observed in a test tube. Platelet counts and Factor VIII or IX levels were collected for hemophiliac donors. Samples were treated with fluorescently conjugated monoclonal antibodies against platelet CD41a and fibrin. Within 5 min of the blood draw, labeled samples were perfused over a collagen type I surface in a microfluidic device consisting of eight individual channels at 100/s. Platelet adhesion and fibrin accumulation were measured in 30 s intervals over a 20 min time period.
Results: Platelets deposited onto the collagen surface from healthy WB samples within 30 s. Onset of fibrin generation required a minimum of 6 min for all healthy donors and was donor dependent, with a maximum time of 9 min. Maximum platelet and fibrin generation was typically observed between 10–15 min, resulting in full channel occlusions. Addition of Factor VIII (FVIII) inhibitory antibodies abolished fibrin generation in healthy donors, confirming that intrinsic coagulation was the trigger for thrombin generation. In patients with hemophilia A and B who ranged from severe to mild disease, platelet deposition measured after 10 min of perfusion correlated strongly with FVIII levels but not with platelet count. Fibrin generation required a minimum of 5% of normal FVIII levels, but was highly variable above this threshold.
Conclusions: We have developed a model of hemostasis under flow that combines platelet adhesion to a collagen surface and intrinsically activated coagulation. We demonstrated robust generation of fibrin on platelet deposits in healthy donors, which was absent when antibodies against FVIII were used or samples from hemophiliacs with low (< 5%) FVIII/IX levels were considered. We have also demonstrated that platelet deposition is a strong function of FVIII levels, likely due to the potent activating potential of thrombin.

OC 24 – Platelet and Coagulation Interaction

OC 24.1

A new role for integrin outside-in signaling in the regulation of platelet packing density, solute transport and fibrin deposition following vascular injury *in vivo*

Stalker T, Welsh JD, Wu J, Diamond SL and Brass LF
University of Pennsylvania, Philadelphia, PA, USA

Background: Prior studies have demonstrated that platelet activation within a hemostatic plug is heterogeneous. We recently demonstrated

that the platelet mass which forms after penetrating injuries is composed of distinct regions defined by the extent of platelet activation and other properties (Stalker, et al. Blood 2013). At least two regions are apparent: a core of fully activated and degranulated platelets immediately adjacent to the site of injury, which is overlaid by a shell of less activated platelets that have not undergone a-granule secretion. Platelets in the core are packed more closely together, facilitating contact-dependent signaling and restricting the entry of plasma-borne molecules. Aims and Methods

Here we used high-resolution confocal intravital imaging to test two hypotheses. The first hypothesis is that platelet accumulation and activation create distinct microenvironments within the different regions of a hemostatic plug. The second hypothesis is that integrin outside-in signaling plays a role in shaping the structure and transport properties of the core region. Hemostatic thrombus formation was observed in mouse cremaster muscle arterioles in response to a penetrating injury. Fluorescently-labeled albumin and dextran were used to measure the spaces between platelets (a measure of porosity) and the velocity of solute transport within the thrombus.

Results: When measured over the full thrombus, porosity and solute transport velocity were reduced in the spaces between platelets compared to the blood flow outside of the thrombus. An analysis by regions showed that this reduction was greater in the core than in the outer shell of loosely adherent platelets. To examine the impact of integrin outside-in signaling, we utilized mice in which two Tyr residues in the cytoplasmic domain of the β chain of $\alpha_{IIb}\beta_3$ integrin were replaced with Phe (diYF). Prior studies have shown that this double substitution impairs outside-in signaling and causes unstable platelet aggregation. It also results in defective fibrin clot retraction despite normal fibrinogen binding. We found diYF mice formed smaller hemostatic plugs following vascular injury. The decrease in total platelet accumulation was specifically due to reduced formation of the core region, while platelet recruitment and retention in the shell region were unaffected. We also found a decrease in fibrin generation, indicating a reduction in thrombin activity within the hemostatic plug.

Conclusions: Taken together, these results support the hypothesis that tight platelet packing provides a protected microenvironment in which bioactive molecules such as thrombin may accumulate to support platelet activation. They also identify a novel role for $\alpha_{IIb}\beta_3$ outside-in signaling in the structure of the hemostatic response and the regulation of hemostatic plug formation. The authors acknowledge support from the NHLBI and the American Heart Association.

OC 24.2

Rap signaling is central to the pro-adhesive and pro-coagulant platelet response

Getz TM[1], Stefanini L[1], Piatt R[1], Paul D[1], Cholka A[1], Walton BL[1], Wolberg AS[1], White GC III[2] and Bergmeier W[1]

[1]UNC, Chapel Hill, NC; [2]Blood Research Institute Milwaukee, USA, Milwaukee, WI, USA

Background: The small GTPase Rap1B, which accounts for ~90% of Rap GTPases in platelets, plays a critical role for platelet activation at sites of vascular injury. In our previous work, we have identified signaling by the guanine nucleotide exchange factor CalDAG-GEFI (CDGI) and the ADP receptor P2Y12 as the main pathways leading to the activation of all Rap GTPases in platelets. Platelets lacking functional CDGI and P2Y12 were strongly defective in all major platelet responses, including phosphatidylserine exposure and microvesiculation.

Aim: In this study, we aimed to better understand how Rap1B and other Rap GTPases contribute to platelet activation. We therefore evaluated the pro-adhesive and pro-coagulant response of platelets from *Rap1b−/−* and clopidogrel-treated *CalDAG-GEFI−/−* (CDGI/clopidogrel) mice.

Methods: Integrin activation (JON/A-PE), granule secretion (anti-P-selectin), and PS exposure (annexinV) were assayed by flow cytometry. Platelet-dependent thrombin generation was measured by calibrated automated thrombography (CAT). Platelet adhesion under flow conditions was studied in heparin anticoagulated blood perfused over fibrillar type I collagen. Thrombus formation *in vivo* was monitored in the cremaster muscle microcirculation after laser injury.

Results: Integrin activation and granule secretion were virtually abolished in CDGI/clopidogrel platelets activated with convulxin (Cvx) or PAR4p. Both responses, however, were only partially reduced in *Rap1b−/−* platelets and no dose response shift was observed. Consistent with these findings, Rap1B-deficient platelets adhered significantly better to collagen under flow conditions than CDGI/clopidogrel cells. In contrast, coated platelet formation, induced by simultaneous stimulation with Cvx and PAR4p, was almost completely abolished in both CDGI/clopidogrel and *Rap1b−/−* platelets. This defect in PS exposure and microvesiculation was not due to impaired calcium mobilization in *Rap1b−/−* platelets. Coated platelet formation was also significantly reduced in platelets treated with inhibitors to Rac1 and Erk MAP kinases, two downstream targets of Rap1b. Consistent with these studies, platelet-dependent thrombin generation was significantly reduced in *platelet-rich-plasma* from *Rap1b−/−*and CDGI/clopidogrel mice. *In vivo*, thrombus formation was observed in Rap1b−/− but not CDGI/clopidogrel mice. In ongoing studies, we will measure thrombus size/stability and fibrin formation at sites of vascular injury to determine if impaired platelet procoagulant activity contributes to the protection of Rap1b−/− mice from thrombosis.

Conclusions: We here demonstrate a critical role for Rap1b signaling in coated platelet formation and platelet-dependent thrombin generation *in vitro*. Our studies further suggest that other Rap isoforms compensate for the pro-adhesive, but not the pro-coagulant signaling provided by Rap1B.

OC 24.3

Contribution of intrinsic and extrinsic coagulation pathways to whole blood clot and thrombus formation under flow

Swieringa F[1], Kuijpers MJE[1], Lamers M[1], Renné T[2], Heemskerk JWM[1] and Van Der Meijden PEJ[1]

[1]Maastricht University, Maastricht, the Netherlands; [2]Karolinska Institutet and University Hospital, Stockholm, Sweden

Background: The formation and composition of platelet-fibrin clots under flow is a dynamic process, tightly controlled by the vascular surface and the local rheological conditions, both of which are different for the arterial and venous systems. Arterial thrombi are enriched in platelets, while venous thrombi are more enriched in fibrin. This implies a different way of control of the thrombus-forming process by thrombin at arterial or venous conditions. Thrombin can be generated via the extrinsic coagulation pathway via factor (F)VIIa (triggered by tissue factor, TF) or the intrinsic pathway via FXIIa (collagen, polyphosphates). How these two pathways contribute to thrombus formation under various flow conditions is largely unknown.

Aim: To study the contribution of thrombin formed via the extrinsic and intrinsic pathways to the formation of platelet-fibrin clots under flow conditions, mimicking those in veins and arteries.

Methods: Blood was used from healthy donors, patients and coagulation factor-deficient mice. Platelet-fibrin clot formation was measured by perfusion of recalcified whole blood over microspotted surfaces, triggering the extrinsic (TF) and/or intrinsic (collagen) coagulation pathways. Employed shear rate were 150, 1000 and 1500/s. Microspots contained low or high contents of TF (1–10 pg/spot) and collagen (5–25 ng/spot). Line-scanning confocal microscopy gave time traces of focal accumulation of fluorescently-labeled platelets ($DiOC_6$), fibrin (AF647-fibrinogen) and coagulant platelet activation (FITC-annexin A5).

Results: Perfusion of human blood over TF alone failed to produce platelet adhesion or fibrin formation. Perfusion over a surface trigger-

ing the extrinsic and intrinsic pathways (TF/collagen) resulted in platelet-enriched thrombi at high shear rate and fibrin-enriched thrombi at low shear rate. This was attributed to a reduced platelet accumulation at low shear (mean covered area 16 ± 2%), compared to the higher shear conditions (41 ± 4% and 47 ± 5%). The time of onset and extent of fibrin formation were comparable for all shear rates. Lowering of the TF content delayed the time to fibrin formation, and FXIIa inhibition caused a further delay, but was without effect on early platelet deposition. Lowering of the collagen content produced the formation of fewer but larger thrombi, with more activated platelets. Lowering of collagen also delayed fibrin formation from 3 ± 1 to 5 ± 1 min, an effect that was mimicked by FXII deficiency. Interestingly, regardless of the surface type and shear rate, thrombin inhibition by hirudin decreased the number and size of platelet thrombi, while fibrin formation was abolished. At various shear rates, deficiency of murine FVIII or FIX, but to a lesser extent FXII, resulted in smaller size thrombi with fewer activated platelets and in little fibrin formation. These effects were maintained in the absence of TF activity, and were normalized upon addition of recombinant FVIII or FIX, respectively.

Conclusion: Thrombin formed by both intrinsic as well as extrinsic pathways stimulates the formation of large multi-platelet thrombi at all shear rates, but most strongly contributes to platelet-fibrin formation at low shears and low collagen. Under flow, TF accelerates this effect of thrombin via FVIII and FIX activation.

OC 24.4

The polyphosphate-binding proteins in the human platelet secretome

Smith SA, Yau PM and Morrissey JH

University of Illinois, Urbana, IL, USA

Background: Inorganic polyphosphates (polyP) are negatively charged, linear phosphate polymers that are secreted from dense granules of activated human platelets. We and others have shown that polyP has potent prohemostatic, prothrombotic and proinflammatory properties. In particular, we have shown that polyP binds to several blood clotting proteins and modulates certain steps of the clotting cascade. Given the extensive platelet secretome, we hypothesized that polyP released from platelet dense granules may interact with proteins secreted following platelet activation. Identification of these proteins could provide important clues regarding new biological functions for polyP, beyond its previously documented roles in modulating the plasma clotting cascade.

Aim: To identify the major polyP-binding proteins in the platelet secretome.

Methods: Purified polyP was covalently end-labeled with biotin, which in turn was bound to streptavidin-conjugated magnetic beads (Dynabeads). The resulting polyP-Dynabeads were incubated with releasates obtained from human platelets that had been activated with TRAP (thrombin-receptor agonist peptide). PolyP-Dynabeads were then washed repeatedly and the polyP-binding proteins were eluted with 1 M NaCl. The eluted proteins were identified by MudPIT (Multidimensional Protein Identification Technology) using 2D liquid chromatography and mass spectrometry.

Results: Using MudPIT, we unambiguously identified a total of 157 candidate polyP-binding proteins from the platelet secretome. These proteins fell into several functional groups, including: *Hemostasis-related proteins* (prekallikrien, fibrinogen, plasminogen, multimerin, protein S, and clotting factors V, XIII, and XI); *Serpins* (protease nexin-1, protein C inhibitor, α1-antitrypsin, plasminogen activator inhibitor 1); *Prolyl-isomerases* (parvulin, cyclophilin, and FKBP3 peptidyl-prolyl cis-trans isomerase); *Complement proteins* (factors B, H, C1q, C3, C4A, and C5); *Growth factors* (VEGF, PDGF, and TGFbeta-binding protein); *Adhesive receptors and ligands* (CD42c, CD42d, and fibronectin); *Apolipoproteins* (apoB and apoJ); and *Others* (thrombospondin, beta-thromboglobulin, platelet factor 4, and heparanase). In addition, several proteins with no known function were also identified.

Conclusions: We have now identified a number of new candidate polyP-binding proteins in the human platelet secretome, including proteins known to participate a multitude of cellular processes. We previously reported that polyP triggers the contact pathway of blood clotting, accelerates certain downstream clotting reactions, enhances fibrin clot structure and delays fibrinolysis. Our new findings indicate that polyP may bind to certain serpins and other known regulators of the clotting system, suggesting additional sites at which polyP may modulate hemostasis and thrombosis. Furthermore, given the nature of additional candidate polyP-binding proteins in the platelet secretome, polyP may also influence platelet-mediated inflammatory responses, cell-cell interactions, angiogenesis, intercellular communication, and apoptosis. The many roles of polyP in platelet biology are likely to expand, an area that clearly warrants further investigation.

OC 25.1

A novel and selective proteasome inhibitor modulate expression of molecules linked to coagulation and angiogenesis independent of NF-kB activation in tumor cells

Chudzinski-Tavassi AM, Pacheco MTF, Berra CM, Moraes KLP, Sciani, Bosch RV and Onuki

Biochemistry and Biophysics Laboratory, São Paulo, Brazil

Amblyomin-X is a Kunitz-like recombinant protein which has shown inhibitory properties on factor Xa and tenase complex and also inhibits proteasome in human tumor cell lines but not in normal human fibroblasts. Proteasome inhibition generates aggresomes transported by dynein in which K48 and K63-linkage of ubiquitin signaling is involved. This signaling is also important to NF-kB pathway and studies have been reported that recruitment of dynein translocate p65/p50 heterodimer to act as an activator of a large number of genes like tissue factor (TF), TFPI and VEGF. The p50 subunit is generated by its precursor molecule p105 that is processed by the proteasome. TFPI not only inhibits thrombin generation by inhibiting FXa which then inactivates TF/FVIIa complex but also can act as adhesive ligand for cancer cells to extracellular matrices. Additionally, TF can enhance tumor metastasis and VEGF contributes to angiogenesis. The present study intends to evaluate the pathway that links coagulation and cancer in the antitumoral mechanism of action of Amblyomin-X.

Cell culture: Normal human fibroblasts, Mia-PaCa-2 and SK-Mel-28 tumor cell lines.

Real-Time PCR: SYBR® green based reaction.

Aggresome formation: Commercial kit for flow cytometry and fluorescence microscopy. Ubiquitin signaling: Flow cytometry with specific K63 and K48 antibodies.

Western blotting: Cell lysis and immunoblotting after SDS-PAGE with specific antibodies. NF-kB, dynein, Ubc13, VEGF and TF gene expression were upregulated in Mia-PaCa-2 after 24 h of Amblyomin-X treatment. Only NF-kB, Ubc13 and dynein genes were upregulated in SK-Mel-28. Fibroblasts have normalized the expression levels of the targets analyzed in 24 h. Protein expression of some targets has been modified in tumor cells while only p50 has been modulated in fibroblasts. Amblyomin-X induced aggresome formation only in tumor cells. The K63 linkage signal was increased in all cell lines and corroborates with Ubc13 upregulation while K48 linkage has decreased only in tumor cells. Amblyomin-X inhibits proteasome and induces aggresome formation only in tumor cells. The molecule seems to trigger NF-kB signaling as a cell response in fibroblasts but do not target proteasome and cell death. Our data indicates that NF-kB, although high expressed, can be inactive to transcript its targets like TFPI, TF and VEGF, since proteasome inhibition can prevent degradation of IKB, a natural inhibitor of NFkB, which in turns, could remain sequestered and inactive. Moreover, protein expression of p50 subunit has also

decreased in tumor cells and its precursor p105 has increased indicating that proteasome inhibition had affected its proteolysis. Additionally, K63 signaling for aggresome formation and decreased K48 signaling as a cell response, contributes to inactivate NF-kB pathway. Therefore, increased mRNA levels of TF and VEGF in Mia-PaCa-2 indicates that these targets may have its gene expression activated by another pathway independent of NFkB activation, as a tumor response to Amblyomin-X treatment. Aggresome formation and increased TFPI expression may contribute respectively to cell apoptosis and metastasis reduction, effects already observed *in vivo* in previous data, in the mechanism of action of Amblyomin-X.

OC 25.2

Prostate cancer cells signal through Syk-PKC intracellular molecules to induce platelet secretion

Mitrugno A and Moran N
Royal College of Surgeons in Ireland, Dublin, Ireland

The critical role played by platelets in cancer metastasis is mostly related to their function as a dynamic reservoir of effector molecules which can facilitate tumour vascularisation, growth and metastasis. However, very little information is available about the mechanism of tumour cell induced platelet secretion (TCIPS) or the molecular machinery by which this mechanism is elicited. In the current study, we demonstrate that tumour cells directly induce platelet exocytosis. The molecular mechanisms involved in this response were explored. Platelet secretion was assessed by employing a luminometric assay capable of detecting ATP/ADP released by platelet dense granules following activation. Pre-incubation of platelets with increasing doses (10^2–10^5 cells/mL) of human colon cancer cells (Caco-2) or prostate cancer cells (PC3M-luc) for up to 60 min resulted in a marked dose-dependent secretion from dense granules. Importantly, tumour cell induced platelet secretion (TCIPS) preceded aggregation and was related to the malignancy of the tumour cell line used. Because tumour cell induced platelet aggregation (TCIPA) can be modulated by pharmacological inhibitors of ADP, we first investigated the effect of ADP receptor antagonists, MRS2395 ($P2Y_{12}$) and MRS2179 ($P2Y_1$), on TCIPS mediated by PC3M-luc. In contrast to aggregation, inhibition of platelet ADP receptors enhanced tumour cell mediated platelet secretion, reinforcing the hypothesis that TCIPA is secondary to secretion. We next examined the role of TxA_2receptors (TP) and molecular mediators of TxA_2 synthesis (PLA2 and COX-1), PAR-1 Thrombin receptor, the integrin cell adhesion molecule, GpIIbIIIa and the intracellular signalling molecules Src and PI3K by examining the effects of pharmacological inhibitors. Whereas blockade of TP, PAR-1, PLA2, COX-1, Src and PI3K did not reduced platelet secretion in response to PC3M-luc cells, inhibition of integrin GpIIbIIIa, with either Abciximab or CD41/SZ22 monoclonal antibodies, significantly decreased TCIPS (maximum secretion reduced to $74.24 \pm 9.6\%$; $^*P < 0.05$). Finally, in order to gain specific insights into the molecular machinery of TCIPS we next chose to target Protein kinase (PKC) and upstream intracellular molecules, Syk and PLC, whose role in agonist induced-platelet secretion has been well established. In the presence of GF109203X, PKC broad-spectrum inhibitor, platelet ATP/ADP release was completely abolished in response to PC3M cells (100 vs 28.05 ± 7.4; $^{***}P < 0.0001$) suggesting an essential role for PKC. Importantly, TCIPS was also dramatically inhibited after platelet pre-treatment with either Bay 61-3606 (100 vs 59.09 ± 9.36; $^{**}P < 0.01$) or Piceatannol (100 vs 20.57 ± 5.88; $^{***}P < 0.0001$), both potent Syk inhibitors. In contrast, the broad spectrum PLC inhibitor U73122, had no effect on platelet secretion induced by cancer cells. In conclusion, this study showed for the first time, the capability of cancer cells to directly promote platelet secretion and has identified the major molecular mediators involved in this response, providing initial guidelines for developing promising anti-metastatic therapies.

OC 25.3

A role of CLEC-2 in tumor growth and metastasis

Shirai T, Inoue O, Hirayama K, Endo H, Fujii H, Utida-Sato H, Ozaki Y and Suzuki-Inoue K
University of Yamanashii/Japan, Chuo-shi; [2]University of Yamanashii, Chuo, Yamanashi, Japan

Background: A platelet activation receptor CLEC-2 binds to podoplanin on the surface of tumor cells and facilitates hematogenous tumor metastasis. It has been reported that anti-podoplanin antibody inhibited hematogenous tumor metastasis in experimental lung metastasis model in mice. However, a role of CLEC-2 in tumor growth and lymphogenous metastasis has not been elucidated to date.
Aims: The aim of the study is to investigate roles of CLEC-2 in tumor growth and lymphogenous metastasis. We also investigate whether CLEC-2 blockade inhibits hematogesous metastasis.
Methods: CLEC-2 chimeras and wild type (WT) chimeras were generated by transplantation of fetal liver cells from CLEC-2−/− or CLEC-2+/+ embryos. B16F10, a podoplanin-positive melanoma cell line, and 3LL, a podoplanin-negative lung carcinoma cell line, were inoculated intravenously into the tail vein of CLEC-2-chemeras or WT-chimeras. After 20 days, the mice were killed and the surface lung metastatic foci were counted. Podoplanin-positive B16F10 cells and podoplanin-negative B16 cells were incubated with or without washed CLEC-2−/− or CLEC-2+/+ platelets and cell numbers were counted after 2 days. B16F10 and 3LL were inoculated into foot pads of CLEC-2- or WT-chimeras. After 20 days, metastasis to the lymph nodes and tumor growth were analyzed by flow cytometry and gravimetry, respectively.
Results: The number of B16F10 metastatic foci in the lung of CLEC-2 chimera was significantly inhibited compared with that in the lung of WT chimeras, whereas no difference was observed in the case of 3LL. Co-culture with WT platelets significantly increased the cell number of B16F10, but not that of 3LL. On the other hand, the numbers of both cell lines did not significantly increase in the presence of CLEC-2−/− platelets. To our surprise, tumor growth and lymphatic metastasis is rather facilitated in CLEC-2-chimera compared with WT chimera.
Conclusions: CLEC-2 in platelets binds to podoplanin in tumor cells and facilitates hematogenous tumor metastasis *in vivo* and tumor growth *in vitro*. However, lymphatic metastasis and tumor growth *in vivo* are facilitated in the absence of CLEC-2. This difference may be due to effects of CLEC-2 on tumor angiogenesis and/or tumor lymphangiogenesis, which is now under investigation.

OC 25.4

Observational study of alternative platelet parameters to predict bleeding risk in patients with hematological malignancies (ATHENA study)

Estcourt L[1], Powter G[2], Harding K[2], Howgate S[3], Dyer C[2], Mumford AD[4], Stanworth S[5], Harrison P[3] and Murphy M[5]
[1]University of Oxford; [2]NHS Blood and Transplant; [3]Oxford University Hospitals NHS Trust, Oxford; [4]University Hospitals Bristol NHS Foundation Trust, Bristol; [5]Nuffield Department of Medicine, Oxford, UK

Background: Previous studies have shown that the platelet count is a poor predictor of bleeding in severely thrombocytopenic patients with hematological malignancies.
Aims: The aim of this study was to evaluate whether other routinely available platelet parameters (mean platelet volume (MPV), platelet mass, immature platelet fraction (IPF), absolute immature platelet number (AIPN), platelet function analyzer-100 (PFA-100)) were better at predicting bleeding than the platelet count.
Methods: A prospective cohort study of adults with a haematological disorder undergoing intensive chemotherapy or stem cell transplant (ISRCTN81226121) at two UK centers (Bristol and Oxford) between September 2010 and September 2012. The study inclusion criterion

was development of thrombocytopenia (platelet count $\leq 50 \times 10^9$/L. From the start of thrombocytopenia, the participants underwent daily formalized bleeding assessments until platelet count recovery, hospital discharge, death, or for up to 30 days. Alongside routine tests, additional venous blood samples were collected into EDTA collection tubes thrice weekly for detailed analysis of platelet parameters. Analysis of the data was performed using a generalized linear model with binomial family and logit link function clustered on patient identity to account for repeated measures.

Results: All 50 participants were followed up until study completion. The baseline characteristics were: mean age 51.0 years; male (33/50); diagnosis (leukemia 16/50; lymphoma 14/50; myeloma 9/50; other 11/50); treatment (chemotherapy 4/50; allograft 33/50; autograft 13/50). Bleeding symptom data were available for 99.7% of study days. The participants had median 3 days of bleeding (any severity) (interquartile range (IQR) 0–6); and median 11 days (IQR 8–16) with platelet count $\leq 50 \times 10^9$/L.

The unadjusted odds ratio (OR) for bleeding the following day when the platelet count was $\leq 50 \times 10^9$/L was 0.98 (95% confidence interval (CI) 0.97–1.00; $P = 0.03$) for the total platelet count; 0.60 (95% CI 0.41–0.88; $P = 0.008$) for the AIPN; and 0.97 (95% CI 0.90–1.03; $P = 0.346$) for the IPF. The AIPN result remained statistically significant when adjusted to account for the total platelet count [OR 0.68 (95% CI 0.52–0.90; $P = 0.007$)]. The IPF result remained statistically non-significant when adjusted to account for the total platelet count [OR 0.94 (95% CI 0.89–1.01; $P = 0.079$)]. The total platelet count result was no longer statistically significant when adjusted to account for the AIPN [OR 1.00 (95% CI 0.99–1.02; $P = 0.442$)] or IPF [OR 0.99 (95% CI 0.97–1.01; $P = 0.246$)]. The full blood count analyzer was unable to report MPV in 36.2% of samples when the platelet count was $\leq 50 \times 10^9$/L, precluding further analysis of MPV and platelet mass. In the PFA-100 test, firm closure occurred in only 9.3% of samples using the PFA-ADP cartridge and 22.4% of samples using the PFA-Innovance cartridge when the platelet count was $\leq 50 \times 10^9$/L.

Conclusions: This preliminary study suggests that the AIPN is a better predictor of bleeding than the total platelet count. The MPV, platelet mass and PFA-100 closure times were not useful because these variables were frequently not estimable during thrombocytopenia.

Ang-(1-7) and Mas decrease thrombosis in Bdkrb2−/− mice by increasing NO and prostacyclin to reduce platelet spreading and GPVI activation

Fang C[1], Stavrou E[1], Schmaier A[2], Grobe N[3], Chen A[1], Nieman T[1], Adams GN[1], LaRusch GA[1], Bilodeau ML[1] and Schmaier AH[1]

[1]Case Western Reserve University, Cleveland, OH; [2]University of Pennsylvania, Philadelphia, PA; [3]Wright State University, Dayton, OH, USA

Background: Little is known how the plasma kallikrein-kinin (KKS) and renin angiotensin systems (RAS) influence thrombosis risk *in vivo*. We reported (Blood 2006;108:192) that bradykinin B2 receptor deleted mice (*Bdkrb2−/−*) have delayed thrombosis and prolonged bleeding times due to elevation of angiotensin II (AngII) and angiotensin receptor 2 (AT2R) producing increased plasma nitric oxide (NO) and prostacyclin (PGI_2). New investigations in *Bdkrb2−/−* show that the angiotensin receptor 1 antagonist losartan lowers AngII levels but does not reduce thrombosis time. These data indicate that lowering of AngII alone is insufficient to change thrombosis risk. Further, the significance of the long bleeding time in *Bdkrb2−/−*needs characterization.

Aims: Identify additional mechanism(s) for thromboprotection and the precise influence of increased plasma NO and PGI_2 on platelet function in *Bdkrb2−/−*.

Methods: Real-Time PCR was used to measure expression of ACE and Mas. AngII, angiotensin-(1-7) (Ang-(1-7)), NO, PGI_2, cGMP and cAMP were examined by ELISA. Mas, AT2R, GPVI and pSyk were examined by immunoblot. Thrombosis times were assayed using Rose Bengal and Ferric Chloride on carotid arteries. Bleeding time was by tail incision. Platelet function was examined on aggregation, adhesion, spreading, and flow cytometry with JON/A antibody for murine activated integrin $\alpha_{2b}\beta_3$ and WugE9 antibody for P-selectin. JAQ-1 characterized murine GPVI. Platelet spreading was on collagen, GFOGER, and fibrinogen. Platelet flow cytometry was after α- or γ-thrombin, CRP, or convulxin stimulation. Fibrinogen binding was used to characterize ADP stimulation. Bone marrow (BM) transplantation determined if the spreading and thrombosis defects were due to host factors.

Results: New investigations show that *Bdkrb2−/−* have elevated Ang-(1-7), the breakdown product of AngII. Renal mRNA and protein for the receptor of Ang-(1-7), Mas, is also increased. Blockade of Mas with its antagonist A-779 in *Bdkrb2−/−* shortens thrombosis times (58 ± 4 min to 38 ± 4 min), bleeding times (170 ± 13 s to 88 ± 8 s) and lowers plasma nitrate (22 ± 4 mM to 15 ± 5 mM), and 6-keto-$PGF_{1\alpha}$ (259 ± 103 pg/mL to 132 ± 58 pg/mL) ($P < 0.01$ in all cases). *Bdkrb2−/−* platelets have normal α- and γ-thrombin-induced activation and ADP-induced fibrinogen binding. *Bdkrb2−/−* platelets express increased NO, cGMP and cAMP with reduced spreading on collagen, GFOGER, or fibrinogen. *In vivo* treatment with A-779 or combined L-NAME and nimesulide corrects the spreading defect on collagen. *Bdkrb2−/−* platelets have decreased convulxin- or CRP-induced JON/A and P-selectin expression that are partially corrected by *in vivo* A-779, nimesulide, or L-NAME treatment. *Bdkrb2−/−* platelets have reduced ligation-dependent Syk phosphorylation. *In vitro* pretreatment of normal platelets with carbaprostacyclin reduced spreading on collagen and GFOGER, and attenuated Syk phosphorylation and CRP activation. Transplantation experiments show that normal BM in *Bdkrb2−/−* hosts produced platelets with a spreading defect and delayed thrombosis. Transplantation of *Bdkrb2−/−*BM into normal hosts produced platelets with normal spreading and normal occlusion times.

Conclusion: In *Bdkrb2−/−*, combined AT2R and Mas over-expression produce elevated plasma PGI_2 and NO leading to acquired platelet defects in spreading on integrins and attenuated CRP activation, that contribute to thromboprotection. In addition to contact activation, the KKS influences thrombosis risk through the RAS in the vessel wall.

OC 26.2

GRP/Ucma: a novel member of the class of vitamin K-dependent proteins is involved in osteochondrogenic transdifferentiation of vascular smooth muscle cells

Willems BAG[1], Chatrou MLL[2], Kusters HM[2], Theuwissen E[1], Simes D[3], Vermeer C[1], Reutelingsperger CPM[2] and Schurgers LJ[2]

[1]VitaK/Maastricht University; [2]Maastricht University, Maastricht, the Netherlands; [3]CCMAR, Faro, Portugal

Background: Vitamin K-dependent carboxylation of coagulation factors is essential to proper blood coagulation. Warfarin, a frequently prescribed vitamin K-antagonist, impairs blood coagulation by inhibiting carboxylation. Warfarin also inhibits functionality of vitamin K-dependent proteins which are not participating in blood coagulation but which are involved in maintaining homeostasis of the blood vessel wall. Gla Rich Protein (GRP/Ucma) is a recently discovered novel member of the class of vitamin K-dependent proteins and is potentially a target of warfarin. Its (patho)physiological function, however, is still unknown. It has been shown that GRP/Ucma suppresses osteogenic differentiation of pre-osteoblasts *in vitro*. We and others demonstrated that GRP/Ucma is expressed by vascular smooth muscle cells (VSMCs) and that atherosclerotic plaques, especially calcified ones, contain GRP/Ucma. Since VSMCs can transdifferentiate towards an osteochondrogenic phenotype, we hypothesized that GRP/Ucma sup-

presses osteochondrogenic differentiation of VSMCs and, thereby, contributes to preventing mineralization of the blood vessel wall.
Aims: To investigate the potential role of GRP/Ucma in osteogenic differentiation of VSMCs *in vitro*.
Methods: Human VSMCs were cultured in M199 medium containing 20% fetal bovine serum (FBS). Mouse VSMCs were isolated from aortas dissected from wild type (WT) and $GRP^{-/-}$ C57BL6 mice and maintained in DMEM containing 10% FBS. Cells were pretreated with control medium, heparin (200 U/mL), PDGF-BB (20 ng/mL) or Pi (2 mM) in control medium. After pretreatment, cells were incubated with medium supplemented with 5.4 mM calcium. Mineralization was quantified and normalized to total protein content. Aortic sections from $ApoE^{-/-}$ mice on warfarin were stained immunohistochemically for GRP/Ucma.
Results: In the control, limited mineral depositions were observed whereas in PDGF-BB treated VSMCs, disperse mineralization throughout the entire extracellular matrix was present. Pi treatment of cells resulted in severe mineral depositions, concentrated at focal areas in the extracellular matrix. We observed that VSMCs treated with Pi underwent morphological changes in addition to nodule formation. These nodules co-localized with the focal areas of mineral deposition. Cells treated with heparin underwent morphological changes as well, but not to the extent of nodule formation or mineral deposition. Additionally, heparin treated VSMCs stopped proliferating. In mice VSMCs, mineralization was significantly increased in $GRP^{-/-}$ VSMCs as compared to WT VSMCs. The mechanism for this difference in mineralization remains to be determined. As compared to human VSMCs, initial experiments in which mouse VSMCs were pretreated with Pi, showed no noticeable effect on further increasing mineralization or nodule formation. Immunohistochemical staining of GRP mainly localized to osteochondrogenic cells, present in atherosclerotic plaques of $ApoE^{-/-}$ mice.
Summary: Osteochondrogenic differentiation of VSMCs is a key feature of the vulnerable atherosclerotic plaque. Pi pretreatment of primary VSMCs can mimic this transdifferentiation *in vitro*. Preliminary data in $GRP^{-/-}$ VSMC suggests a role for GRP/Ucma in suppressing osteochondrogenic differentiation of VSMCs *in vitro* thereby attenuating mineralization. In atherosclerotic plaques, osteochondrogenic cells were positive for GRP/Ucma. Future experiments aim at identifying mechanisms through which molecular pathways GRP/Ucma exerts this effect.

OC 26.3
Accelerated senescence of cord blood endothelial progenitor cells in premature neonates is driven by SIRT1 decreased expression

Simoncini S[1], Frizera-Vassallo P[1], Ligi I[1], Sabatier F[1], Simeoni U[1], Magdinier F[2], Dignat-George F[1] and Anfosso F[1]
[1]Inserm UMR_S 1076; [2]Inserm UMR_S 910, Marseille, France

Background: Since their discovery, endothelial progenitor cells have emerged as an important biological marker for a variety of cardiovascular disease. Both their numbers and their angiogenic potential are decreased in diseases associated with a cardiovascular risk (diabetes, atherosclerosis, …). Among them a specific subtype called Endothelial Colony Forming Cells (ECFC) have been recently characterize both in cord and peripheral blood. These cells emerged as adherent colonies after culture of mononuclear cells under endothelial proceedings conditions and developed as typical endothelial monolayer. They have proliferative potential, express endothelial markers, have the capacity to incorporate into neo-vessels and participle in maintaining of vascular homeostasis *in vivo*. Preterm birth is known to critically increase cardiovascular risk at aduldhood. Epidemiological and experimental studies indicate that early vascular dysfunction occurs in preterm neonates with a low birth weight (PT) and is associated with an impairment of angiogenic properties of ECFC.
Aims: We hypothesized here that ECFC dysfunction might result from premature senescence and investigated the underlying mechanisms.
Methods: We used a cohort of ECFC isolated from cord blood of PT ($n = 29$) or term ($n = 18$) neonates. This research was approved by local ethic committee, and all the parents have provided written informed consent for the use of cord blood in accordance with the Declaration of Helsinki. Senescence of ECFC was judged by senescence-associated ß-galactosidase assay (SA-ß-Gal), morphological appearance and cell cycle analysis.
Results: PT-ECFC displayed an accelerated senescence inversely correlated with gestational age, sustained by growth arrest and increased SA-ß-Gal activity. Increased p16*INK4A* expression together with reduced p21*WAF* level, in the absence of telomere shortening, indicated that premature PT-ECFC ageing results from stress-induced senescence rather than replicative senescence. Interestingly, we found that expression of SIRT1, a NAD-dependent deacetylase possessing anti-aging activities, was dramatically decreased at the RNA and protein levels in PT-ECFC. SIRT1 deficiency was subsequent to epigenetic silencing of its promoter and triggered accelerated senescence of PT-ECFC. Transient *SIRT1* overexpression or chemical-induction by resveratrol treatment led to a significant reduction of SA-ß-Gal staining and senescence in PT-ECFC, accompanied by increased cell proliferation. Furthermore, resveratrol treatment reversed senescence and rescued PT-ECFC angiogenic defect in a SIRT1-dependent manner.
Conclusions: We demonstrate that SIRT1 decreased expression drives accelerated senescence of PT-ECFC, and acts as a critical determinant of PT-ECFC angiogenic defect. Moreover, our findings lay news grounds for understanding the increased risk of cardiovascular diseases of individuals born prematurely and open new perspectives for a targeted therapeutic strategy.

OC 26.4
Endothelial progenitor outgrowth cells on ePTFE grafts respond to hemodynamic preconditioning

Hinds MT, Glynn J and Anderson EJD
Oregon Health & Science University, Portland, USA

Background: Endothelial progenitor outgrowth cells (EOCs), isolated from whole blood, are a promising cell source for the endothelialization of small diameter vascular graft materials. The ability to incorporate a native endothelium onto a graft may reduce the thrombosis and intimal hyperplasia, the role of hemodynamics on the ability of EOCs to regulate thrombosis and intimal hyperplasia is unknown. This work was performed using well-established, non-human primate models for testing EOC-coated ePTFE grafts *ex vivo* and *in vivo*. The utilization of EOCs and ePTFE vascular grafts represent a clinically-relevant cell source and biomaterial for determining the effects of hemodynamic preconditioning on graft performance.
Aims: This study examined the hypothesis that hemodynamic preconditioning of EOCs reduces their *in vitro* markers of thrombosis and inflammation, reduces platelet and fibrin accumulation on an *ex vivo* shunt, and reduces initial hyperplasia in an *in vivo* graft implant.
Methods: EOCs were seeded on collagen-coated ePTFE grafts and stimulated with 15 dynes/cm^2 steady fluid shear stress. All assays were performed on paired static and hemodynamic stimulated EOC-seeded grafts. EOC expression of key markers of thrombosis and inflammation [CD39, endothelial protein C receptor (EPCR), thrombomodulin (TM), tissue factor (TF), tissue factor pathway inhibitor (TFPI), endothelial nitric oxide synthase (eNOS), intracellular adhesion molecule (ICAM), vascular cell adhesion molecule (VCAM), and platelet endothelial cell adhesion molecule (PECAM)] were quantified using quantitative RT-PCR. EOC production of activated protein C (APC) and factor Xa (FXa) was quantified. Using a well-established arteriovenous shunt model, platelet accumulation and fibrin deposition during 60 min of non-anti-coagulated blood flow were quantified. Additionally, EOC-seeded grafts were implanted with bilateral controls as aorto-iliac bypass grafts for 4 weeks. After explant, histology sections of

the grafts were analyzed for the degree of intimal hyperplasia at each anastamosis.

Results: Hemodynamic stimulation of EOC altered their expression of thrombosis and inflammation-related genes. The hemodynamic stimulation increased EOC expression of genes for CD39 (1.13 ± 0.72, fold change compared to 0 for static), and EPCR (1.18 ± 0.73), while there was a trend for increased expression of TF and TM. Additionally, EOC expression of TFPI (−0.53 ± 0.70) and ICAM (−1.25 ± 1.27) decreased significantly. Hemodynamic stimulation increased EOC production of both FXa ($P = 0.05$) and APC ($P = 0.091$). Interestingly, in *ex vivo* studies, there was no significant difference in platelet accumulation between the hemodynamically stimulated EOCs and the static samples, yet the hemodynamic stimulation did significantly decrease fibrin deposition on the EOC-coated grafts ($P = 0.05$). Initial *in vivo* studies suggest that ePTFE grafts coated with hemodynamically stimulated EOCs decrease the intimal hyperplasia area of 1.49 ± 0.32 mm^2 compared to static cell-seeded grafts with 2.64 ± 0.65 mm^2.

Summary/Conclusion: In a clinically relevant vascular graft model, hemodynamic stimulation of EOCs induced significant changes in gene expression and production of FXa, yet platelet adhesion to the grafts were not significantly altered. Experiments with oscillatory flow-stimulated EOCs in the arteriovenous shunt model are currently underway. Interestingly, *in vivo* implantation of the EOC seeded grafts indicated the hemodynamic stimulation altered the vascular healing response and decreased the extent of anastomotic intimal hyperplasia at 1 month.

OC 27 – Antiphospholipid Syndrome

OC 27.1

Antiphospholipid antibodies induce NF-kB activation exclusively from endosomal compartments of human monocytes

Brandt KJ[1], Fickentscher C[1], Frizon de Lamotte G[1], Boehlen F[2], Reber G[2], Kruithof E[2] and De Moerloose PH[2]

[1]University of Geneva; [2]University Hospital of Geneva, Geneva, Switzerland

Background: Antiphospholipid antibody syndrome (APS), caused by pathogenic antiphospholipid antibodies (aPLA), is an auto-immune disease associated with thrombosis and/or recurrent fetal loss. We recently demonstrated TLR2 as one of the TLRs involved in the recognition of aPLA by monocytes. While TLR4 is known to transmit signals from both plasma membrane and endosomal compartments, less is known about the function of endosomal trafficking on TLR2 signaling.

Methods: Primary human monocytes and HEK-Blue2[TRADEMARK] cells were treated with aPLA or with TLR2 ligands, <i*e*. LTA and Pam_3CSK_4, in the presence of endocytosis inhibitors. Expression of TNF and tissue factor (TF) as well as NF-B activation was assessed. In order to evaluate the importance of receptor internalization, clathrin expression was reduced by siRNA and NF-kB activation assessed after treatment with aPLA and TLR2 ligands. Endocytosis of biotinylated LTA and Pam_3CSK_4 or aPLA was evaluated by flow cytometry.

Results: We demonstrate that blocking antibodies to TLR2, TLR1 or TLR6, as well as antibodies to the TLR co-receptor CD14, significantly decreased TNF and TF responses to aPLA, Pam_3CSK_4 and LTA. TLR2 ligands internalization is observed in primary human monocytes and HEK-Blue2[TRADEMARK] cells and we show that NF-kB-mediated cell activation is dependent on ligand internalization. Pharmacological blockade and siRNA approaches revealed the importance of the clathrin/dynamin-dependent endocytic pathway in ligand-induced NF-kB activation. In addition, aPLA, Pam_3CSK_4 and LTA immobilized on large beads, preventing their internalization, are unable to activate NF-kB. Furthermore, in a similar manner as TLR4, we demonstrate that TLR2 ligand uptake is regulated by CD14. Unlike LPS, TLR2 ligands do not induce phosphorylation of IRF-3 or IFNβ expression. Finally, NF-kB activation induced by aPLA, Pam_3CSK_4 and LTA in HEK-Blue2[TRADEMARK] cells or primary human monocytes is regulated by CD14-dependent endocytosis.

Conclusions: Our results reveal that TLR2-ligand complexes are internalized via clathrin- and CD14-dependent endocytosis into primary human monocytes and HEK-Blue2[TRADEMARK] cells; endocytosis of these complexes is required for NF-kB activation. This highlights a new important aspect of the regulation of TLR2-dependent signaling. Although present at the cell surface, TLR2-ligands induce NF-kB activation exclusively from an endosomal compartment. This study provides new insight that may be used for the development of novel therapies through the control of endocytosis and/ or the blockade of CD14 with monoclonal antibodies. In addition, the evidence that TLR1 and TLR6 play also a role in the pathogenesis of aPLA contributes to a better understanding of the antiphospholipid syndrome.

OC 27.2

Beta2-glycoprotein I selectively inhibits the procoagulant functions of thrombin

De Filippis V[1], Acquasaliente L[1], Pozzi N[1], Frasson R[1], De Cristofaro R[2], Arcovito A[2], Banzato A[1] and Pengo V[1]

[1]University of Padova, Padova; [2]Catholic University, School of Medicine, Rome, Rome, Italy

Background: β2-glycoprotein I (b2GpI) is an abundant plasma protein has been identified as the major antigen in the antiphospholipid syndrome (APS), a severe thrombotic autoimmune disease. Notwithstanding, the physiological role of β2GpI is still elusive. β2GpI is composed of five domains and displays remarkable structural heterogeneity, varying from a circular closed conformation to an open J-shaped conformation. Thrombin exerts either procoagulant and anticoagulant functions in haemostasis. The procoagulant functions mainly entail conversion of fibrinogen into fibrin and activation of platelets through cleavage of type-1 Protease Activated Receptor (PAR1), whereas the anticoagulant functions are related to its ability to activate the anticoagulant protein-C (PC) in the presence of thrombomodulin (TM). Thrombin accomplishes most of its activities through its hydrolytic active site and two positively charged exosites.

Aim: Quantify and mapping β2GpI-thrombin interaction; study the effect of physiological concentrations of β2GpI (4 μM) on the procoagulant (fibrin generation and platelet aggregation) and anticoagulant (active protein C generation) functions of thrombin.

Methods: Binding of β2GpI to thrombin was studied by Surface Plasmon Resonance on a Biacore X100 instrument. The effect of β2GpI on thrombin-mediated fibrin generation and platelet aggregation was investigated on gel-filtered platelets by turbidimetric and immunocytofluorimetric measurements. The activity of β2GpI on platelet aggregation was also evaluated on healthy donors whole blood by Multiple Electrode Aggregometry. PC activation by thrombin was monitored by measuring the rate of S2366 hydrolysis. Thrombin mutants were expressed in E. coli and *in vitro* refolded. The structural model of β2GpI-thrombin complex was obtained by HEX-6.3 software.

Results: Biacore analysis of β2GpI-thrombin interaction yields $K_d = 34$ nM. Displacement experiments, carried out with specific binders of thrombin exosite-1 (hirugen and HD1 aptamer) or exosite-2 (fibrinogen γ'-peptide and HD22 aptamer) and with thrombin mutants (Arg73Ala and Arg101Ala), having one of the two exosites selectively compromised, indicate that both exosites are involved in β2GpI binding. β2GpI does not affect the affinity of the enzyme for some active-site inhibitors, like p-aminobenzamidine and the N-terminal domain 1–47 of hirudin. β2GpI significantly prolong the clotting time in fibrin generation assay and hinders platelets aggregation ($IC_{50} = 0.36$ mM) by inhibiting cleavage of PAR1 on intact platelets ($IC_{50} = 0.32$ mM). Finally, β2GpI does not alter the ability of thrombin to generate the active protein C, in the presence or in the absence of TM. The docking model indicates that domains III to V of β2GpI interact with thrombin exosites, without masking the protease active pocket.

Conclusion: β2GpI binds to thrombin at both exosites, while leaving the protease active site accessible. β2GpI inhibits the key procoagulant properties of thrombin, without affecting its unique anticoagulant function. These results allow us to speculate that under physiological conditions β2GpI may function as a plasma-soluble anticoagulant protein acting in those vascular compartments where the more potent TM-thrombin pathway poorly functions, as in the large vessels, or is even absent, as in the brain vasculature. Our results can also explain the positive correlation existing between the presence of neutralising auto-antibodies against β2GpI and thrombotic manifestations in APS patients.

OC 27.3

High levels of β2-glycoprotein I protects against secondary major adverse cardiovascular events after PTCA

Van Holten TC[1], Urbanus RT[1], Jukema WJ[2], Pijls HJ[3], Van Zonneveld AJ[2], Pasterkamp G[1], Hoefer I[1], Roest M[1] and De Groot PG[1]

[1]UMC Utrecht, Utrecht; [2]Leiden UMC, Leiden; [3]Catharina Hospital, Eindhoven, the Netherlands

Background: We have recently published that high circulating levels of beta2-glycoprotein I is associated with a reduced risk of myocardial infarction in elderly men (Blood 2009; 114: 3656–61).
Aim: Here we studied whether high levels of plasma beta2-Glycoprotein I has also a predictive value for secondary cardiovascular events after percutaneous transluminal coronary angioplasty (PTCA).
Methods: Four hundred andfifty-seven patients with angina pectoris and scheduled for PTCA were included in four different Dutch hospitals (Catharina Hospital, Eindhoven, University Medical Centre, Maastricht, University Medical Center, Leiden and University Medical Center, Utrecht). Informed consent from all patients was obtained. Approval from local ethics committees was obtained. Patients were followed for 60 and 90 days after invention for major adverse cardiovascular events (MACE) being myocardial infarction, PTCA, coronary artery bypass graft or death by cardiovascular disease. Receiver operating characteristic (ROC) curves were used to determine cut-off values for beta2-glycoprotein I.
Results: Of the 457 patients included, 312 were male. The median age was 62 years. At 60 days follow up, 13 patients suffered from MACE, at 90 days 15 individuals suffered from MACE. The mean level of beta2-glycoprotein I in patients without MACE was 444 ± 10.6 μg/mL, the mean level of beta2-glycoprotein I in patients with MACE was 355 ± 50.6 μg/mL. At 60 days of follow-up, a HR of 0.10 (95% ci: 0.03–0.32) for levels above 156 μg/mL beta2-glycoprotein was found. At 90 days of follow-up, a HR of 0.30 (95%ci: 0.11–0.92) for above 368 μg/mL was found. No correlation was found between plasma levels on von Willebrand factor and the risk of MACE after 60 or 90 days. The protection for MACE associated with increased levels of beta2-glycoprotein I did not attenuate after adjusting for age and gender and HS-CRP for both follow-up periods (60 days: HR 0.11, 95% ci 0.03–0.35; 90 days HR 0.32, 95% ci 0.11–0.95), but after adjusting for NT-proBNP the association at 90 days disappeared.
Conclusion: High circulating levels of beta2-glycoprotein I is associated with a reduced risk of recurrence of cardiovascular events after PTCA.

OC 27.4

Anti-β2-glycoprotein I antibodies inhibit the prothrombinase complex in a phospholipid-independent manner

Pennings MT[1], Drost-Verhoef S[1], Meijers JC[2], De Groot PG[1] and Urbanus RT[1]

[1]University Medical Center Utrecht, Utrecht; [2]Academic Medical Center Amsterdam, Amsterdam, the Netherlands

Background: Antiphospholipid syndrome (APS) is diagnosed in patients with thrombosis or pregnancy morbidity who have persistent antiphospholipid antibodies. Of all antiphospholipid antibody subtypes, the presence of the phospholipid-dependent coagulation inhibitor known as lupus anticoagulant (LA) correlates best with thrombosis. The current paradigm is that LA is caused by competition between antibody-β2-glycoprotein I (β2-GPI) complexes and vitamin K-dependent coagulation factors for binding sites on negatively charged phospholipids. Different observations we have made challenge this axiom.
Aim: To study the effects of LA-inducing antibodies on coagulation:
Methods: We analyzed the effects of LA-inducing monoclonal anti-β2GPI antibody 3B7 and different variants of β2GPI on contact activation and thrombin generation. Moreover, we studied the effects of 3B7 and β2-GPI on intrinsic tenase and prothrombinase complexes.
Results: Lowering the phospholipid concentration in thrombin generation experiments results in both an increased lag time and a decrease in endogenous thrombin potential (ETP). In contrast, addition of 3B7 induced an increase in lag time and had no effect on ETP, suggesting phospholipid-independent effects on coagulation. We further analyzed the effects of 3B7-β2GPI complexes on coagulation with purified coagulation factors. β2GPI in complex with 3B7, but not β2GPI or 3B7 alone, inhibited the prothrombinase complex for 30% and the intrinsic tenase complex for 70%. Substitution of wild-type β2GPI for a mutant that does not bind to phospholipids (β2GPI W316S) abolished the inhibitory effects of antibody-β2GPI complexes on the intrinsic tenase complex, whereas inhibition of the prothrombinase complex remained unaltered. Surface plasmon resonance analysis showed that complexes of 3B7 and wild-type β2GPI or the W316S mutant, but not β2GPI itself, directly interact with activated factor V (K_D: 25 nM), but not with factors VIII, IX, X, and II. To determine the contribution of inhibition of either the intrinsic tenase complex or the prothrombinase complex to lupus anticoagulant activity, we performed an APTT in the presence or absence of the thrombin inhibitor argatroban. As expected, 3B7 prolonged the APTT. Addition of argatroban and analysis of factor Xa generation with a fluorescent substrate showed that 3B7 did not inhibit factor Xa formation in plasma.
Conclusion: Anti-β2-glycoprotein I antibodies differentially interfere with the coagulation reaction. Whereas β2GPI-antibody complexes compete with the intrinsic tenase complex for phospholipid binding, prothrombinase inhibition is independent of phospholipid binding. In plasma, inhibition of the prothrombinase complex seems to be the determining step in anti-β2GPI antibody-induced lupus anticoagulant. We hypothesize that this inhibition is mediated by a direct inhibition of factor Va.

OC 27.5

Pathological mechanisms of antiphospholipid antibodies in trophoblastic cell fusion

Marchetti T[1], Cohen N[2] and De Moerloose PH[1]

[1]University Hospital of Geneva; [2]Laboratory of Hormonology, Geneva, Switzerland

Background: Antiphospholipid Syndrome (APS) is an acquired thrombophilia associated with arterio-venous thrombosis and/or obstetrical complications, and the presence of antiphospholipid antibodies (aPL) in the plasma of patients. It has been suggested that aPL could affect directly invasion and fusion of trophoblastic cells. However, their

pathogenicity is poorly understood. Toll-like Receptors (TLR) have been implicated in pathological activation of aPL on endothelial cells, monocytes and platelets.
Although inflammation has been incriminated in this process, it has been hypothesized that imbalance between autophagy and apoptosis could be related to trophoblastic fusion impairment. Moreover, TLR4 has been implicated in autophagy signalling cascade.
Hydroxychloroquine (HCQ) is an antimalarial molecule safely used during pregnancy and associated with a reduction in fetal losses in lupic patients with aPL.
Aims: The aim of our study was to evaluate the effects and pathological mechanisms of aPL on trophoblastic cell fusion and whether they could be reversed by HCQ treatment.
Methods: The human choriocarcinoma cell line BeWo is regularly used as a cell culture model to mimic trophoblastic cell fusion, triggered by forskolin. Cells were treated or not with forskolin in presence or not of antiβ2GP1 antibodies (antiβ2GP1-Ab) for 48 h. Fusion index (FI) was then determined by immunocytochemistry (ICC) and biochemical differentiation was determined by ELISA measuring hCG secretion. Antiβ2GP1-Ab toxicity was determined by MTT assay.
To assess the role of TLR in the pathological mechanisms of antiβ2GP1-Ab on BeWo cells, TLR expression was determined by qPCR and Western Blot (WB) in the presence or not of antiβ2GP1-Ab. Effects of membranous TLR (respectively 1, 2, 4 and 6) on BeWo cell fusion were then evaluated by ICC, using specific blocking molecules such as anti-TLR2 and 4 antibodies and peptide binding for TLR1/6, 2 and 4, or decreased expression of TLR4 (shRNA) in the presence or not of antiβ2GP1-Ab.
After determining a potent role of TLR4 in trophoblastic cell fusion impairment by antiβ2GP1-Ab, we investigated the expression of some target genes of TLR4 signalling cascades.
Interactions between HCQ and TLR4 were then determined by FI by ICC, hCG secretion by ELISA, qPCR and WB.
Results: FI and hCG secretion are decreased by addition of antiβ2GP1-Ab in a dose-dependent way, independently of antibodies toxicity. In the presence of antiβ2GP1-Ab and anti-TLR4 blocking antibodies, BeWo cell fusion and hCG secretion were restored.
In BeWo cells transfected with shRNA TLR4, antiβ2GP1-Ab do not affect cellular differentiation. Increase in autophagy gene expression (Beclin-1, GABARAPL1 and LC3B) was observed in BeWo cells stimulated by antiβ2GP1-Ab, but not in BeWo cells transfected with shRNA TLR4 plasmid and stimulated by antiβ2GP1-Ab, suggesting that antiβ2GP1-Ab treatment triggers autophagy and that autophagy was at least partly regulated by the TLR4 pathway.
Treating BeWo cells with HCQ decreased autophagy gene and TLR4 expression, and restored BeWo cell differentiation.
Summary/Conclusion: Antiphospholipid antibodies interfere with fusion process and biochemical differentiation of BeWo cells *via* TLR4. HCQ decreases TLR4 and autophagy gene expression and restores differentiation of BeWo cells suggesting its therapeutic interest for aPL affected pregnancies.

OC 27.6

MicroRNA expression in monocytes and neutrophils from primary antiphospholipid syndrome and systemic lupus erythematosus patients. Potential value as biomarkers of atherothrombotic disease

Perez-Sanchez C[1], Ruiz-Limón P[2], Aguirre MA[2], Barbarroja N[2], Rodriguez-Ariza A[2], Collantes E[2], Cuadrado MJ[3], González-Conejero R[4], Martínez C[5] and López-Pedrera C[2]
[1]IMIBIC; [2]IMIBIC/Reina Sofia Hosp., Córdoba, Spain; [3]Lupus Unit, St Thomas Hospital, London, UK; [4]Regional Centre for Blood Donation, University of Murcia, Murcia, Spain; [5]University of Murcia, Murcia, Spain

Background: miRNAs are key players in a wide range of molecular and pathophysiological processes. Recently, several studies have examined their involvement in the pathogenesis of systemic lupus erythematosus (SLE) and antiphospholipid syndrome (APS). However, no study has evaluated the expression profile of miRNAs associated with the cardiovascular and the atherothrombotic risks observed in these autoimmune diseases.
Aims: To identify the miRNAs involved in the regulation of pro-inflammatory, prothrombotic and oxidative status in SLE and APS patients.
Patients and Methods: *In silico* search was performed to find putative binding sites of miRNAs in various mRNA of proinflammatory factors (MCP-1, MIP-1a, IL-1b, -2, -6, -8, -17, -23, VEGF and tPA) prothrombotic proteins (TF and PAR2) and oxidative stress markers (peroxides production, antioxidant enzymes and mitochondrial activity) was performed. Neutrophils and monocytes were isolated from 11 APS patients, 17 SLE patients and 26 healthy donors. Selected miRNAs were quantified by RT-PCR. The expression of proinflammatory proteins was evaluated by flow cytometry and flow cytomix. Antioxidant enzymatic activity was also quantified. C*arotid intima*-media *thickness*(CIMT) was measured as a marker of early atherosclerosis.
Results: *In silico* search reported miR-124a, -125a, -125b, -146a, -155, and -222 as candidates to regulate the expression of several proinflammatory proteins and oxidative status observed in SLE and APS patients. The expression levels of these miRNAs appeared significantly decreased in neutrophils from SLE and APS patients compared to healthy donors. However, only the miR-124a was found reduced in monocytes from SLE and APS patients, while miR-146a was increased. The expression levels of the miRNAs analyzed in SLE patients negatively correlated with the disease activity (SLEDAI) and the anti-dsDNA titers. In addition, an inverse correlation between anticardiolipin antibody titers and miRNAs expression was found in APS patients. Moreover, significant negative correlations between miRNAs expression and molecules related to mitochondrial dysfunction and oxidative stress were observed in APS monocytes and neutrophils. Inflammatory proteins showed specificity in their association with miRNAs depending on the disease analyzed, so that in APS inverse correlations were found with VEGF-R1, IL-8 and PAR2, while in LES significant correlations related to IL-2, IL-6, IL-10 and MCP.1 Low levels of miR-146a in APS and SLE neutrophils, and miR-155 in APS neutrophils, were associated with pathological CIMT. The presence of thrombotic events in APS and SLE was associated with low levels of miR-146a and miR-155 in neutrophils and monocytes.
Conclusions: miRNAs differentially expressed in monocytes and neutrophils from APS and SLE patients correlate with markers of autoimmunity, inflammation, thrombosis and oxidative stress, and are associated with atherothrombotic processes. Therefore, these miRNAs might be considered potential biomarkers of pro-inflammatory pathology in both atherosclerosis and autoimmune diseases.

OC 28 – Coagulation Factor VIII

OC 28.1

Factor VIII: where is it synthesized?

Fahs SA, Hille M, Jozwiak M, Shi QK, Weiler H and Montgomery R
BloodCenter of Wisconsin, Milwaukee WI, USA

Background: The precise source(s) of coagulation factor VIII (F8) synthesis has remained controversial. Production of coagulation-related proteins in liver is well documented, but this and other recent studies challenge historical paradigms attributing coagulation F8 expression specifically to hepatocytes. Tissue surveys confirm significant hepatic as well as renal transcription of F8 mRNA, with much lower levels in spleen and many other organs. *In situ* localization of synthesis has not clarified our understanding. At the cellular level, endothelial cells (EC) or sinusoidal EC and a number of other alternative cell types throughout the body have been implicated in F8 synthesis. This prompted our study of F8 synthesis in the whole animal by genetic techniques.

Aims: Defining the site of F8 synthesis using cell-type specific F8 gene inactivation in the mouse.
Methods: We developed a conditional knockout of the murine F8 gene. 'Floxed' ($F8^F$) mice, which express normal levels of plasma F8, were generated by inserting LoxP sites flanking exons 17/18. When $F8^F$ mice are crossbred with various Cre-expressing mouse strains, excision of exons 17/18 occurs, causing F8 gene inactivation in Cre-expressing cells and their progeny. We utilized six strains of mice with differing tissue-specific synthesis of Cre recombinase. Plasma F8 activity was measured by chromogenic assay. Gene inactivation and expression were assessed by PCR and RT-PCR analysis.
Results: Germline (Meox2)-Cre expression results in an inherited, severe hemophilic F8 knockout ($F8^{KO}$) phenotype, while tissue-specific Cre's cause gene inactivation only in specific cell types, depending on the promoter controlling Cre expression. While Alb-Cre drives F8 gene inactivation with high efficiency and specificity in hepatocytes, affected mice are phenotypically indistinguishable from normal controls. In contrast, marked reduction in plasma F8 was seen in all EC-expressing Cre strains tested. Tek-Cre and Cdh5-$Cre^{(Spe)}$ resulted in mice with nearly undetectable plasma F8, while a less efficient Cdh5-$Cre^{(Mlia)}$ model results in a 30–40% reduction in F8. Tek-Cre is expressed with high efficiency in EC generating a functional F8-knockout phenotype, typically with a complete absence of plasma F8. Since each of these 'endothelial' Cre strains express Cre in both hematopoietic and endothelial compartments, we studied a hematopoietic cell-expressed Vav1-Cre model which resulted in modest, but significant F8 reduction. Although plasma F8 activity is undetectable in germline $F8^{KO}$ and affected Tek-Cre mice, low level transcription of exon 17/18-deleted $F8^{KO}$ message continues in liver as two alternatively-spliced mRNA variants expressed at roughly equivalent levels. There is no evidence that these transcripts result in measureable F8 (similar transcripts are identified in current hemophilic mice).
Summary/Conclusion: The completely normal phenotype following F8 gene inactivation by Alb-Cre suggests no significant F8 synthesis in hepatocytes. In contrast, gene inactivation in EC causes reduced plasma F8 activity ranging from moderate to a severe hemophilia phenotype dependent on endothelial Cre efficiency. All currently available EC-specific and hematopoietic-specific Cre models exhibit variable penetrance into both endothelial and hematopoietic compartments that is presumably due to their differentiation from a common hemangioblast progenitor. Altogether our data indicates that F8 synthesis is primarily a function of endothelial cells and not hepatocytes.

OC 28.2

Factor VIII A2 domain stabilization enhances potency and efficacy in hemophilia A mice

Leong L[1], Thompson T[1], Tran K[1], Liu P[1], Sim D[1], Wakabayashi H[2], Fay PHJ[2], Kretschmer P[1], Laux V[1] and Murphy JE[1]
[1]Bayer HealthCare Pharmaceuticals, US Innovation Center, San Francisco, CA; [2]University of Rochester Medical Center, Rochester, NY, USA

Background: An important negative regulator of activated factor VIII (FVIIIa) cofactor activity is subunit dissociation. FVIII molecules with stabilized activity have been generated by elimination of charged residues at the A1-A2 and A2-A3 interfaces. These molecules exhibited reduced decay rates as part of the factor Xase complex and retained their activities under thermal and chemical denaturing conditions (Wakabayashi H, et al. *J Thromb Haemost*. 2009;7[3]:438–444).
Aim: We describe the potency and efficacy of one such variant, D519VE665V, a mutant of B-domain–deleted FVIII (BDD-FVIII).
Methods: FVIII activity was measured using the two-stage chromogenic assay and the one-stage activated partial thromboplastin time (aPTT) assay. Hemostasis parameters were measured using the thrombin generation assay (TGA) and rotational thromboelastometry (ROTEM). Efficacy was assessed in Hemophilia A (HemA) mice subjected to various models of vascular injury (tail clip, laser injury, and tail vein transection).
Results: D519VE665V potency was increased two-fold by the two-stage chromogenic assay relative to BDD-FVIII. The potency was equivalent to BDD-FVIII by the one-stage aPTT assay. Compared with BDD-FVIII, D519VE665V demonstrated enhanced TGA and ROTEM responses: four-fold by peak thrombin and two-fold by clot initiation time, respectively. Efficacy testing in HemA mice demonstrated enhanced efficacy for D519VE665V vs BDD-FVIII. By both the tail clip and tail vein transection models, D519VE665V had a two-fold increase in efficacy, whereas by laser injury, fibrin-thrombi accumulation was greater (four-fold increase in fibrin and eight-fold increase in platelet accumulation, respectively) compared with BDD-FVIII.
Conclusion: These results demonstrate that stabilizing A2 subunit association of FVIII can prolong its cofactor activity and lead to enhanced protection against vascular injury in an animal model of hemophilia.

OC 28.3

Activated blood coagulation factor VIII interacts with cluster III complement-type repeats of the low-density lipoprotein receptor-related protein

Kurasawa JH, Shestopal SA, Lee TK and Sarafanov AG
U.S. Food and Drug Administration, Rockville, USA

Background: It was previously found that the clearance of coagulation factor VIII (FVIII) is mediated by the low-density lipoprotein receptor-related protein (LRP) (Lenting P., et al, 1999 and Saenko E., et al, 1999). Within LRP, FVIII was shown to interact with the complement-type repeats (CRs) of clusters II and IV, but not with cluster III. In LRP, clusters II and IV bind a majority of its known ligands, which exceeds 30. At the same time, cluster III is considered to serve a minor role, since it was shown to interact only with alpha-2-macroglobulin receptor-associated protein (RAP), an intracellular LRP chaperon, and lipoprotein ApoE, constituting beta-VLDL. Previously, we found that upon activation, FVIII (FVIIIa) has some changes in regard to its binding with LRP; in particular, it exposes a high-affinity site in the A2 domain for the clusters II and IV (Sarafanov A., et al, 2007).
Aims: In the present work, we tested in more detail how activation of FVIII affects its interaction with LRP, specifically with its cluster III.
Methods: Recombinant fragments of LRP and their mutant forms were expressed in a baculovirus system. The proteins were purified using combination of affinity and size exclusion chromatography and assessed for the binding with FVIII in a surface plasmon resonance assay.
Results: We found that FVIII and FVIIIa each bind to both clusters II and IV, while FVIIIa produced considerably higher signals. Strikingly, FVIIIa was found to bind cluster III in the same fashion, whereas FVIII remained essentially inactive towards this cluster. The FVIIIa binding to the cluster III was strongly inhibited by an anti-FVIII antibody fragment, iKM33, known to have an epitope within the C1 domain of FVIII light chain. Next, we found that a heterodimer A1/A3-C1-C2, known to be a physiological product of FVIIIa dissociation, also interacted with cluster III and this process was inhibited by iKM33. These data demonstrate that thrombin cleavage of FVIII results in exposure of a binding site on its light chain for LRP cluster III. To map the interactive site on this cluster, we tested binding of FVIIIa with nine CR doublets that spanned cluster III. We identified a number of positive binding CR doublets overlapping an extended region of adjacent CRs within the cluster; specificity of these interactions was confirmed by the inhibitory effect of iKM33 as above. Finally, we tested interaction of FVIIIa and cluster III with a mutated conservative residue within each active binding CR. We observed a significant decrease in the binding that also confirmed the cluster III mapping data.
Summary/Conclusion: We demonstrated that cluster III of LRP binds activated FVIII, and characterized the interactive sites within these

molecules. We also showed that FVIIIa binds LRP clusters II and IV, and is more active for the binding to all three clusters than non-activated FVIII. Altogether, our data indicate that LRP serves a role in clearance of activated FVIII *in vivo*, and cluster III is involved in this process.

OC 28.4

Identification of monoclonal antibodies protecting activated Factor VIII against spontaneous inactivation by A2 subunit dissociation

Ostergaard H, Lambert K, Clausen JT, Balling K, Faber JH, Reedtz-Runge SL, Kjalke M and Holmberg HL
Novo Nordisk A/S, Maaloev, Denmark

Background: Factor VIII (FVIII) is an essential cofactor of the coagulation system. Conversion of FVIII to the active cofactor (FVIIIa) occurs by distinct cleavages that convert it into a heterotrimer consisting of A1 and A2 subunits non-covalently associated with the activated light chain. FVIIIa is inherently unstable and inactivates with a half-life of 2 min as a consequence of spontaneous A2 subunit dissociation. The physiological importance of this mechanism for down-regulation of the coagulation response is suggested by the association of mild haemophilia with point mutations in FVIII that accelerate A2 dissociation.
Aim: Based on the hypothesis that regulation of FVIIIa activity is limiting the generation of thrombin and consequently clot formation under conditions of mild or moderate haemophilia, a screen for antibodies protecting FVIIIa against A2 subunit dissociation was undertaken.
Methods: BALB/c mice were immunized with FVIII and derivatives, and hybridomas prepared by standard methods.
Results: Screening of hybridoma supernatants in a FVIIIa decay-dependent FXa generation assay identified two non-competing classes of antibodies with a hit rate of about 1%. To map their recognition sites on FVIII, hydrogen-deuterium exchange mass spectrometry was employed which identified non-overlapping epitopes in the A2 and A3 domains in agreement with distinct functional properties of the two classes. In particular, antibodies targeting the A3 domain were found to interfere with FVIII activation, while antibodies specific for A2 (represented by 4F143) bound with high affinity to FVIII/FVIIIa and neither affected VWF binding nor activation by thrombin. In a FXa generation assay, 4F143 reduced the apparent rate of FVIIIa decay up to four-fold and normalized the accelerated inactivation of the FVIII S289L variant associated with mild haemophilia A. Interestingly, the protective effect was strictly dependent on the bivalency of 4F143 and also on the presence of a phospholipid membrane surface. Titration studies demonstrated that the membrane dependency was bell-shaped with a progressively declining effect of 4F143 as the vesicle concentration was increased above a peak concentration of 5 μM. Taken together, these data are consistent with a mechanism by which 4F143 simultaneously engages two FVIIIa molecules on the membrane surface. This configuration would promote re-assembly of dissociated FVIIIa by retaining the A2 domain in close proximity to the membrane and thus to any surface-bound A1-light chain fragment available for reassociation.
To explore whether such mechanism would promote sustained thrombin generation in the presence of a physiological surface, 4F143 was tested in congenital haemophilia A plasma supplemented with washed human platelets. In this system, 4F143 was found to restore thrombin generation in the presence of 0.3% FVIII to the level obtained with 1–2% FVIII in the absence of antibody.
Conclusion: In conclusion, the present work demonstrates a novel antibody-based approach to intercept a regulatory pathway of relevance in mild haemophilia A. *In vivo* studies are undertaken to investigate the impact of this pathway on the bleeding phenotype in general haemophilia.

OC 28.5

Clearance of FVIII in a rat perfused liver model and isolated primary liver cells in the presence and absence of VWF

Appa RS[1], Loftager M[1], Pelzer H[1], Karpf M[1], Kjalke M[1], Stennicke HR[1] and Smedsrod B[2]
[1]*Novo Nordisk A/S, Maaloev, Denmark;* [2]*University of Tromsø, Tromsø, Norway*

Background: FVIII is predominantly cleared in the liver. Members of the low density lipoprotein receptor family including the low density lipoprotein-related protein, LRP, have been previously reported to mediate clearance of FVIII either directly[1] or indirectly via VWF[2]. Other potential receptors include macrophage mannose receptor (MMR)[3]. In a genome-wide association study, SNPs in the region of stabilin-2 (Stab2, scavenger-like receptor) were found to correlate with VWF and FVIII levels[4].
Aims: To analyse the relative importance of a selection of clearance receptors in FVIII elimination using an isolated perfused liver model and primary liver cell cultures in the absence and presence of VWF.
Methods: Rat livers were isolated and cannulated via the portal vein and vena cava to generate an *ex vivo* recirculating model. Recombinant human FVIII (2–5 nM) was added to a Krebs Henseleit/BSA perfusate buffer with or without either plasma-derived VWF (20 nM), a VWF fragment containing the FVIII binding site (VWF-D'D3A1) (35 nM), ligands for LRP (receptor associated protein, RAP, 0.7 or 1.2 μM) or MMR (Man6Lys5, 500 nM). Samples from the perfusate were analysed for FVIII and VWF concentrations by activity and antigen assays. For primary liver cell studies, cells were isolated via collagenase perfusion of rat livers. Our previous hepatocellular studies identified hepatocytes (parenchymal cells, PCs) and liver sinusoidal endothelial cells (LSECs) as having a major role in FVIII elimination; therefore, these cells were isolated and separately plated in tissue culture plates. Iodine (^{125}I) or fluorescently labelled FVIII was incubated with cells for up to 2 h with or without VWF, VWF-D'D3A1, RAP, different MMR ligands, as well as, an antibody against Stab2. Membrane bound and internalized radioactivity was subsequently quantified.
Results: Both FVIII and VWF disappeared from the perfusate over time. Almost 80% of FVIII dosed was cleared after 60 min, and approximately 25% of VWF dosed was cleared in the presence and absence of FVIII. As expected, VWF and VWF-D'D3A1 reduced FVIII uptake in the rat livers and in primary liver cells. In contrast, FVIII clearance was not affected by RAP neither when added as a single bolus dose together with FVIII nor when constantly infused during the perfusion. RAP was, however, able to decrease t-PA clearance. Man6Lys5 also had no effect on FVIII liver clearance. In cell studies, an excess concentration of RAP and MMR ligands did not reduce FVIII binding or internalization. Interestingly, an anti-Stab2 antibody inhibited FVIII internalization in LSECs.
Summary/Conclusion: VWF and VWF-D'D3A1 reduced FVIII clearance in isolated rat livers and blocked uptake in primary liver cells, while an excess concentration of ligands to either LRP or MMR did not. In addition, Stab2 may play a role in FVIII uptake in LSECs. These data suggest that other major clearance pathways may be involved in FVIII clearance when LRP and MMR are blocked and that more than one receptor is probably involved in liver clearance of FVIII.

OC 28.6

Difference in the membrane-bound organization of human and porcine factor VIII

Stoilova-McPhie S, Miller JL, Dalm D and Grushin K
University of Texas Medical Branch, Galveston, TX, USA

Factor VIII (FVIII) is a multidomain blood plasma glycoprotein, which causes hemophilia A when defective or deficient. FVIII biological function is a co-factor to the serine protease Factor IXa (FIXa) within the membrane-bound tenase complex assembled on the activated platelet surface during the propagation phase of coagulation. Recombinant human FVIII (hFVIII) concentrate is the most efficient cure for Hemophilia A. Recombinant porcine FVIII (pFVIII) is used in patients developing inhibitory antibodies against the human form. Both hFVIII and pFVIII large single chain glycoproteins composed of six domains: A1-A2-B-A3-C1-C2. Recombinant human and porcine FVIII are usually expressed without the B domain and consist of two non-covalently bound polypeptide chains: the light chain (LC) of the A3-C1-C2 domains holding the membrane interaction sites and the heavy chain (HC) of the A2-A1 domains holding the main FIXa interaction sites. The sequence identity between the two proteins is 84%. pFVIII also binds to human FIXa *in vivo*, forming functional tenase complexes. Cryo-EM is unique in giving direct structural information at closest to physiological conditions and subnanometer resolution. Cryo-EM can study the macromolecular structure of proteins and protein complexes in a lipid environment, since the samples are fully hydrated and the lipid bilayer well resolved.

We have combined cryo-EM and image analysis to study the membrane-bound structure of two recombinant Factor VIII forms, human and porcine helically organized on functionalized single lipid bilayer nanotubes (LNT) resembling the activated platelet surface.

Our results demonstrate unambiguously that human and porcine FVIII, differ significantly in their organization when assembled helically onto LNT at the same conditions (lipids, protein to lipid ration, buffer, salt concentration and temperature). The cryo-EM structures of both proteins at intermediate resolution (~12–14 Å) show that the pFVIII-LNT are tightly packed with a shallow twist angle, resulting in wider tubes. The hFVIII-LNT has a more pronounced twist, extending the protein-protein interaction in the plane of the membrane. Fitting of the hFVIII-BDD structure within the cryo-EM maps confirms a reorganization of the LC domains for both human and porcine FVIII forms, such as the C2 domain interacts directly with the membrane. The C1 domain does not interact directly with the membrane forming an extended interface with the A1 and A3 domain supporting the A2 domain. This organization of the FVIII-LC domains has been previously observed for helically organized hFVIII-LC on LNT, as well as for hFVIII organized in membrane-bound 2D crystals.

Resolving the FVIII membrane-bound organization for different FVIII forms (human and porcine) by cryo-EM reveals the structural role of the significant Hemophilia A mutations and completes our knowledge for FVIII function in hemostasis. Understanding the implication of the difference in sequence for the FVIII membrane-bound organization will help design better drugs and therapies against Hemophilia A.

OC 29 – Fibrinolysis – I

OC 29.1

Pharmacological inhibition of PAI-1 activity prolongs the lifespan of klotho mice, a murine model of accelerated aging

Eren M[1], Miyata T[2] and Vaughan E[1]
[1]Northwestern University, Chicago, IL, USA; [2]Tohoku University, Sendai, Japan

Background: Plasminogen activator inhibitor type-1 (PAI-1) expression is stimulated by biologic stressors that promote cellular senescence and its induction is a validated senescence indicator *in vitro* and *in vivo*. Furthermore, PAI-1 expression levels are inversely proportional to telomere length. Senescent cells accumulate in aging tissues, which likely contributes to physiological aging. In humans, age-dependent increases in PAI-1 levels have been observed in plasma and in a variety of clinical conditions including obesity, insulin resistance, and inflammation. Additionally, PAI-1 levels increase in animals in plasma and in the heart as a function of age. Interestingly, *klotho* (*kl*/*kl*) mice, a murine model of accelerated aging, develop age-dependent increases in PAI-1 levels in plasma, and in tissues, including the kidney, aorta, and heart. Klotho protein regulates fibroblast growth factor-23 (FGF23) signaling and phosphate excretion in the kidney. *kl*/*kl* mice are deficient in the Klotho protein and display numerous phenotypic abnormalities resembling human aging, including emphysema, osteoporosis, arteriosclerosis, and ectopic calcification associated with a markedly shortened average lifespan (64 days).

Aims: To test the hypothesis that PAI-1 is a critical determinant of the aging phenotype in *kl*/*kl* mice. We aimed to investigate the effects of pharmacological inhibition of PAI-1 activity on senescence and survival in a murine model of aging.

Methods: *kl*/*kl* mice were administered a novel PAI-1 antagonist, TM5441 (100 mg/kg/day) mixed in the standard chow diet. Plasma samples were collected at baseline and at 2 and 4 months of treatment. Body weights of mice were monitored weekly. Plasma levels of FGF23 were measured using a commercially available ELISA kit.

Results: While no *kl*/*kl* mice lived longer than 120 days, 100% of *kl*/*kl* mice receiving TM5441 were alive beyond that time point. PAI-1 inhibition prolonged the survival of *kl*/*kl* mice by 4.6-fold with 3/5 of mice receiving TM5441 alive at age 265 days ($P = 0.0004$ by Log-rank test). TM5441 treatment also improved the overall health of *kl*/*kl* mice in terms of weight gain and activity levels. We observed that after 4 months of TM5441 treatment, plasma levels of FGF23 were reduced by 65% in *kl*/*kl* mice ($P = 0.018$).

Conclusion: These results confirm the hypothesis that PAI-1 is a critical determinant of the aging phenotype in *kl*/*kl* mice and clearly demonstrate that pharmacologic inhibition of PAI-1 activity may serve as a novel therapeutic approach to prevent senescence and aging-associated diseases.

OC 29.2

Global gene expression profiling in PAI-1 knockout murine heart and kidney: molecular basis of cardiac-selective fibrosis

Ghosh AK, Murphy SB, Kishore R and Vaughan E
Northwestern University, Chicago, IL, USA

Background: Fibrosis is due to excessive accumulation of extracellular matrix proteins during wound healing. Fibrosis can affect every organ in the body and is one of the major contributors to morbidity and mortality in humans. At present, there is no effective therapy for organ fibrosis. Although extensive studies have been done to understand the molecular basis of fibrosis, there is a lack of fundamental information on the initiators of fibrogenesis. Previous studies demonstrated that aged plasminogen activator inhibitor-1 (PAI-1) knockout mice develop spontaneous cardiac-selective fibrosis without affecting any other organs including kidney, lung and liver. Therefore, the PAI-1 knockout model of cardiac fibrosis provides an excellent opportunity to find novel contributors to cardiac fibrosis.

Aims: We hypothesized that differential expressions of profibrotic and antifibrotic genes in PAI-1 knockout hearts and unaffected organs lead to cardiac-selective fibrosis. The aim of this study was to identify the initiator(s) of fibrosis in PAI-1 knockout hearts and to determine the status of those initiator(s) in PAI-1 knockout kidneys.

Methods: Hearts and kidneys explanted from aged PAI-1 knockout and wildtype mice were subjected to histological study. Levels of collagen were measured by Masson's trichrome staining. To test our

hypothesis, we performed genome-wide gene expression profiling of transcripts derived from aged PAI-1 knockout hearts and kidneys. Total RNA from wildtype and PAI-1 knockout hearts and kidneys were isolated. The variations of global gene expression profiling were compared within four groups: wildtype heart vs. knockout heart; wildtype kidney vs. knockout kidney; knockout heart vs. knockout kidney and wildtype heart vs. wildtype kidney. Array data was validated in wildtype and PAI-1 knockout hearts and kidneys by quantitative PCR analysis and by Western blotting in endothelial cells undergoing endothelial to mesenchymal transition (EndMT).

Results: Results revealed that while myocardial tissues derived from aged PAI-1 knockout mice showed significantly elevated levels of collagen accumulation compared to age- and sex-matched wildtype controls, collagen accumulation in kidneys derived from aged PAI-1 knockout mice were insignificant and comparable with age- and sex-matched wildtype controls. This suggests that PAI-1 deficiency is associated with age-dependent cardiac-selective fibrosis. Analysis of Illumina-based microarray data revealed that several genes involved in different biological processes such as immune system processing, response to stress, cytokine signaling, cell proliferation, adhesion, migration, matrix organization and transcriptional regulation are affected in hearts and kidneys by the absence of PAI-1. Importantly, while the expression of several genes, involved in profibrotic pathways including Ankrd1, Dbp, Egr1, Scx, Klf6, IGFBP6, Timp1/2 and Loxl1, are upregulated in PAI-1 knockout hearts, the expression of those genes is downregulated in PAI-1 knockout kidneys. The quantitative PCR analysis data of a few genes including Ankrd1, Egr1, Dbp and Timp1 further confirmed the microarray data. The protein levels of a few genes including Ankrd1 and Timp1 were elevated during EndMT.

Conclusion: To our knowledge, this is the first comprehensive report on the influence of PAI-1 on global gene expression profiling in heart and kidney. These results have identified new molecular targets for the prevention and treatment of fibrotic disorders.

OC 29.3

Plasmin induces *in vivo* monocyte recruitment through protease-activated receptor-1, MEK/ERK and CCR2 mediated signaling

Carmo AAF[1], Costa BRC[1], Vago JP[1], Oliviera LC[2], Tavares LP[1], Nogueira CRC[1], Brasil BSF[2], Dusse LM[1], Barcelos LS[3], Bonjardim CA[2], Teixeira MM[3] and Sousa LP[4]

[1]Departamento de Análises Clínicas e Toxicológicas; [2]Departamento de Microbiologia, Instituto de Ciências Biológicas; [3]Imunofarmacologia- Departamento de Bioquímica e Imunologia, Minas Gerais; [4]Federal University of Minas Gerais, Belo Horizonte, Brazil

Background: The Plasminogen/Plasmin (Plg/Pla) system is associated with a variety of biological activities beyond the classical dissolution of fibrin clots, including cell migration, tissue repair and inflammation. Although the capacity of Plg to induce cell migration is well defined, the mechanism *in vivo* underlying this process is elusive.

Aims: To investigate the effect of Pla on cell migration *in vitro* and *in vivo* and the role of mitogenactivated protein kinase (MAPK) ERK1/2, protease activated receptor-1 (PAR-1) and CCL2/CCR2 axis in this process.

Methods: We performed *in vitro* migration assay (wound healing assay) in culture of MEFs (Mouse Embryonic Fibroblasts) or mouse leukemia monocyte macrophage (RAW 264.7). The cells were treated with Pla (2 μg/mL) at different times, or pretreated with the MEK1/2 inhibitor U0126 (15 μM), a serine protease inhibitor Leupetin (25 μg/mL) or the lysine analog tranexamic acid (0.01 M) 60 min. prior to and throughout Pla treatment and processed for microscopic counting of migrating cells or western blot analysis for phosphorylated ERK1/2. BALB/C mice were challenged by i.pl. (intrapleural) injection of Pla (2 μg/cavity) and the cells present in the pleural cavity harvested at different times or 48 h after pre-treatment with specific inhibitors (U0126 60 μg/cavity, i.pl.; leupeptin 100 μg/mouse, i.p.; SCH79797, 5 mg/kg, i.p.) 1 hour before Pla. Cells were processed for total and differential leukocyte counts and western blot analysis for P-ERK1/2 and IkB-a. Pleural levels of cytokines IL-1β, IL-6 and TNF-α and the chemokine monocyte chemoattractant protein 1 (MCP-1/CCL2) were analyzed by ELISA. CCR2 knockout mice and wild-type littermates were injected with plasmin and the cells present in the pleural cavity were harvested at 48 h after and processed for total and mononuclear cell count. All procedures described here had prior approval from the Animal Ethics Committee of Universidade Federal de Minas Gerais (CETEA/UFMG, Protocol number: 19/2011).

Results: Pla induced *in vitro* migration of murine fibroblast and macrophages dependent on MEK/ERK pathway and by requiring its proteolytic activity and lysine binding sites on cell surfaces.

Plasmin injection into the pleural cavity of mice induced a time-dependent influx of mononuclear cells that was associated with augmented ERK1/2 and IkB-α phosphorylation and increased levels of CCL2 and IL-6 in pleural exudates. *In vivo* inhibition of protease activity by using leupeptin or a PAR-1 antagonist (SCH79797) prior to Pla injection abolished Pla-induced mononuclear recruitment and ERK1/2 and IkB-α phosphorylation. Interestingly, inhibition of MEK/ERK pathway abolished Pla-induced CCL2 upregulation and mononuclear cell influx. In agreement with a requirement for CCL2 to Pla-induced cell trafficking, CCR2−/− mice were not responsive to Plainduced mononuclear recruitment.

Conclusion: Pla-induced mononuclear cell recruitment *in vivo* was dependent on PAR-1 activation of the MEK/ERK/NF-kB pathway which led to the release of CCL2 and activation of CCR2.

OC 29.4

Metalloproteinase-9 higher increase after thrombolysis is associated with hemorrhagic transformation of lesion and with poor stroke outcome

Giusti B[1], Nencini P[2], Gori AM[1], Nesi M[2], Palumbo V[2], Piccardi B[2], Armillis A[1], Pracucci G[1], Abbate R[1] and Inzitari D[1]

[1]University of Florence; [2]Careggi Hospital, Florence, Italy

Background: In experimental animals metalloproteinases (MMPs) play a detrimental role related to severity and hemorrhagic transformation of the ischemic lesion. Tissue plasminogen activator (tPA) enhances and MMPs inhibitors (TIMPs) antagonize such effects.

Aims: This study aimed to expand clinical evidence in this connection.

Methods: Blood was taken at baseline and 24 h after tPA thrombolysis from 327 patients [mean age = 68 years, mean National Institutes of Health Stroke Scale (NIHSS) = 11.9] with acute ischemic stroke, all treated with i.v. tPA thrombolysis within 4.5 h. MMP-1, -2, -3, -7, -8, -9, and TIMP-1, -2, -4 were measured (in ng/mL) using Bio-Plex suspension array system and R&D kits. Delta median values [(post tPA-baseline)/baseline] of each MMP or TIMP were analyzed related to symptomatic hemorrhage (SICH), death, 3 month modified Rankin Scale (mRS) (3–6 vs. 0–2), and correlated with baseline, 24 h and 7 days NIHSS.

Results: Delta increases: 1) SICH vs. non SICH: significant for MMP-9 and TIMP-4 [MMP-9: 0.38 vs. −0.18, $P = 0.006$; TIMP-4: 0.67 vs. 0.22, $P = 0.015$]; 2) Death vs. survival: significant for MMPs-1, -8, -9 and TIMP-1 [MMP-1: 0.01 vs. −0.14, $P = 0.048$; MMP-8: 0.46 vs. −0.09, $P = 0.011$; MMP-9: 0.37 vs. −0.17, $P = 0.007$; TIMP-1: 0.17 vs. −0.02, $P = 0.011$]; 3) mRS 3–6 vs. 0–2: significant for MMP-8, -9, and TIMP-4 [MMP-8: 0.12 vs. −0.17, $P < 0.001$; MMP-9: 0.11 vs. −0.21, $P < 0.001$; TIMP-4: 0.50 vs 0.16, $P < 0.001$]. Both MMP-9 and TIMP-4 deltas were strongly correlated with baseline, 24 h, and 7 days NIHSS (Spearman P ranging from 0.003 to 0.001). Adjusting for demographics, baseline glucose or NIHSS, infection and atrial fibrillation, only MMP-9 remained an independent determinant of death

[OR = 1.55 (95% CI 1.08–2.21)], SICH [OR = 1.38 (95% CI 1.01–1.90)], or mRS 3–6 [OR = 1.35 (95% CI 1.01–1.80)].

Conclusions: Our data add substantial clinical evidence about MMP-9 as detrimental factor in ischemic stroke patients treated with thrombolysis, and may prompt randomized controlled trials (RCTs) testing the treatment of acute ischemic stroke patients with drugs able to inhibit MMPs in combination with tPA thrombolysis.

OC 29.5

Mechanistic studies on a fibrin specific streptokinase from *Streptococcus pyogenes*

Huish-Williams S, Longstaff C and Thelwell C

National Institute Of Biological Standards & Control (NIBSC), South Mimms, UK

Background: Haemolytic streptococci (Groups A, C and G) are common human pathogens responsible for a range of diseases. As an early defence mechanism bacteria are trapped in fibrin networks at the site of infection, with factor XIII (FXIII) cross-linked fibrin reported to be more effective. In response streptococci secrete streptokinase (SK), a non-proteolytic activator of human plasminogen, to degrade fibrin and aid dissemination of the bacteria throughout the body. Most of our understanding of the mechanism of action of SK is based on SK from the H46a strain of Group C *Streptococcus equisimilis,* because of its long-term use as a thrombolytic drug. Importantly plasminogen activation by H46a-SK is independent of fibrin. SK however contains polymorphic sequence variations, for example SK from M1 type Group A Streptococcus (GAS, *Streptococcus pyogenes*) shares 88% sequence identity with H46a-SK, although the significance of these sequence variations in relation to mechanism of action and pathogenicity is not known.

Aims: The aim of this study was to investigate mechanistic differences between H46a-SK and GAS-SK relating to plasminogen activation, plasmin-SK activity, and in response to FXIII cross-linked fibrin.

Methods: GAS-SK and H46a-SK were cloned and expressed in *E. coli*. Plasminogen activation rates were measured in solution, and at the surface of pre-formed fibrin clots in microtitre plates, against the chromogenic substrate for plasmin S-2251. Amidolytic activity of plasmin and the SK-plasmin complexes was determined against S-2251. Fibrinolytic activity (±FXIII) was measured in two different assay systems: a microtitre plate based method monitoring clot formation and lysis through absorbance change, and a physical method where lysis of a pre-formed clot is determined by collapse of clot structure.

Results: Plasminogen activation and fibrinolysis activity of recombinant H46a-SK was, like native H46a-SK, independent of fibrin. For GAS-SK however plasminogen activation rates in solution were 18-fold lower than H46a-SK, and required fibrin to increase activity to the level of H46a-SK. In the microplate assay fibrinolysis activity of GAS-SK was two-fold higher than H46a-SK, irrespective of cross-linking by FXIII. Both H46a-SK and GAS-SK in complex with plasmin increased plasmin enzyme activity (k_{cat}/K_M) by two-fold against S-2251 compared with plasmin alone, although for H46a-SK the k_{cat} was two-fold higher and for GAS-SK the K_M was two-fold lower relative to plasmin alone. In the physical clot lysis assay the rate of lysis was dose-dependent, with faster fibrinolysis rates at low concentrations for GAS- and H46a-SK-plasmin compared to plasmin alone.

Conclusions: We have identified an SK from GAS with fibrin-targeted plasminogen activation and increased fibrinolytic activity over H46a-SK. In complex with plasmin both SKs increase amidolytic activity, but through a different underlying mechanism. At low concentrations SK increases plasmin fibrinolytic activity, and our results suggest this could relate to differences in substrate specificity or fibrin binding. GAS is generally regarded as the more important human pathogen, and this difference in mechanism of action may contribute to the difference in pathogenicity. An understanding of the structural interactions critical to the fibrin-targeted activity may also provide a rationale for the design of new thrombolytic drugs.

OC 29.6

Platelet factor XIII stabilises thrombi via cross-linking of a2antiplasmin to fibrin

Mitchell JL, Lionikiene AS, Fraser SR, Booth NA and Mutch NJ

University of Aberdeen, Aberdeen, UK

Background: We have shown that the antifibrinolytic function of plasma-derived factor XIII (FXIII) is exclusively mediated via cross-linking of $\alpha_2$antiplasmin(α_2AP) to fibrin[1]. Platelets contain three distinct pools of FXIII; cellular FXIII (FXIII-A) in the cytoplasm and plasma derived FXIII within the α-granules and on their membrane surface.

Aim: To investigate the contribution of platelet FXIII to thrombus stability.

Method: Platelet-poor plasma (PPP) or platelet-rich plasma (PRP) was prepared by centrifugation of whole blood. Washed isolates of platelets were also prepared. Model thrombi were generated from PPP, PRP, FXIII-depleted plasma or α_2-AP depleted plasma ± isolated platelets. In some cases a TG inhibitor (1 mM) or neutralising antibody to α_2-AP (150 μg/mL) was included. Incorporation of FITC-labelled fibrinogen allowed thrombus lysis to be quantified as release of fluorescence. FXIII activity in plasma, platelet releasates and platelet fractions was analysed by an in-house activity assay and detected on Western blots with monoclonal antibodies to FXIII-A and FXIII-B subunits.

Results: FXIII activity was considerably higher in PRP (1.5 ± 0.05 IU/mL) than PPP (0.9 ± 0.12 IU/mL; $P < 0.005$, $n = 4$) and was below the limit of detection in FXIII-depleted plasma. Lysis of thrombi formed with FXIII-depleted plasma was increased 11.8-fold relative to normal plasma (184 ± 6.87 FU/min compared to 15.6 ± 6.29 FU/min). Addition of different concentrations of platelets stabilised model thrombi formed from FXIII-depleted plasma to increasing extents; 0.5×10^8 platelets/mL (1.8-fold; 104 ± 22.8 FU/min); 1×10^8 platelets/mL (2.6-fold; 71 ± 25.5 FU/min); 2.5×10^8 platelets/mL (6.8-fold; 27 ± 10.6 FU/min); and 5×10^8 platelets/mL (15.5-fold;11 ± 4.2 FU/min). Stabilisation of thrombi formed from FXIII-depleted plasma was evident whether freshly isolated or lysed platelet preparations were used, indicating that the source of FXIII was present on the platelet surface or was actively released during platelet activation. Inclusion of an antibody to α_2-AP in thrombi formed from FXIII-depleted plasma had no effect in the absence of platelets, but increased lysis 11.6-fold in the presence of 5×10^8 platelets/mL (11.7 ± 1.4 FU/min vs 136 ± 23.1 FU/min). Thrombi formed from α_2-AP-depleted plasma lysed at a rapid rate (120 ± 11.4 FU/min) and were not stabilised by addition of 5×10^8 platelets/mL. No change in lysis was noted on inclusion of a TG inhibitor in thrombi formed from α_2-AP-depleted plasma ± 5×10^8 platelets/mL, indicating that in the absence of plasma α_2-AP, platelet FXIII was unable to stabilise thrombi. Western blotting of lysed preparations of platelets showed a band at 83 kDa, consistent with the presence of FXIII-A subunit. No FXIII-B subunit could be detected, suggesting that cellular FXIII-A from the cytoplasm contributes to thrombus stabilisation.

Conclusions: We have shown that platelets supply a pool of FXIII-A that confers antifibrinolytic function by cross-linking plasma α_2-AP to fibrin. The magnitude of the effect is concentration dependent, with normal circulating concentrations necessary for maximal thrombus stabilisation.

OC 30 – Inherited Risk Factors for Venous Thrombosis – I

OC 30.1

Towards identification of novel inherited genetic risk factors for venous thromboembolism

Cunha M, Fouchier SW, Meijers JC and Middeldorp S
Academic Medical Center, Amsterdam, the Netherlands

Background: Venous thromboembolism (VTE) is a multicausal disease that can be attributed to both genetic and environmental risk factors. Nowadays, genetic risk factors can be identified in approximately half of the patients with VTE, even if stringent criteria are applied, such as the absence of clinical risk factors or old age. This suggests that our knowledge about the genetic basis of venous thrombosis is incomplete, and novel thrombophilic defects remain to be found. To address this issue the GENES study was initiated. We collected Dutch families with unexplained thrombophilia, in which deficiencies of protein C, protein S and antithrombin, the presence of factor V Leiden and prothrombin G20210A, and persistently elevated levels of factors VIII, IX and XI were excluded.
Methods: In order to identify new hereditary risk factors for VTE, we selected two large GENES families (Family D and Family K), in which 5 or more individuals had had objectively confirmed VTE.
Whole exome sequencing data was generated for 5 affected individuals from each family. With the assumption of a dominant trait, all heterozygous single nucleotide variants (SNVs), insertions and deletions (INDELs) being present in all affected relatives, unique for each family, as well as shared by both families, were selected. The list of candidate variants was further down-sized by excluding non-coding variant without any potential splice site prediction and involving a low conserved base pair, as well as synonymous variants without any potential splice site prediction. In a first approach we restricted our focus to all candidate variants located in the established or possibly related genes to thrombosis ($N = 125$).
Results: None of the candidate variants were shared by all ten affected individuals. In family D, two variants located in genes associated with thrombosis were identified, in STX2 (c.94T>G, p.Phe32Val) and in ITGB3 (c.176T>C, Leu59Pro). In family K, three variants located in genes associated with thrombosis were identified, in APOH (c.796G>T, p.Val226Leu), KLK8 (c.595G>A, p.Val199Ile) and in KLK11 (c.146G>A, Gly49Glu). None of these variants have a low minor allele frequency (MAF): respectively 2.5%, 16.2%, 23.8%, 5.2% and 7.5% for the European-American population. Only the STX2 variant is predicted to be deleterious by four different algorithms for predicting pathogenicity (SIFT, PolyPhen2, LRT and MutationTaster).
Conclusion: Although all variants, with exception of the STX2 variant, show relatively high MAF, co-segregation analysis and assessment of the presence and frequency of these mutations in case-control populations is necessary to determine their role in VTE. The STX2 gene, reported to be associated with von Willebrand factor levels, seems to be the most interesting candidate. Additionally, variants in other genes than the 125 included in this analysis could explain the phenotype in our families, and further evaluation is ongoing.

OC 30.2

Hidden antithrombin deficiencies

Navarro-Fernández J[1], Padilla J[1], Martínez-Martínez I[1], Águila S[1], De La Morena-Barrio ME[1], Miñano A[1], Bohdan N[1], Martínez C[2], Vicente V[1] and Corral J[1]
[1]*Centro Regional de Hemodonación. Hospital Morales Meseguer. UMU. IMIB;* [2]*Hospital General Universitario Los Arcos del Mar Menor, Murcia, Spain*

Background and Aims: The key anticoagulant role of antithrombin explains the high risk of thrombosis associated to even minor reductions. Thus, functional assays to detect antithrombin deficiency are included in thrombophilic tests despite the low incidence of this disorder (1%). Molecular analysis of *SERPINC1*, the gene encoding antithrombin, is restricted to patients with evident deficiency (< 70%) and shows a high mutation detection rate (85–95%). However, no molecular analysis is routinely done in cases with anticoagulant activity within the normal range.
Methods and Results: During the last 10 years, we received 137 samples from patients with potential antithrombin deficiency, all identified with functional methods (anti-FXa) performed at least 6 months after the thrombotic event. We confirmed the deficiency in 88 cases, but 49 cases had no deficiency in the sample delivered to our centre. We also sequenced *SERPINC1* in these 49 cases. We pointed out the high prevalence of the Cambridge II variant (Ala384Ser): 6/49 patients carried this mutation in heterozygosis (12%). A borderline deficiency (70%) was detected at origin in five cases, but 1 reported severe deficiency (50%). This mutation, relatively common in Spain (0.3%), moderately increases the risk of thrombosis (3/5-fold) since it only mildly impairs the anti-FIIa activity without effect on the anti-FXa activity. The reduced levels identified in one determination are explained, according to *in vitro* results, by a moderate antithrombin consumption when the thrombin generated under some specific conditions is not fully controlled by the Cambridge II variant. The second mutation was identified in the asymptomatic mother of a 2-year old child with deficiency (30–35%) who died after a cerebral vein thrombosis despite anticoagulant therapy. This case had conflictive anti-FXa results at origin (two determinations of 40% and one of 100%). Interestingly, heating the plasma delivered to our centre (93%) at 42 °C for 15 min resulted in a 45% loss of activity. The proband had a mutation in heterozygosis not previously described: Val105Ala, that affects a conserved residue located at the end of the C-helix. Recombinant expression in HEK-EBNA cells produced a highly unstable protein. The third mutation identified in a 38-year old patient who suffered a pulmonary embolism, affected the signal peptide, three positions before the proteolitic cleavage (Val-3Glu), resulting in a smaller variant lacking the first two residues of the mature molecule (Antithrombin Dublin). The pathological relevance of this variation, which is a low prevalent polymorphism (0.2%) has been suggested but no demonstrated, as this variant has normal activity and heparin affinity. The mechanism responsible for the reduced activity identified at one moment in this patient (68%) has to be characterized.
Conclusion: Our study suggests that the prevalence of antithrombin deficiency in venous thrombosis may be underestimated. We identified three *SERPINC1* variations, two polymorphisms and a new mutation that are not detected using functional tests, but that under specific conditions caused a reduced anticoagulant capacity potentially increasing the risk of thrombosis. Our data stimulate the molecular analysis of *SERPINC1*, particularly the genotyping of Ala384Ser, in cases with one positive determination of antithrombin deficiency.

OC 30.3

The risk of venous thrombosis varies in different ethnic groups

Rezende SM[1], Lijfering WM[2], Rosendaal FR[2] and Cannegieter SC[2]
[1]*Universidade Federal de Minas Gerais, Belo Horizonte, Brazil;* [2]*Leiden University Medical Center, Leiden, the Netherlands*

Background: Ethnic differences in the incidence of venous thrombosis have been appreciated for many years. However, with few exceptions, most of the studies are based on administrative databases from North America and China.
Aim: The aim of this study was to investigate the risk of venous thrombosis in different first and second generation immigrant groups.
Methods: The MEGA (Multiple Environmental and Genetic Assessment of risk factors for venous thrombosis) study is a population-based case-control study on risk factors for venous thrombosis from the Netherlands. Inclusion criteria consisted of patients and controls

of whom information was available on the country of birth. For the analysis related to immigration background, patients were compared with random digit dialing (RDD) controls. First generation immigrants were classified as those who were born outside the Netherlands. Second generation immigrants were similarly defined as first generation immigrants, except that second immigrants were born in the Netherlands, while both parents were born in the same country except Netherlands. In total, 6899 participants were included, of whom 4300 patients and 2599 RDD controls. Odds ratios (ORs) with 95% confidence intervals (95% CIs) were calculated as estimates of the relative risk, and were adjusted for age, sex, body mass index, smoking, hormonal factors, alcohol consumption, physical activity and malignancy by unconditional logistic regression.

Results: The risk of venous thrombosis varied according to the region of birth. When compared with the Dutch, Eastern Europeans reached the highest and East/Southeast Asians the lowest risk of venous thrombosis with OR of 2.35, (95% CI, 1.09–4.59) and 0.44 (95% CI, 0.29–0.68), respectively after multivariate adjustments. Caribeans showed an intermediate lower risk of 0.69 (95% CI, 0.36–1.30) after multivariate adjustments. We did not observe a major difference on the risk for VT between first and second generation immigrants, although the number of second generation immigrants was small for some groups. Subgroup analysis did not show major differences according to immigration groups, except for Eastern Europeans, who had a higher risk for unprovoked event with an OR of 3.79 (95% CI, 1.44–9.97). In comparison with Dutch controls, East/Southeast Asians controls had lower prevalence of factor V Leiden (6% and 1%, respectively) and the prothrombin G20210A mutation (2% and 1%, respectively) but higher blood group non-O (54% and 62%, respectively). Risk of VT in East/Southeast Asians adjusted for age, sex, factor V Leiden and blood group non-O was 0.53 (95% CI, 0.35–0.80). Analysis of a panel of procoagulant, anticoagulant, profibrinolytic and genetic factors are underway and is expected to be available before the ISTH 2013 congress.

Conclusion: The risk of VT varies in different populations. The risk of VT in East/Southeast Asians was the lowest and was virtually unchanged after adjustment for several environmental and genetic known risk factors for VT.

OC 30.4

Genetic influence on risk of venous thromboembolism in women

Bruzelius M, Sabater-Lleal M, Strawbridge RJ, Bergendal A, Silveira A, Sundström A, Kieler H, Odeberg J and Hamsten A
Karolinska Institute, Stockholm, Sweden

Background: Several studies have suggested an important genetic contribution to the risk of developing venous thromboemblism (VTE), with an estimated heritability of around 50–60%. Single nucleotide polymorphisms (SNPs) in the *F5*, *F2*, *FGG* and *F11 genes*, together with ABO blood group genotype, are firmly established as risk factors. A number of additional SNPs have emerged in the literature as being associated with the risk of VTE, but with less supportive replication data.

Aims: To perform a comprehensive analysis of both established and emerging genetic risk variants for VTE in a case-control study of women with a first VTE.

Method: We studied 2775 women from a national-wide case-control study, the ThromboEmbolism Hormone Study (TEHS). TEHS was conducted in Sweden in 2002–2008 and focused on women taking hormone compounds (mean age 46 (18–65) years). The study was approved by the regional medical ethics committee, and all women signed an informed consent. Forty selected SNPs were genotyped using the Illumina Goldengate platform, Pyrosequencing[TRADEMARK] technology or Taqman[TRADEMARK] technology. Associations were assessed by logistic regression. Adjustment in different models was made for age, body-mass index (BMI), and estrogen intake. In addition, interaction between SNPs and estrogen intake was also evaluated. Finally, weighted genetic risk scores were computed and examined in relation to disease.

Results: Association with VTE could be confirmed ($P \leq 0.001$) for *F5* (rs6025, odds ratio (OR) 3.51 (CI 2.77–4.45)), *F2* (1799963, OR = 1.86 (CI 1.27–2.73)), *ABO* (rs579459 (used as proxy for rs2519093), OR = 1.57 (Cl 1.39–1.78)), *ABO* (rs514659, OR = 1.51 (Cl 1.35–1.69)), *FGG* (rs2066865, OR = 1.38 (Cl 1.22–1.55)), *FGB* (rs1800788, OR = 1.28 (Cl 1.13–1.45)) and *F11* (rs2289252, OR = 1.19 (Cl 1.19–1.32 $P = 0.002$)) after adjustment for age. Further adjustments for BMI and estrogen intake influenced the results marginally. Even if both covariates are strongly associated with VTE, no significant interaction was demonstrated with the selected SNPs. A genetic risk score, based on significantly associated SNPs in TEHS, was compared with the top 5 VTE SNPs used in an earlier publication. Both models explained approximately the same proportion of the clinical phenotype, with the area under the ROC curve attaining 0.65. When age, BMI and estrogen intake were added to the model, the area under the ROC curve increased to 0.73

Summary/Conclusion: TEHS confirms the role of established genetic risk variants for VTE in the setting of women with a first thrombosis. With the exception of *ABO* rs579459, used as proxy for rs2519093, it failed to replicate less established SNPs selected from the literature. A genetic risk score based on the most robustly associated risk SNPs and established clinical risk factors may improve the prediction of VTE.

OC 30.5

Candidate genetic polymorphisms and their associations with incident and recurrent venous thrombosis

Blondon M[1], Wiggins K[1], Harrington L[1], McKnight B[1], Taylor K[2], Rosendaal FR[3], Heckbert SR[1], Psaty B[1] and Smith N[1]
[1]University of Washington, Seattle, WA; [2]Cedars-Sinai Medical Center, Los Angeles, CA, USA; [3]Leiden University Medical Center, Leiden, the Netherlands

Background: The prediction of recurrent venous thrombosis (VT) remains a challenge and needs to be improved to guide treatment options. Multiple genetic variants have been associated with incident VT, but their associations with recurrent VT are mostly unknown.

Aims: The aim of this study was to estimate associations between candidate single nucleotide polymorphisms (SNPs) and incident/recurrent VT. SNPs were selected if we found prior published evidence for validated associations with incident VT.

Methods: We studied 22 candidate SNPs in the following genes: ABO, F2, F5, F11, F13, SERPINE1, PROC, FGG, SERPINC1, GP6, HIVEP1, STXBP5, VWF, KNG1, KLKB1, TC2N, and PROCR. SNPs were either measured or imputed using information from several genotyping panels. Participants were of European ancestry and part of a large, population-based study of VT in Washington State, USA. In a case-control study of incident VT (women only), we compared cases with a first validated VT (deep vein thrombosis and/or pulmonary embolism [PE]) from 1995 to 2010 with controls matched on age and study design variables using logistic regression adjusted for matching factors and the genotype panel used. In an inception cohort, men and women with incident VT were followed for a second VT and associations with recurrent VT were estimated using a Cox proportional hazards model adjusted for sex, age and the genotype panel used.

Results: For incident VT, 897 cases were compared with 2644 controls (mean age 66.6 years, BMI 28.9 kg/m2). Forty percent of cases were idiopathic and 34% presented with PE. A total of 662 cases (89% women, 51% idiopathic, 58% PE) with a mean age of 65.8 years at the first VT were followed for a median of 5.1 years for the development of recurrent VT ($n = 100$ recurrent events). Factor V Leiden (rs6025) and prothrombin mutation G20210A (rs1799963) were strongly associated with both incident VT (OR 3.8, 95%CI 2.8–5.1 and OR 1.7,

95%CI 1.1–2.7, respectively) and recurrent VT (HR 1.8, 95%CI 1.1–3.1 and HR 2.4, 95%CI 1.1–5.3, respectively). SERPINE1 rs2227631 was also associated with both incident (OR 1.2, 95%CI 1.0–1.3) and recurrent VT (HR 1.3, 95%CI 1.0–1.8). For ABO polymorphisms, associations with recurrent VT were slightly weaker than associations with incident VT: rs8176719 HR 1.2 (95%CI 0.9–1.7) vs. OR 1.5 (95% CI 1.3–1.7); rs2519093 HR 1.3 (95%CI 0.9–1.9) vs. OR 1.4 (95%CI 1.2–1.7). We found associations in opposite directions between FGG rs2066865 and incident VT (OR 1.3, 95%CI 1.1–1.5) and recurrent VT (HR 0.8, 95%CI 0.5–1.0, $P = 0.08$). No other associations with recurrent VT were observed.

Summary/Conclusion: Among 22 SNPs with previously demonstrated associations with incident VT, 3 showed associations with recurrent VT in this population-based inception cohort. Although power was limited for the recurrence analyses, we identified genetic prediction for recurrent VT that included a novel finding for SERPINE1 rs2227631; this needs replication in an independent cohort. Further, the predictive value for recurrent VT of Factor V Leiden and G20210A was higher than reported previously.

OC 30.6

Sex difference in incidence of first venous thrombosis: a higher risk in men than in women

Roach REJ, Lijfering WM, Rosendaal FR, Cannegieter SC and Le Cessie S

Leiden University Medical Center, Leiden, the Netherlands

Background: Previous analyses reported a higher risk of recurrent venous thrombosis in men than in women, while no contrast in the frequency of first venous thrombosis was apparent. A possible explanation could be that, for a first event, a risk difference between the sexes is masked by female exposure to hormonal risk factors.

Aims: The aim of our study was to assess the risk of a first venous thrombosis in men compared with women once hormonal risk factors (defined as oral contraception use, postmenopausal hormone therapy use or pregnancy/ puerperium) have been accounted for.

Methods: From the MEGA study, a large case-control study on risk factors for first venous thrombosis, consecutive patients with a first episode of venous thrombosis were included. Partners of patients were invited to participate as controls if they had no history of venous thrombosis. For the current analyses all complete couples in whom the woman was not exposed to hormonal risk factors were analyzed: 1868 in total. As nearly all partner controls (98%) were of the opposite sex to the patient, if men and women experience first venous thrombosis at a similar rate, one would expect the male/ female ratio in the MEGA study to be approximately 1:1. To assess whether this was the case, conditional logistic regression was used to calculate odds ratios (OR) and 95% confidence intervals (95% CI) for venous thrombosis in men compared with women without hormonal risk factors. Analyses were stratified in 10-year age categories and adjusted for body mass index and smoking. The study was approved by the Medical Ethics Committee of the Leiden University Medical Center and all participants provided written informed consent. Funding: Netherlands Heart Foundation (grant NHS 98.113), Netherlands Organisation for Scientific Research (grant 912-03-033|2003), Dutch Cancer Foundation (grant RUL 99/1992).

Results: Overall, there were more couples in whom the patient was male and the partner was female (67%) than couples in whom the patient was female and the partner was male (33%). Men had a 2.2-fold (95% CI, 1.9–2.5) higher risk of first venous thrombosis than women without hormonal risk factors. When 10-year age categories were viewed separately, risk estimates ranged from 4.8 (95%CI, 1.1–21.6) for the age group 18–30 years, to 2.1 (95%CI, 1.6–2.7) for the age group 60–70 years. Adjustment for body mass index and smoking did not materially affect the results.

Summary/Conclusions: Men have a higher risk of first venous thrombosis than women when exposure to hormonal risk factors is accounted for. This shows that the sex-difference found for recurrent venous thrombosis also exists for a first event. As risk estimates were highest in the youngest age categories, one of the genetic differences between men and women may explain our findings.

OC 31 – Mechanisms in Cancer and Haemostasis

OC 31.1

Association of mean platelet volume with cancer-associated venous thromboembolism: results from the vienna cancer and thrombosis study (CATS)

Riedl J, Reitter E-M, Marosi C, Jäger U, Schwarzinger I, Zielinski C, Pabinger I and Ay C

Medical Universtiy of Vienna, Vienna, Austria

Background: Cancer patients are at increased risk of venous thromboembolism (VTE). Recently, several parameters have been identified to predict VTE in cancer patients. High platelet counts were consistently shown to be associated with increased risk of VTE. Mean platelet volume (MPV), which has been proposed to reflect platelet activity, was reported to be associated with arterial and venous thrombosis in patients without cancer. Data on the role of MPV in cancer patients are scarce and its association with risk of cancer-associated VTE is not known.

Aims: The aim of the study was to analyse MPV in patients with different types of cancer compared to healthy individuals and to investigate the association of MPV with risk of occurrence of cancer-associated VTE.

Methods: MPV were routinely determined in EDTA blood samples using a Sysmex XE-2100 hematology analyzer in the Vienna Cancer and Thrombosis Study, which is an ongoing prospective, observational cohort study that started in 2003. Patients with newly diagnosed cancer or progressive disease after remission were included and followed for a maximum of 2 years. Primary endpoint was occurrence of symptomatic VTE. Sixty-five age- and sex-matched healthy subjects served as controls.

Results: A total of 1544 patients (700 women; median age 62 years) with tumours of the lung ($n = 250$), breast ($n = 225$), brain ($n = 200$), colon ($n = 159$), prostate ($n = 148$), pancreas ($n = 99$), stomach ($n = 52$); lymphoma ($n = 217$) and other tumour entities ($n = 194$) were included in the study. Cancer patients had lower median MPV levels (fL) compared to healthy controls (10.2, [25th–75th percentile: 9.6–10.8] vs. 10.3 [10.0–11.0]; $P = 0.022$). During a median observation time of 506 days, 114 (7.4%) cancer patients developed VTE. MPV was inversely correlated with platelet count ($r = -0.29$; $P < 0.001$). The hazard ratio (HR) of MPV per 1 fL increase for VTE was 0.86 ([95% CI: 0.70–1.05], $P = 0.136$). High MPV ($\geq$ 75th percentile of all cancer patients; $\geq$ 10.8 fL) was associated with a statistically significantly decreased risk of VTE compared to MPV below the 75th percentile (HR [95% CI]: 0.58 [0.36–0.93], $P = 0.024$). In multivariable analysis, including platelet count and soluble P-selectin, this association remained statistically significant (0.56 [0.35–0.91], $P = 0.018$). In Kaplan-Meier analysis, the cumulative probability of VTE after 1 year was 4.7% in patients with high MPV and 8.3% in those with lower MPV (Log-rank test: $P < 0.001$). In subgroup analysis, the association of high MPV ($\geq$ 10.8 fL) with decreased VTE-risk was most pronounced in pancreatic cancer (HR [95% CI]: 0.16 [0.04–0.71], $P = 0.016$). After one year, the probability of VTE was 5.1% in those with high MPV compared to 27% in those with lower MPV ($P = 0.006$).

Summary/Conclusions: MPV was lower in cancer patients compared to controls. Interestingly, high MPV was associated with decreased risk of VTE in cancer patients and might have a favourable effect on development of cancer-associated VTE. However, this finding is contrary to results observed in patients without cancer patients. Further studies

are needed to confirm our results and to elucidate the underlying mechanisms, which influence platelet count, platelet size and VTE in cancer.

OC 31.2

Protease-activated receptor-1 in the pancreatic tumor microenvironment favors cancer progression and chemoresistance

Queiroz KCS, Shi K, Duitman JW, Aberson HL, Wilmink JW, Van Noesel CJM, Richel J and Spek CA

Academic Medical Center, University of Amsterdam, Amsterdam, the Netherlands

Background: Pancreatic cancer is often accompanied by ongoing coagulation activation as evident from elevated markers of thrombin generation like thrombin-anti-thrombin and prothrombin activation fragment F1.2. In line with the emerging role of thrombin-PAR-1 signalling in pathophysiology, this axis is suggested to favor cancer progression. Indeed, PAR-1 is expressed in several invasive cancers of epithelial origin, and tumor cell PAR-1 seems to directly promote invasion and tumorigenesis. Interestingly, we observed that PAR-1 is mostly expressed in the microenvironment of pancreatic tumors and not in tumor cells themselves. The importance of PAR-1 in the tumor microenvironment of pancreatic cancer remains unexplored however.
Aim: Considering the apparent importance of coagulation in pancreatic cancer progression and the presence of PAR-1 in the stromal compartment of this tumor type, we challenge the hypothesis that thrombin-PAR-1 signalling in the tumor microenvironment drives pancreatic cancer progression and drug resistance.
Methods: 4×10^5 PANC02 cells were orthotopically injected into the pancreas of wildtype and PAR-1 deficient mice. From day 7, mice were treated with gemcitabine or saline twice weekly. Four weeks after cancer cell inoculation, mice were sacrificed to assess tumor weight and volume and to perform histopathological and immunohistochemical analyses of primary tumors and metastatic sites. Moreover, *in vitro* experiments were performed in order to determine the role of PAR-1 in macrophage recruitment and chemokine production.
Results: PAR-1 deficient animals presented smaller primary tumors (weight of 0.95 ± 0.14 g and volume of 0.94 ± 0.15 cm^3) than wildtype controls (weight of 1.96 ± 0.36 g and volume of 1.95 ± 0.43 cm^3) and only 1 mouse (1/8) presented metastasis as compared to all wildtype controls. Interestingly, the number of CD31 positive vessels in tumors from wildtype animals (42.3 ± 1.5) was around 1.5-fold higher than the number in those from PAR-1 deficient animals (27.5 ± 0.8) suggesting PAR-1-dependent angiogenesis to drive pancreatic cancer growth.
Intriguingly, the combination of routine gemcitabine chemotherapy with the absence of PAR-1 in the microenvironment almost completely blocked pancreatic cancer growth and only two out of eight animals still presented very small tumors. Immunohistochemical examination of these tumors showed a remarkable (three-fold) reduction in the number of macrophages in the tumor microenvironment of PAR-1 deficient mice as compared to wildtype controls. In line, thrombin stimulation of monocyte/macrophage cells (RAW264.7) potentiated their migration towards MCP-1 by around four-fold. Importantly, thrombin-driven migration was inhibited by pre-treatment with the specific PAR-1 inhibitor P1pal-12. In addition, we observed that fibroblasts secrete MCP-1 in a PAR-1-dependent manner and that fibroblast conditioned medium acts as a strong chemoattractant for RAW264.7 cells. Interestingly, fibroblast conditioned medium prepared in the presence of thrombin further enhanced migration. Moreover, we show that once monocytes have migrated into the tumor microenvironment, they enhance subsequent monocyte migration by secreting MCP-1 (in part) in a PAR-1-dependent manner. The migrated monocytes/macrophages subsequently induce drug resistance as evident from experiments in which monocyte conditioned medium reduced gemcitabine-induced pancreatic cancer cell death.
Conclusion: We identify a novel role of PAR-1 in the pancreatic tumor microenvironment and pinpoint PAR-1 as a potential target to combat drug resistance of pancreatic cancer.

OC 31.3

Kinome profiling of coagulation factors VIIa, Xa and thrombin-dependent signaling reveals common and coagulation factor-unique signaling pathways

Borensztajn KS[1], Parikh K[2], Hoogendijk AJ[2], Spek A[2] and Peppelenbosch MP[3]

[1]Inserm U700, Paris, France; [2]Academic Medical Center, Amsterdam; [3]Erasmus Medical Center, Rotterdam, the Netherlands

Rationale: It is well established that, beyond their role in hemostasis, coagulation factors(F)VIIa, FXa and thrombin are involved in the pathogenesis of a broad range of diseases, among which cancer, via signaling through their cellular receptors, the Protease-activated receptors (PARs). These G protein-coupled receptors (GPCRs) are irreversibly activated through proteolytic cleavage by coagulation proteases. Among the four currently known PARs, PAR-1, -3 and -4 are cleaved by thrombinFVIIa signals through PAR-2 whereas FXa can activate both PAR-1 and PAR-2. PAR activation in turn induces transmembrane signalling to G proteins, thereby impacting on a substantial network of signalling pathways. So far, conclusions drawn about the molecular mechanisms that govern cellular effects induced by coagulation factors are based mainly on measurement of phosphorylation of a few signalling pathways, leaving an incomplete picture of the underlying intracellular events. Additionally, PARs display functional selectivity or 'biased agonism', a process known for GPCRs by which distinct ligands acting on the same receptor can elicit different signaling responses.
Aims: To generate a comprehensive overview of the total complement of cellular kinase activity, thereby enabling analysis of coagulation factors signaling effects without *a priori* assumptions as to signaling pathways affected by these proteases.
Methods: The highly metastatic breast carcinoma cell line MDA-MB-231, which constituvely express PAR-1 and -2, were stimulated for 10 min with FVIIa, FXa or thrombin. Subsequently, we used kinomics peptide arrays, containing 1024 specific kinase substrate sequences, to produce a systems biology analysis of the cellular kinase activity in lysates of cancer cells stimulated with the different coagulation factors. The results were validated by western blots
Results: FVIIa, Xa and thrombin induced substantial signaling events. Single data analysis of arrays with cell lysates resulted in significant differences in the phosphorylation of 44 kinases between cells stimulated with FVIIa and vehicle, 25 kinases between FXa and vehicle, and 34 kinases between thrombin and vehicle. Phosphoproteome profiles also revealed common and divergent coagulation factor-dependent kinase activity. FVIIa modulated specifically the activity of 14 kinases, FXa of 4 kinases and thrombin of 5 kinases. FVIIa and FXa shared a modulation in the activity of 5 kinases, FXa and thrombin of 4 kinases, while FVIIa and thrombin had in common the modulation of the activity of 13 kinases. Finally, the activity of 11 kinases was found to be commonly regulated by all three coagulations factors. Gene ontology analyzis revealed that FVIIa triggered an early induction of metabolism and MAPKinase cascades, while FXa regulates signaling pathways classically associated with inflammation. Thrombin, on the other hand, governs pathways regulating cell cycle and apoptosis.
Conclusion: Overall, we generated a comprehensive overview of individual coagulation-induced signalling pathways in cancer cells. These data might be of importance for a better understanding for the role of coagulation factor in pathophysiology and thus provide potential therapeutical targets for therapy.

OC 31.4

Elevated aPC levels reduce cancer metastasis independent of aPC's cytoprotective effect

Crudele JM[1], Van Sluis GL[2], Margaritis P[1], Siner JI[1], Sliozberg M[1], Faella A[1], Zhou S[1], High KA[1], Spek CA[3] and Arruda VR[1]

[1]Children's Hospital of Philadelphia, Philadelphia, PA, USA; [2]Amsterdam Medical Center; [3]Cemm, Amsterdam Medical Center, Amsterdam, the Netherlands

Background: Recent studies have suggested that the activated protein C (aPC) pathway plays a role in limiting tumor metastasis, with data supporting the hypothesis that this is reliant upon the cytoprotective effects of endogenous aPC mediated through the S1P1 receptor downstream of protease activated receptor 1, PAR1. While convincing work has been done to explore this mechanism by blocking endogenous aPC, it is not known if elevated aPC levels protect against cancer progression via the same mechanisms.

Aim: This study aimed to determine the relevant function(s) of overexpressed aPC in reducing tumor metastasis.

Methods: A liver gene transfer model using viral vectors was utilized to achieve a wide range of sustained expression of wildtype (WT) or mutant murine aPCs. C57BL/6 experimental mice expressing stable levels of aPCs and age and gender matched control mice receiving PBS were injected intravenously with 2.5×10^5 murine melanoma B16F10 cells, which metastasize to the lungs. After 3 weeks the number of pulmonary tumors was determined.

Results: Overexpression of WT aPC in C57BL/6s decreased the rates of metastases in a dose-dependent manner compared to PBS controls. WT aPC expression levels 4× normal (7.3 ± 1.5 ng/mL) did not reduce the number of pulmonary tumor foci compared to PBS controls (aPC < 3 ng/mL). However, mid-dose expression 7× normal (25.6 ± 4.8 ng/mL) and high-dose expression 28× normal (118 ± 6 ng/mL) led to increasing reduction in tumor rates ($P < 0.05$ and < 0.01, respectively). Modified aPCs were then tested to identify the critical functions responsible for protection with aPC overexpression. Two mutants with reduced anticoagulant function but intact cytoprotective function, L38D and 5A, were generated. aPC-L38D cannot interact with its cofactor, protein S, and has ~two-fold reduced anticoagulant function, though at the high doses used there was no prolongation of the aPTT. Compared to PBS controls, aPC-L38D expression significantly reduced the number of tumor foci ($P < 0.01$), similar to WT aPC. Conversely, aPC-5A, which consists of five mutations in the protease domain and leads to ~10-fold reduction of anticoagulant function, was unable to protect against metastasis, even at high doses and with intact cytoprotective effect. An additional mutant, aPC-E149A, which is unable to interact with the main aPC cytoprotective receptor, PAR1, was generated to further explore the involvement of the aPC cytoprotective effect. Mice expressing high levels of aPC-E149A were equally protected against metastases as those expressing WT aPC compared to PBS controls ($P < 0.01$).

Conclusion: In contrast to early findings that endogenous aPC helps control cancer progression in a PAR1-mediated, cytoprotective effect-dependent fashion, our findings suggest that the large reductions seen in tumor metastasis with overexpression of aPC are independent of the cytoprotective effects of the aPC pathway.

OC 31.5

Synergistic anti-cancer effects with dabigatran etexilate and cisplatin or cyclophosphamide

Gilmour SK[1], Hayes CS[1], Shicora A[1], Goss AM[2], Van Ryn J[3] and Gilmour SK[1]

[1]Lankenau Institute for Medical Research, Wynnewood, PA; [2]Boehringer Ingelheim Pharmaceuticals Inc., Ridgefield, CT, USA; [3]Boehringer Ingelheim Pharma GmbH & Co KG, Biberach an der Riss, Germany

Background: Coagulation proteases and the generation of thrombin are increased in tumors. In addition, chemotherapeutic agents commonly used to treat malignant cancers have been shown to increase cancer-associated thromboses. Thrombin can modify tumor cell behavior directly through the activation of protease-activated receptors (PAR) or indirectly by generating fibrin matrices.

Aims: To investigate the extent to which treatment with the oral thrombin inhibitor, dabigatran etexilate (Pradaxa®), will act synergistically with chemotherapeutic agents to block tumor growth and metastasis in murine tumor models.

Methods: The effect of combined treatment with standard chemotherapeutic agents (i.e. cyclophosphamide or cisplatin) and dabigatran etexilate was evaluated following (i) orthotopic injection of 4T1 mammary adenocarcinoma cells in the mammary fat pad of Balb/c mice, and (ii) i.p. injection of ID8 ovarian adenocarcinoma cells in C57BL6 mice. 4T1 tumor growth was monitored by caliper measurements. Peritoneal tumor spread of ID8 tumor cells expressing the luciferase reporter gene was monitored by bioluminescence imaging. Treatment was initiated when 4T1 primary tumors were palpable (30–80 mm^3) at 2 weeks following 4T1 tumor cell injection or when ID8 bioluminescence was elevated at 5 weeks past ID8 tumor cell injection. Mice were treated once a week with cyclophosphamide (50 mg/kg, i.p.) or cisplatin (2 or 4 mg/kg, i.p.) with or without dabigatran etexilate (oral gavage, 80 mg/kg, bid).

Results: Dabigatran treatment alone had no significant effect on the growth of the primary 4T1 tumor, but it decreased the number of lung metastases. Dabigatran treatment resulted in no weight loss in mice. Cisplatin (4 mg/kg) alone inhibited both primary tumor growth and the number of lung metastases. Whereas treatment with only cyclophosphamide had no significant inhibitory effect on the growth of the primary tumor, treatment with both cyclophosphamide and dabigatran etexilate significantly inhibited growth of primary 4T1 tumors. Compared with treatment with dabigatran alone, there were fewer 4T1 lung metastases in mice treated with both 1) dabigatran and cyclophosphamide or 2) dabigatran and cisplatin. In the ID8 tumor model, single treatment with dabigatran etexilate, cisplatin, or cyclophosphamide exerted a transitory inhibition of tumor spread, but only co-treatment with both dabigatran etexilate and cisplatin (2 mg/kg) significantly decreased ID8 tumor spread as measured by bioluminescence.

Conclusion: Co-treatment with dabigatran etexilate and low doses of either cisplatin or cyclophosphamide synergistically inhibits tumor growth and metastasis. These results suggest that dabigatran may be beneficial in not only preventing thrombotic events in cancer patients, but also as adjunct therapy to treat malignant tumors.

Supported by funds from Boehringer Ingelheim Pharma.

OC 31.6

Protease-activated receptor 2 in the tumor microenvironment inhibits lymphangiogenesis and subsequent lymph node metastasis in a murine pancreatic cancer model

Shi K, Queiroz KCS and Spek CA

Academic Medical Center, Amsterdam, the Netherlands

Background: ancreatic cancer is among the most common malignancies associated with thromboembolic events and thromboembolic events confer a significantly worse prognosis in pancreatic cancer. The underlying mechanisms are poorly understood but it is well accepted that protease activated receptors (PARs) may be the key receptors at the interface between coagulation and cellular process involved in cancer progression. PAR-2 specifically functions as a cell-surface sensor for coagulation factors VIIa and Xa and the proteolytic activation of PAR-2 on tumor cells is suggested to induce angiogenesis and breast cancer development. The importance of PAR-2 in the tumor microenvironment in general and in pancreatic cancer specifically remains unexplored however.

Aims: To elucidate the importance of PAR-2 in the tumor microenvironment during pancreatic cancer development. We specifically aimed to determine whether PAR-2 would drive tumor growth and/or metastasis, and to elucidate the underlying mechanism.

Methods: Wildtype murine pancreatic cancer cells (PANC02; 4×10^5 cells in 50 μL PBS) were orthotopically injected into the pancreas of 6 week old wildtype C57BL/6 mice and/or PAR-2 deficient mice (eight mice per group). Five weeks after cancer cell inoculation, all mice were sacrificed after which pancreatic tumors and lymph nodes were collected for further analysis. Tumour cell proliferation were tested by ki67 staining (*in vivo*) and BrdU cell proliferation assay (*in vitro*). Tumour angiogenesis was analyzed by CD31 and lyve-1 staining (*in vivo*) and tube formation assay (*in vitro*).

Results: At the moment of sacrifice, tumors in wildtype animals had a mean weight of 1.82 ± 0.46 g and a mean volume of 2.75 ± 0.67 cm^3. Interestingly, tumors in PAR-2 deficient mice were significantly smaller (1.10 ± 0.42 cm^3) and lighter (0.91 ± 0.44 g) than in wildtype untreated animals. Immunohistochemical analysis of primary tumours for ki67 (proliferation marker) showed that the remaining tumours in PAR-2 deficient mice are less proliferative. Ongoing *in vitro* BrdU assays suggest that cells in the tumor microenvironment indeed drive pancreatic cancer cell proliferation in a PAR-2 dependent manner.

Interestingly, in contrast to the smaller primary tumors, the size and number of metastasis to the lymph nodes was dramatically increased in PAR-2 deficient animals compared to wildtype mice. Immunohistochemical analysis of primary tumors for CD31 (endothelial cell marker) and lyve-1 (specific for lymph endothelial cells) showed that the number of blood vessels did not differ between wildtype and PAR-2 deficient animals, whereas the number of lymphatic vessels within the tumor was significantly increased in mice lacking PAR-2 in their microenvironment. *In vitro* tube formation assay show that PAR-2 does not inhibit the intrinsic tube forming capacity of human lymphatic endothelial cells. Interestingly however, blocking PAR-2 signaling on these human lymphatic endothelial cells potentiates cancer cell induced tube formation.

Conclusion: PAR-2 expression in the tumor microenvironment plays a dual role during pancreatic cancer progression. On one hand it facilitates primary tumor growth whereas on the other hand it limits lymph angiogenesis and subsequent metastasis to the lymph nodes.

OC 32 – Mechanisms of Atherosclerosis

OC 32.1

Role of platelet-specific junctional adhesion molecule. A (JAM-A) in atherosclerosis progression

Koenen R[1], Karshovska E[2], Zhao Z[2], Von Hundelshausen P[2] and Weber C[2]

[1]Maastricht University, Maastricht, the Netherlands; [2]University Clinic of the LMU Munich, Munich, Germany

Background: Junctional adhesion molecule A (JAM-A) is a transmembrane adhesion glycoprotein from the IgG superfamily expressed by endothelial and epithelial cells as well as by leukocytes and platelets. JAM-A contributes to the organization of endothelial tight junctions and participates in platelet adhesion and leukocyte transmigration by homo- and heterophilic interactions.

Aims: This study sought to characterize the molecular mechanism that controls JAM-A on platelets (trJAM-A) and to identify the role of JAM-A in the pathology of atherosclerosis.

Methods: In our studies we used mice with a specific trJAM-A-deletion after cross-breeding of JAM-$A^{flox/flox}$ mice and mice that express cre-recombinase under control of the platelet factor 4 promoter. For the atherosclerosis experiments we used double knock-out mice in an apolipoprotein E-deficient (ApoE$^{-/-}$) background (trJAM-$A^{-/-}$ and $^{+/+}$ ApoE$^{-/-}$).

Results: Our results revealed that expression of JAM-A was almost completely absent on platelets of trJAM-$A^{-/-}$ mice, based on western blot, flow cytometry and quantitative immunofluorescence microscopy experiments. JAM-A expression on leukocytes, endothelial- and smooth muscle cells in different tissues did not show any difference between trJAM-$A^{-/-}$ and JAM-$A^{+/+}$ mice, as shown by western blotting and double immunofluorescence staining against JAM-A and von Willebrand factor (endothelium cells) and α-smooth muscle actin (smooth muscle cells). Furthermore, Multiplate® functional analysis *in vitro* showed that lack of trJAM-A resulted in an increased platelet aggregation in response to agonists like adenosine diphosphate (ADP), indicating for platelet hyperresponsivity, consistent with a recent previous study (Naik et al., Blood 2012). To answer the question whether trJAM-A is involved in atherosclerosis progression, we fed double knock-out mice (trJAM-$A^{-/-}$ and $^{+/+}$ ApoE $^{-/-}$) a high fat diet for 12 weeks, harvested aorta and aortic root for plaque quantification. *En face* lipid staining on aorta revealed that lack of trJAM-A significantly increased plaque formation in the whole aorta (10.6 ± 2.35 vs. $24.6 \pm 4.50\%$, $n = 7–9$) and in thoraco-abdominal part (9.70 ± 2.53 vs. $21.3 \pm 4.46\%$, $n = 7–9$) but did not show any change neither in the aortic arch nor in the aortic root. These observations supported the hypothesis that trJAM-A may play role in early atherosclerosis. In addition, investigating the plaque composition in the aortic root did not show any significant difference, neither in macrophage- (MAC-2 staining), smooth muscle cells-, endothelium cells content nor in CD3-positive T cell recruitment into the plaque. Nevertheless, assessment of plaque phenotype revealed that deletion of trJAM-$A^{-/-}$ resulted in significantly more plaques with an advanced phenotype. This indicates that lack of trJAM-A, besides accelerating plaque development during early stages, may also play a role in macrophage polarization and differentiation during the progress of atherosclerosis.

Summary/Conclusion: Our results identify JAM-A as an endogenous inhibitor of platelet function and of early atherosclerosis progression. These results will advance our knowledge about JAM-A in platelet function and the molecular mechanisms of JAM-A and of platelets in the pathophysiology of atherosclerosis.

OC 32.2

The role of vessel wall P2Y12 in early atherogenesis is not blocked by ticagrelor or clopidogrel

West LE, Steiner T, Francis SE and Storey RF
University of Sheffield, Sheffield, UK

Background: The pivotal role of platelets in atherothrombosis is well defined but the extent of their role in early atherogenesis is less clear. The $P2Y_{12}$ receptor is responsible for amplifying and sustaining platelet activation and inhibition of $P2Y_{12}$ modulates the vessel wall response to injury. $P2Y_{12}$ inhibitors, including ticagrelor and clopidogrel, perform a crucial role in the treatment and prevention of thrombotic events. Ticagrelor is also an inhibitor of adenosine reuptake by erythrocytes and has been shown to block ADP-induced vasoconstriction in isolated arteries. Ticagrelor, compared to clopidogrel, reduces mortality risk in patients with acute coronary syndromes but the mechanisms for this mortality reduction remain to be established.
Aims: Our aims were to investigate the role of $P2Y_{12}$ in atherogenesis and determine any $P2Y_{12}$-mediated or non-$P2Y_{12}$-mediated effects of ticagrelor and clopidogrel on this process.
Methods: $ApoE^{-/-}$ and $ApoE^{-/-}P2Y_{12}{}^{-/-}$ male mice were fed either chow or western diet for 12 weeks and atherosclerotic burden was assessed by *en face* oil red O (ORO) staining of whole aortae and histological analysis of the aortic sinus and brachiocephalic artery. Bone marrow transplants were performed to determine the roles of platelet versus vessel wall $P2Y_{12}$ in early atherogenesis following 4 weeks of western diet. The effects of pharmacological inhibition of $P2Y_{12}$ on atherosclerotic burden were investigated using $ApoE^{-/-}$ and $ApoE^{-/-}P2Y_{12}{}^{-/-}$ mice fed western diet and either twice-daily doses of ticagrelor (100 mg/kg), daily clopidogrel (20 mg/kg) or mannitol (control) for 4 weeks. Platelet $P2Y_{12}$ inhibition was assessed by PAR4-mediated P-selectin expression.
Results: ORO staining showed no difference in total lesion area between $ApoE^{-/-}$ and $ApoE^{-/-}P2Y_{12}{}^{-/-}$ mice for either diet when assessing the aorta as a whole. However, further analysis of the aortic arch alone uncovered a significant reduction in atheroma in $ApoE^{-/-}P2Y_{12}{}^{-/-}$ mice fed a western diet ($P < 0.0001$). Similarly histological analysis revealed lesion area was attenuated in the brachiocephalic artery ($P < 0.05$) but not in the aortic sinus. Bone marrow transplants demonstrated that mice deficient in vessel wall $P2Y_{12}$, regardless of platelet $P2Y_{12}$ expression, had significantly reduced lesion area in both the aortic sinus and brachiocephalic artery ($P < 0.001$).
$ApoE^{-/-}$ and $ApoE^{-/-}P2Y_{12}{}^{-/-}$ mice fed either ticagrelor or clopidogrel exhibited no reduction in whole aortae lesion area compared to controls despite effective $P2Y_{12}$ inhibition. Separate analysis of the aortic arch and descending aorta, demonstrated no region-specific differences in lesion formation. Histological analysis of the aortic sinus confirmed these results.
Summary/Conclusion: Vessel wall $P2Y_{12}$ plays an important role in promoting atherosclerotic lesion development. Despite the proven role of platelets in atherothrombosis, we found no role of platelet $P2Y_{12}$ in early atherogenesis. Ticagrelor and clopidogrel were unable to inhibit lesion development in $ApoE^{-/-}$ or $ApoE^{-/-}P2Y_{12}{}^{-/-}$ mice, indicating these $P2Y_{12}$ inhibitors have no effect on early atherogenesis via $P2Y_{12}$- or non-$P2Y_{12}$-mediated routes.

OC 32.3

Deficiency of the anticoagulant annexin A5 attenuates atherosclerotic plaque development in ApoE−/− mice

Kusters D[1], Chatrou MLL[1], Willems BAG[1], Schutters K[2], Schurgers LJ[1] and Reutelingsperger CPM[1]
[1]*Maastricht University, Maastricht, the Netherlands;* [2]*Aachen University, Aachen, Germany*

Background: Annexin A5 (anxA5) is a human anticoagulant that inhibits the formation of thrombin by shielding procoagulant surfaces containing phosphatidylserine (PS). Thrombin is implicated as key regulator of atherosclerotic plaque formation. Inhibition of thrombin has been shown to attenuate atherosclerotic plaque progression.
Aims: The aim of this project is to explore the role of anxA5 in atherosclerotic plaque development in a murine model for atherosclerosis.
Methods: AnxA5 deficient mice were created by homologues recombination by replacing intron 3 and 4 with the β-galactosidase gene. $ApoE^{-/-}$:$anxA5^{-/-}$ double knock-out mice were generated by backcrossing $anxA5^{-/-}$ with $ApoE^{-/-}$ for at least five generations (both C57Bl6 background). Both $apoE^{-/-}$ and $apoE^{-/-}$:$anxA5^{-/-}$ mice were fed normal chow diet and sacrificed at 14, 20 and 26 weeks of age. The aortic arch was dissected and used to assess plaque size and phenotype by (immuno)-histological and mRNA analysis.
Results: Baseline characteristics including cholesterol, triglycerides and blood- and bone marrow cell composition were not significantly different between $apoE^{-/-}$ and $apoE^{-/-}$:$anxA5^{-/-}$ mice. However, $ApoE^{-/-}$:$anxA5^{-/-}$ deficient mice had less circulating B-cells as compared to $apoE^{-/-}$ mice.
At 14 weeks of age no neo-intima formation was present in either single or double knock-out mice, which is in agreement with data published on the $apoE^{-/-}$ model. At 20 and 26 weeks of age however, in the lesser curvature of the arch a significantly smaller plaque was formed in the $apoE^{-/-}$:$anxA5^{-/-}$ compared to the $apoE^{-/-}$. Additionally, $apoE^{-/-}$:$anxA5^{-/-}$ mice displayed a more stable phenotype with significantly more collagen (at 20 weeks) and less apoptotic cells (at 26 weeks).
Summary/Conclusion: Our data indicate that the anticoagulant protein anxA5 is involved in plaque development and stability in the aortic arch and in the brachiocephalic artery. Recent data show reduced phagocytosis by anxA5, indicating that the absence of anxA5 *in vivo* might have increased phagocytosis and thus a decreased plaque development. The effect of anxA5 on angiogenesis, vascular leakage and smooth muscle cell migration is currently under investigation.

OC 32.4

Calcium, cholesterol and TLT-1 in atherosclerosis

Gonzalez M[1], Reyes F[1], Marrero D[1], Collado C[1] and Washington AV[2]
[1]*Universidad Central del Caribe, Bayamon;* [2]*Universidad de Puerto Rico, Rio Piedras Campus, San Juan, Puerto Rico*

Background: Vascular injury and inflammation represent a vicious cycle that involves activation of platelets, leukocytes, and endothelial cells. Platelet activation not only leads to subsequent deposition of cytokines in the arterial wall but also to the expression of platelet a-granule receptors; P-selectin, and the Triggering Receptor Expressed in Myeloid cells (TREM)-like transcript (TLT-1). Previous studies removing p-selectin in either an APOE or LDLR-deficient genetic background have demonstrated that p-selectin deficiency leads to a reduction of fatty lesions compared to $apoE^{-/-}$ or $LDLR^{-/-}$ mice. These results suggest that p-selectin promotes atherosclerotic lesion progression. TLT-1 is found exclusively on megakaryocytes and platelets and like p-selectin, is stored in the a-granules of resting platelets.
Aims: Studies with *treml1*−/− mice demonstrated seemingly overlapping phenotypes with p-selectin−/− including prolonged bleeding times, delayed neutrophil migration, higher basal neutrophil counts, and hemorrhage in response to the Shwartzman reaction. The similar phenotypes upon removal of P-selectin and TLT-1 lead us to hypothesize that removal of TLT-1 would also delay the formation of atherosclerotic lesions in an *apoE* deficient mice model
Methods: In this novel atherosclerosis mouse model, we evaluated lesion development and cholesterol levels in mice on an atherogenic diet at different time points.
Results: Lesion evaluation demonstrated three surprising revelations. First, an unexpected trend where the lesions in the *apoE*/*treml1* double null mice have intensified compared to the *apoE*−/− or *treml1*−/− mice. Second, this trend is reversed after 20 weeks of high fat diet

where although both mice progressed to an advance fibrous plaque stage and the differences in lesion sizes were not significantly different, however a significantly higher number of apoE mice display calcification compared to the DN mice. Third, and perhaps the most intriguing finding was that the DN mice have significantly higher cholesterol levels when compared to apoE−/− mice. The increased cholesterol levels extend to the *treml1*−/− mouse when compared to wild type mice at 4 weeks on HFD, this difference, however, gradually subsides as wild type mice cholesterol levels increase over 20 weeks. Interestingly, cholesterol levels in 50 week old mice on chow diet revealed minimal differences between test and control mice suggesting the higher cholesterol levels are related to increased dietary intake

Summary: Our work defines a surprising role for TLT-1 in the progressing of atherosclerosis and in the regulation of serum cholesterol levels during atherogenesis. Collectively, our data suggest that the HFD may induce the expression of TLT-1 at secondary sites outside of platelets and has prompted a search for other cell types that may produce TLT-1. The current status of our investigation will be presented in this poster.

OC 32.5

Sphingosine-1-phosphate induced TNF-a expression in natural killer T (NKT) cell hybridomas through S1P2/Gq/PLC/PKC pathway and mediated migration of NKT cell hybridomas

Ito S[1], Kondo R[1], Iwaki S[1], Iwabuchi K[2] and Fujii S[1]

[1]Nagoya City University Graduate School, Nagoya; [2]Kitasato University School of Medicine, Sagamihara, Japan

Background: Natural killer T (NKT) cells are unique lymphocytes that recognize glycolipid antigen and produce various cytokines through T cell antigen receptor. NKT cells contribute to metabolic disorders such as glucose intolerance and cardiovascular diseases. Sphingosine-1-phosphate (S1P) is a bioactive sphingolipid released from red blood cells or activated platelets. S1P regulates cell proliferation, inflammation and migration via S1P receptors. There are five subtypes of S1P receptors ($S1P_1$-$S1P_5$) and each of them is coupled with G proteins. NKT cells express $S1P_1$, $S1P_2$ and $S1P_4$. We have previously shown that S1P increased the expression of tumor necrosis factor-α (TNF-α) in NKT cell hybridomas via $S1P_2$ receptor. TNF-α is a representative pro-inflammatory cytokine and a risk factor of insulin resistance. TNF-α produced by NKT cell could exacerbate atherosclerosis and diabetes. High-fat-diet induces infiltration of NKT cells in mouse adipose tissue and S1P receptor is also reported to mediate the migration of T lymphocytes.

Aims: We aimed to clarify the mechanism of S1P-induced TNF-α expression in NKT cell hybridomas, and to determine whether S1P induces the migration of NKT cell hybridomas.

Methods: NKT cell hybridoma, 1B6 cells and 2E10 cells, were established by fusing sorted mouse NKT cells with BW1100 thymoma cells. These cells were used as a model of NKT cells. Hybridomas were treated with Rho kinase inhibitor (Y-27632), MAP kinase kinase inhibitor (U0126), uncoupler of Gi and Go proteins from the S1P receptors (pertussis *toxin)* or protein kinase C (PKC) inhibitor (Ro-31-8220), and then stimulated with 1 μM S1P. TNF-α mRNA expression and TNF-α protein production were determined by real-time PCR and ELISA, respectively. Cell migration assay was performed with modified Boyden chamber system (Chemotaxcell).

Results: S1P receptor antagonists decreased the TNF-α mRNA expression induced by S1P in NKT cell hybridomas. Y-27632 and pertussis toxin did not inhibit the increased expression of TNF-α induced by S1P. U0126 and Ro-31-8220 inhibited the S1P-inducible TNF-α expression. The migration of NKT cell hybridomas was increased by S1P. FTY720, an immunosuppressive S1P receptor modulator, reduced their migration induced by S1P.

Conclusions: These results suggest that $S1P_2$/Gq/PLC/PKC pathway could mediate the increased TNF-α expression in NKT cells induced by S1P. Overexpression of TNF-α by S1P may induce glucose intolerance. S1P also induced the migration of NTK cell hybridomas, potentially provoking inflammatory response. S1P and S1P receptor might be attractive therapeutic targets for metabolic syndromes and atherothrombotic disorders.

OC 32.6

Effect of immunization of C5a and C3a released from complement component C5 and C3 respectively on early atherosclerotic lesion in Apobtm2SgyLdlrtm1Her/J mouse model

Lu X[1], Xia M[1], Chen D[2], Endresz V[3], Faludi I[3], Szabo A[3], Mundkur L[1] and Kakkar V[1]

[1]Thrombosis Research Institute; [2]King's College London, London, UK; [3]University of Szeged, Szeged, Hungary

Background: C5a and C3a are protein fragments released from complement component C5 and C3 containing 74 and 77 amino acids in human, respectively. Complement is a central effector system within the immune system and is implicated in a range of inflammatory disorders and complement components have been detected in atherosclerotic lesions, from the fatty streak through fibrous to complicated plaques. Binding of both C3a and C5a to their receptors lead to important biological functions. Both receptors are expressed in human atherosclerotic coronary plaques. Therefore, investigation of the mechanisms of the effect of C5a or C3a may provide some important information for the treatment of atherosclerosis. In the present study we have therefore studied the role of C5a and C3a in atherosclerotic lesion development through immunization of $Apob^{tm2Sgy}Ldlr^{tm1Her}$/J mice with these proteins.

Aim: To assess whether immunizing $Apob^{tm2Sgy}Ldlr^{tm1Her}$/J mice with C5a and C3a is effective in reducing atherosclerotic lesions.

Results: Immunization with C5a and C3a elicited high level of antibodies against C5a and C3a in $Apob^{tm2Sgy}Ldlr^{tm1Her}$/J mice. In addition, mice immunized with the C5a (GST-tagged) and C3a (GST-tagged) showed a greater reduction in lesion size by 24% ($P = 0.007$) and 19% ($P = 0.042$), respectively compared to the control mice immunized with GST only and the immunization was also associated with a significant decrease in lesion area in descending aortas compared with that in controls, showing 74.5% ($P = 0.003$) and 57.1% ($P = 0.003$) reduction for C5a and C3a-immunized mice, respectively. The reduction in the lesion size in aorta sinus and in descending aortas correlated with a change in cellular composition of the plaques, and an altered cytokine/chemokine secretion in serum or in stimulated spleen cells as well as specific cellular immune responses when compared with controls. Conclusions

Immunization of mice with C5a and C3a was effective in reducing early atherosclerotic lesions.

The hepatic Ashwell-Morell receptor regulates thrombopoietin production

Hoffmeister KM, Grozoswky R, Jurak Begonja A, Hartwig JH and Hoffmeister KM

Harvard Medical School, Boston, MA, USA

Introduction: The highly conserved hepatic Ashwell-Morell (asialoglcyoprotein) receptor (AMR) can bind and remove blood asialoglycoproteins although the identity of endogenous ligands has

been elusive. We previously showed that desialylated cold-stored platelets are ingested by hepatic AMR. We now hypothesized that desialylated platelets serve as communicators between the AMR to stimulate thrombopoietin (Tpo) production and to regulate bone marrow homeostasis.

Results: (i) Desialylated human platelet uptake by AMR stimulates hepatic Tpo mRNA translation *in vitro*. Human platelets were desialylated using a2-3, -6, -8 sialidase from *Clostridium perfringens* or left untreated and incubated with HepG2 cells *in vitro*. The relative ratio of Tpo mRNA/CycloA mRNA in the human hepatic cell line HepG2 was determined and compared. Tpo mRNA expression increased 30 min after addition of desialylated platelets, and further increased by 2.2 and 2.9-fold after 4 and 6 h, respectively. In marked contrast, Tpo mRNA translation in HepG2 cells incubated with control platelets was only slightly increased. (ii) Transfusion of desialylated (using a2-3, -6, -8 sialidase) mouse platelets into wild type (WT) mice stimulates hepatic Tpo mRNA expression *in situ*. Hepatic Tpo mRNA levels increased by ~50% after 12 h of platelet infusion into WT mice, and plasma Tpo levels increased by 36% (24 h) to 58% (48 h) following infusion of desialylated platelets. (iii) Endogenously desialylated platelets were isolated from *St3gal4*$^{-/-}$ or AMR null mice (*Asgr2−/−)* mice. These mice lack either the critical sialyltransferase ST3GalIV, which adds sialic acid to glycoproteins (*St3gal4*$^{-/-}$) or the ability to remove senile, desialylated platelets (Asgpr2$^{-/-}$). Desialylated platelets isolated from the *St3gal4−/−* or *Asgr2−/−* mice and infused into WT mice caused an increase in hepatic Tpo mRNA levels at 12 h post-transfusion. Plasma Tpo concentrations increased in parallel with Tpo mRNA levels, peaking by day two post-infusion. Desialylated platelets given to *Asgr2−/−* mice had no effect on Tpo mRNA synthesis or on Tpo plasma levels. WT, but not mice receiving desialylated platelets rapidly (within 24 h) released new platelets into blood and on day 10 post-treatment, corresponding to the Tpo plasma increase. Accordingly, following desialylated platelet transfusion, megakaryocyte numbers increase in the bone marrow of WT but not of *Asgr2−/− mice*. (iv) Desialylated platelet uptake by AMR regulates hepatic Tpo mRNA expression *in situ*, as evidenced by reduced hepatic Tpo mRNA levels were reduced by ~50% in *Asgr2−/−* mice which lack the ability to take up desialylated platelets. In contrast, livers isolated from *St3gal4−/−* mice in which platelet turnover is accelerated due to inefficient membrane glycoprotein sialyation and the uptake by the AMR receptor, exhibit increased Tpo mRNA levels relative to WT livers. The difference in the Tpo mRNA levels between the two mouse genotypes reveals that platelet uptake stimulates a 1.9-fold increase in Tpo mRNA expression.

Conclusion: Our data support the hypothesis that uptake of desialylated platelets via AMR stimulates Tpo mRNA expression. We conclude, that platelets desialylate as they circulate and become the primary AMR ligand in blood, thus providing a novel physiological feedback mechanism to regulate plasma Tpo levels and platelet production.

OC 33.2

Microthrombocytopenia and impaired platelet integrin function in conditional profilin1-deficient mice

Stritt S[1], Bender M[1], Nurden P[2], Gupta S[1], Thielmann I[1], Hartwig JH[3] and Nieswandt B[1]

[1]*University Hospital and Rudolf Virchow Center, Wuerzburg, Germany;* [2]*Plateforme Technologique d'Innovation Biomédicale, Hôpital Xavier Arnozan, Pessac, France;* [3]*Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA*

Background: Blood platelets are small anucleated cell fragments generated from bone marrow megakaryocytes (MKs) by a cytoskeleton–driven process. Thereby, mature MKs form long cytoplasmic protrusions, so-called pro-platelets, which extend into the sinusoids within the bone marrow and are finally released through a shear-dependent mechanism. Profilin1 is a small actin-binding protein catalyzing the exchange of nucleotides on G-actin monomers. Moreover, it was shown to incorporate ATP-G-actin into growing actin filaments, therefore directly interfering with actin assembly. However, the overall significance of profilin1 in platelet formation and function is unknown.

Aim: We aimed to investigate the function of profilin1 in platelet production and function.

Methods: Platelet formation and function was analysed in mice lacking profilin1. To delete profilin1 exclusively in MKs and platelets, mice with a floxed profilin1 gene were crossed with PF4 (platelet factor 4)-Cre mice.

Results: Mice lacking profilin1 in MKs and platelets suffered from a microthrombocytopenia with a platelet count reduction of 30–40%. The circulating small platelet population was discoid with well distributed granules and displayed markedly impaired integrin inside–out activation and outside-in signalling. Interestingly, profilin1–deficiency had no effect on F-actin assembly in a flow cytometry–based assay but resulted in significantly increased platelet microtubule content as revealed by Western blot analysis and transmission electron microscopy. Furthermore, the microtubules were severely misorientated in resting and spread profilin1–deficient platelets as shown by confocal fluorescence microscopy. The mutant platelets displayed delayed spreading on a fibrinogen-coated surface and were unable to form filopodia on a von Willebrand factor matrix.

In vivo, profilin1 deficiency did not affect MK numbers in the bone marrow but the cells displayed an altered ultrastructure with an increased formation of empty membranes and microparticles. Confocal microscopy on cryo-sections of whole femora revealed pre-platelet release within the bone marrow, which indicates an accelerated pro–platelet production. The premature platelet release, in combination with an increased clearance of the circulating platelets, contributed to the observed thrombocytopenia.

Conclusion: The profilin1 knockout mouse constitutes a rare model of thrombocytopenia with small platelet size. Further, these data demonstrate that profilin1 is crucial for proper platelet formation and sizing but also in the regulation of the tubulin cytoskeleton and integrin function in these cells.

OC 33.3

Functional characterisation of novel regulators of haematopoiesis: from GWAS to function

Bielczyk-Maczynska EK[1], Soranzo N[2], Ouwehand WH[1] and Cvejic A[1]

[1]*University of Cambridge;* [2]*Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK*

Background: Platelet count and volume are independent risk factors for heart attacks and ischaemic strokes. We therefore used meta-analyses studies (GWAS) to identify genes encoding novel regulators of megakaryopoiesis and platelet formation (HaemGen Consortium, Nature, 2011:480, 201). For about three-quarters of the 68 genetic signals associated with platelet count and volume credible gene candidates could be inferred. Two-third of these encode proteins hitherto unknown to be implicated in megakaryopoiesis and platelet formation. We hypothesise and have preliminary evidence that these new proteins are important rate-limiting factors of megakaryopoiesis and platelet formation, making them prime targets for further functional characterisation.

Aim: To delineate the function of genes identified by a platelet GWAS by gene knockdown in a relevant model organism

Methods: To this end, we performed a high-throughput reverse genetic screen in zebrafish using morpholino (MO) knock down approach. This was followed by in-depth functional analysis of selected genes using a wide panel of different haematopoietic markers with the main aim to further our understanding of the function of the novel regulators of blood formation.

Results: We included 16 genes in the screen to identify novel pathways essential in thrombopoiesis and haematopoiesis in general. Knock down of all but four resulted in 50–90% reduction in the number of thrombocytes in a CD41-transgenic zebrafish. To further investigate lineage-specific effects of the candidate genes we assessed the status of definitive erythropoiesis, myelopoiesis and lymphopoiesis in MO injected embryos. The information gleaned from the initial knock-down/phenotyping was used to generate heat-map of gene expression profiles and to cluster genes with similar phenotypes. Consequently, we were able to hierarchically position candidate genes on the haematopoietic tree and to assign them a potential role during haematopoietic differentiation.

Conclusion: Using the from-GWA study-to-function strategy we have not only identified a series of genes that represent novel regulators of thrombopoiesis and haematopoiesis, but this work also represents, to our knowledge, the first example of a functional genetic screening strategy that is a critical step toward obtaining biologically relevant functional data from GWA study for blood cell traits. The results of these studies are now informing our next step in exploring the relationship between rare sequence variants in platelet GWAS-genes and the count and volume of platelets.

OC 33.4

PEAR1 attenuates megakaryopoiesis via regulation of the PTEN/PI3K pathway

Kauskot A, Vandenbriele C, Louwette S, Freson K, Verhamme P and Hoylaerts MF

[1]*KU Leuven, Leuven, Belgium*

Background: Platelet endothelial aggregation receptor-1 (PEAR1) is expressed on platelets and endothelial cells. We recently reported that interactions between PEAR1, C-src, Fyn and the p85/Phosphoinosite 3-kinase (PI3K) subunit constitute a signaling complex, causing sustained aIIbb3 activation via Akt phosphorylation. The overexpression of PEAR1 in mouse bone marrow cells decreased the number of myeloid progenitors during *in vitro* clonogenic assays, suggesting that PEAR1 regulates the early stages of hematopoietic differentiation. Whether PEAR1 is a determinant of megakaryocyte (MK) differentiation is presently unclear.

Methods and Results: To investigate the role of PEAR1 in platelet formation, we assessed and manipulated PEAR1 expression *in vitro* in differentiating human $CD34^+$ hematopoietic progenitor cells and *in vivo in* zebrafish embryos. We abolished expression of PEAR1, via lentiviral vectors encoding shPEAR1 in human $CD34^+$ cells and via morpholino injection in zebrafish embryos.

PEAR1 expression increased during $CD34^+$ cell differentiation up to the megakaryocyte stage. Lentiviral-mediated PEAR1 knockdown in $CD34^+$ cells enhanced cell proliferation three-fold and the formation of CFU-MK, without substantially modifying progenitor maturation and the number of CFU-erythrocytes. To characterize PEAR1 target genes in MKs grown from cytapheresis isolates, we compared control shDsRed- and shPEAR1-transduced MKs on day 12 by profiler qRT-PCR analysis. Interestingly, we found that a target of the Notch pathway, *HES1*, was upregulated without expression modification of Notch receptors. *PTEN*, a phosphatase regulating the PI3K pathway, and *CCND1* (cyclin D1) were both downregulated. Although GATA-1 and PU-1 transcription factors are implicated in megakaryopoiesis, their expression was not affected in the absence of PEAR1. To study the role of PEAR1 *in vivo*, CD41:eGFP zebrafish were chosen, expressing GFP under control of the CD41 promotor. In these zebrafish, *Pear1* expression increased progressively the first 3 days of embryo development. Correspondingly, low concentrations (50 mM) of ATG- and splice-blocking PEAR1 morpholinos enhanced thrombopoiesis in the zebrafish, without affecting erythropoiesis at day 2 or 3, confirmed by western blotting of GFP. The injection of 50 mM PEAR1 MO resulted in elevated Akt phosphorylation, as revealed by western blots of 3-day-old *Pear1* knockdown zebrafish, coupled to transcriptional downregulation of the phosphatase PTEN isoform *Ptena*. Neutralization by morpholinos of *Ptena,* but not of *Ptenb,* phenocopied the *Pear1* zebrafish knockdown and triggered a rise in Akt phosphorylation and thrombocyte numbers. At higher MO concentrations, the thrombocyte count dropped, in relation to developmental problems, which worsened dose-dependently, upon injection with more PEAR1 MO. Up to 50 mM PEAR1 MO, no defects were observed, but at 100 mM PEAR1 MO, 42% of the fish presented a mild (23%) to severe (19%) morphological phenotype. Abnormalities ranged from defective development of the nervous system (lack of eyes and head) to severe phenotypic abnormalities, motility limitations and lethality at 500 mM.

Conclusions: In summary, the present study reports that PEAR1 is progressively upregulated during human megakaryopoiesis. PEAR1 is a negative regulator of cell proliferation, but not of MK maturation. This work demonstrates for the first time that PEAR1 modulates the PI3K/PTEN pathway, a critical determinant of Akt phosphorylation, megakaryopoiesis and thrombopoiesis.

OC 33.5

Tropomyosin 4 is a novel regulator of platelet production in mice and humans

Pleines I[1], Chappaz S[1], Lane R[1], Kostadima MA[2], Schevzov G[3], Ghevaert C[4], Gunning P[3], Ouwehand WH[5] and Kile BT[1]

[1]*The Walter and Eliza Hall Institute of Medical Research, Parkville, Australia;* [2]*European Bioinformatics Institute (EMBL-EBI), Wellcome Trust Genome Campus, Cambridge, UK;* [3]*School of Medical Sciences, The University of New South Wales, Sydney, Australia;* [4]*University of Cambridge;* [5]*University of Cambridge and Wellcome Trust Sanger Institute, Cambridge, UK*

Background: Alterations in platelet count (PLT) and size (MPV) are associated with an elevated risk of cardiovascular disease. To elucidate the molecular mechanisms controlling PLT and MPV, genome-wide association studies (GWAS) have been undertaken to detect common genetic variants associated with these traits. A recent GWAS meta-analysis led to the identification of single nucleotide polymorphisms (SNPs) in two novel loci encoding the actin cytoskeletal regulators *Tropomyosin (TPM) 1* and *TPM4* (Gieger et al. Nature 2011). Both common SNPs were associated with platelet volume and count in healthy individuals. Silencing of the gene homologues in zebrafish abolished the formation of thrombocytes. Together, these findings suggest an important role for tropomyosins in platelet production. The physiological functions of tropomyosins in hematopoiesis have yet to be elucidated.

Aim: Define the roles of tropomyosins in hematopoiesis, with a particular focus on the megakaryocyte lineage.

Methods: We identified a mouse model of *Tpm4* dysfunction in a mouse mutagenesis screen. Platelet and megakaryocyte function were assessed *in vitro* and *in vivo* employing cell biology, biochemistry and microscopy. Results were complemented with bioinformatic analysis of human blood cells.

Results: In a mouse mutagenesis screen for novel regulators of platelet production in mice we identified a pedigree harbouring a splice site mutation in the *Tpm4* gene. The mutant allele appears to be hypomorphic, expressing almost undetectable levels of the major Tpm4 protein isoform. Importantly, consistent with the phenotype associated with the SNP identified in humans (Gieger et al. Nature 2011), *Tpm4* dysfunction leads to macrothrombocytopenia in mice. Bone marrow transplants demonstrated that this phenotype is intrinsic to hematopoietic cells. Erythroid, myeloid and lymphoid cell numbers are normal indicating a highly specific role of *Tpm4* in platelet production.

Notably, *Tpm4* dysfunction did not affect the life span or *in vitro* function of mutant platelets. Likewise, megakaryocyte numbers and maturation appeared normal. However, mutant megakaryocytes displayed

markedly decreased proplatelet formation *in vitro*, and increased premature fragmentation in the bone marrow.
Together, these results indicate a crucial role of *Tpm4* specifically in the terminal stages of platelet production. Ongoing studies suggest that *Tpm4* dysfunction affects the activity of cofilin, thus linking *Tpm4* to several cytoskeletal signaling pathways implicated in platelet production in mice and humans.
Summary: We identified a mouse line with *Tpm4* dysfunction, which exhibits a platelet phenotype that corroborates the observed effect of the common SNP rs8109288 in the human *TPM4* gene on platelet volume and count. Our results provide evidence that *TPM4* is a direct regulator of platelet production in mice and humans and specifically required for the terminal stages of platelet production. They also suggest that tropomyosins might play an important role in hematopoiesis more broadly.

OC 33.6

Redundant functions of RhoA and Cdc42 in platelet biogenesis

Popp M[1], Cherpokova D[1], Dütting S[1], Pleines I[1], Krohne G[2], Nurden P[3], Brakebusch C[4] and Nieswandt B[1]
[1]University Hospital and Rudolf Virchow Center; [2]University of Würzburg, Würzburg, Germany; [3]Hôpital Xavier Arnozan, Pessac, France; [4]University of Copenhagen, Copenhagen, Denmark

Background: The Rho GTPase family members RhoA, Cdc42 and Rac1 play major roles in cytoskeletal reorganisation that occurs during platelet production from megakaryocytes (MK) and their activation at sites of vascular injury. We have shown that a MK-specific RhoA-deficiency results in a moderate macrothrombocytopenia and impaired platelet responses downstream of G_{13}- and G_q-coupled receptors. On the other hand, mice with a MK-specific Cdc42-deficiency also display a moderate thrombocytopenia but increased agonist-induced secretion, whereas mice lacking Rac1 in MKs display normal platelet counts but defective phospholipase C γ2-mediated platelet activation. Although the signalling pathways downstream of RhoA, Cdc42, and Rac1 partially overlap, possible redundant functions of these Rho GTPases in regulating platelet biogenesis and function have remained elusive.
Aims: The aim of this study was to investigate functional redundancies of RhoA and Cdc42 or Rac1 in platelet production and function.
Methods: Mice with MK-/platelet-specific (PF4-Cre/loxP) double-deficiencies in RhoA and Cdc42 (referred to as *RhoA/Cdc42−/−*) as well as RhoA and Rac1 (referred to as *RhoA/Rac1−/−*) were generated by intercrossing the respective single knockout mice. Platelet function was assessed by biochemical methods. Platelet and MK morphology, and proplatelet formation were investigated *in vitro* and *in situ* by confocal and transmission electron microscopy (TEM).
Results: In contrast to single deficiency of either RhoA or Cdc42, which displayed only moderately reduced platelet counts, double-deficiency in RhoA and Cdc42 resulted in a severe macrothrombocytopenia with platelet counts below 25% of control mice. The size of the remaining platelets was very heterogeneous with some platelets of enlarged size and detailed analysis by TEM revealed a highly abnormal ultrastructure concerning shape, vacuoles, paucity in granules, and abnormal distribution of microtubules resulting in a pronounced reduced platelet life span. Furthermore, *RhoA/Cdc42−/−* mice displayed impaired integrin activation upon stimulation with G protein coupled receptor- and (hem) immunoreceptor tyrosine-based activation motif-agonists. Histological analyses revealed only a slight increase in MK number in bone marrow but a five-fold increase in the spleen that did not correlate with signs of splenomegaly. Interestingly, RhoA/Cdc42 double-deficiency did not impair *in vitro* MK differentiation and quantitative proplatelet formation as assessed by light microscopy. However, MKs showed a severely altered ultrastructure *in situ*. In contrast to this phenotype, RhoA/Rac1 double-deficiency phenocopies the respective single knockouts without any additional effects in the double-knockout animals.
Conclusion: These results demonstrate for the first time a functional redundancy of RhoA and Cdc42, but not RhoA and Rac1, in platelet biogenesis.

Functional studies and proteomics in platelets and fibroblasts reveal a lysosomal defect with increased cathepsin-dependent apoptosis in ATP1A3 defective alternating hemiplegia of childhood

Di Michele M, Goubau C, Waelkens E, Thys C, Overbergh L, Buyse G, Casaer P, Van Geet C and Freson K
KU Lueven, Leuven, Belgium

Background: Alternating hemiplegia of childhood (AHC) is a rare syndrome with repeated hemiplegic episodes, paroxysmal events and global neurological impairment. Symptoms start early and typically disappear during sleep. Only very recently, heterozygous *de novo* missense mutations in the *ATP1A3* gene, coding for the isoform a3 of the sodium/potassium ATPase alpha-3 subunit, have been identified in AHC patients. However, the underlying pathogenesis mechanism remains unknown.
Aims: The aim of this work was to elucidate the biological mechanisms at the basis of *ATP1A3* defective AHC.
Methods: As platelets are relatively easy available cells and represent a good cellular model to study defects in neuropathologies with a subclinical platelet defect, morphological and functional experiments were performed in nine unrelated AHC patients.
Results: Mutation analysis of *ATP1A3* revealed mostly D801N or E815K variants. Platelets from the AHC patients presented with structural and functional abnormalities of granules positive for the lysosomal marker CD63. Electron microscopy showed dense granules with an abnormal core often polygonal and irregular with an empty border instead of a round dense core. Platelets spread on fibrinogen and stained for lysosomal marker CD63 showed significantly more centralized and fused platelet granules in the AHC cases compared to control platelets. The epinephrine-induced platelet aggregation lacked the secretion-dependent secondary activation step in the patients, while other aggregations with standard concentrations of ADP and collagen were normal. The patients' fibroblasts also showed abnormal granule structures with a five-fold higher number of autophagic vacuoles compared to controls and again CD63 staining was increased for the patients. Proteomic analysis of platelets and fibroblasts showed a total of 93 differentially expressed proteins in AHC, mainly involved in metabolism. Pathway analysis performed on these proteins showed a major alteration of the network of 'cell function and maintenance' in this disease, a function that can be attributed to lysosomes. Interestingly, 7 of these altered proteins were detected in both platelets and fibroblasts, including the lysosomal protein cathepsin. AHC fibroblasts revealed significantly increased levels of activated cathepsin B and a stronger activation of cathepsin-dependent apoptosis.
Summary/Conclusions: Our study is the first to link *ATP1A3* defects in AHC to a platelet and fibroblast lysosomal defect with evidence of increased apoptosis. However, further studies are needed to define how this lysosomal defect is related to decreased ATPase activity.

OC 34.2

Identification of novel FLI1 mutations in two families with a platelet secretion defect

Stockley J[1], Jones M[2], Bem D[3], Mundell S[2], Gissen P[3], Mumford AD[2], Makris M[1], Watson SP[3] and Daly ME[1]

[1]*Haemostasis Research Group, Sheffield;* [2]*University of Bristol, Bristol;* [3]*University of Birmingham, Birmingham, UK*

Background: Inherited platelet function disorders (PFD) that cause mild mucocutaneous bleeding symptoms are heterogeneous and can seldom be linked to a causative gene defect using clinical and laboratory phenotype alone. We recently developed a strategy for diagnosis of PFDs using in-solution enrichment and next generation sequencing (NGS) of 216 candidate genes (*J Thromb Haemost, 2012;10:306*). In this study, we have adopted this approach to investigate affected members of two families with a heritable bleeding tendency and a diagnosis of storage pool disease.

Aims: To utilise NGS to investigate the genetic basis of a PFD in two families with the laboratory features of storage pool disease.

Methods: Two parent/child pairs from unrelated families, in which both mild bleeding and alopecia segregated with a platelet dense granule release defect were recruited through the UK-Genotyping and Phenotyping of Platelets (UK-GAPP) study. The coding and flanking intronic sequences of 260 genes encoding mediators of platelet function and number were captured from genomic DNA using an Agilent-SureSelect targeted array and sequenced on an ABI-SOLiD 3+ platform. Sequences were mapped to the UCSC hg19 reference sequence using BWA and Bowtie and previously identified population variants were removed from the analysis. Novel single nucleotide variants (SNVs) that were common to each of the parent/child pairs were confirmed by Sanger sequencing. Site-directed mutagenesis was used to introduce two SNVs identified in *FLI1* into the pSG5-FLI1 expression construct. The ability of the recombinant FLI1 mutants to bind to an ETS site in the *GP6* promoter was examined in HEK 293T cells using the dual-luciferase reporter assay to measure *GP6* promoter activity.

Results: NGS of 260 platelet genes identified 4 SNVs in four genes that were common to both affected members of Family-1, including a heterozygous *FLI1* c.1009C>T transition, predicting a p.R337W substitution in the FLI1 DNA binding domain. The two affected members of Family-2 shared only a heterozygous *FLI1* c.1028A>G transition predicting a p.Y343C substitution, also in the FLI1 DNA binding domain. Comparison of the transcriptional activities of wild-type (WT) FLI1 and the R337W and Y343C variants on the *GP6* promoter revealed a complete loss in transcriptional activity of the R337W and Y343C FLI1 variants when compared to WT-FLI1. When either the R337W or the Y343C variant was co-expressed with WT-FLI1, there was a significant reduction in the transcriptional activity of approximately 50% compared to WT-FLI1 alone ($P < 0.05$) demonstrating that these variants result in a loss of function of FLI1.

Conclusions: We have identified two novel *FLI1* variants which cause a loss in transcriptional activity of FLI1 *in vitro* in two families with storage pool disease. Given the role of FLI1 in megakaryopoiesis, and in regulating several haemostasis related genes, these loss of function variants are likely to contribute to the phenotype in these families. Our results support the use of NGS technology in the investigation of patients with inherited PFDs.

OC 34.3

A mutation in β3 integrin causing macrothrombocytopenia displays constitutive active aIIbβ3 and aVβ3 and proplatelet-like structures on immobilized fibrinogen

Hauschner H[1], Messineo S[2], Seligsohn U[1], Savoia A[2] and Rosenberg N[1]

[1]*Sheba Medical Center and Tel-Aviv University, Ramat-Gan, Israel;* [2]*Institute for Maternal and Child Health, IRCCS, Burlo Garofolo, Trieste, Italy*

Background: Mutations in integrin αIIb or β3 usually cause Glanzmann thrombastenia (GT), an autosomal recessive severe bleeding disorder characterized by absence of platelet aggregation with all physiological agonists, and normal platelet count and morphology. Some rare mutations in the αIIb or β3 genes have been reported and are characterized by macrothrombocytopenia and autosomal dominant inheritance. These entities were termed GT-like syndromes. One such example is a recently described mutation in two unrelated Italian patients. Molecular analysis revealed an in frame deletion of exon 13 of ITGB3 gene causing loss of amino acids 647–686 of the βTD ectodomain (Haematologica 2009, 94:663–9). The patients exhibited macrothrombocytopenia, impaired ADP and epinephrine induced platelet aggregation, slightly decreased surface expression of αIIbβ3 but with slightly increased ligand binding and normal adhesion of platelets to immobilized fibrinogen yet with impaired spreading. Further characterization of the effects of the mutation was however hampered because the patients' platelets harbored one normal allele.

Aim: To examine the influence of the natural mutation on αIIbβ3 and αVβ3 functions.

Methods: We expressed the β3-βTD_del with wild type (WT) αIIb in baby hamster kidney (BHK) cells and compared surface expression and function with cells harboring WT αIIb and β3.

Results: The surface expression of the mutated αIIbβ3 integrin was not significantly different from cells expressing WT-αIIbβ3. However, the mutated cells bound soluble fibrinogen and PAC-1 antibody indicating that the mutant cells were constitutively active unlike WT cells. The integrin chimera αV(hamster)β3 (human)-βTD_del was expressed similarly to WT-αV(hamster)β3 (human) and was also constitutively active. Cells expressing the αIIbβ3-βTD_del displayed increased adhesion and spreading on immobilized fibrinogen. After 2 h of incubation, the spreading was accompanied by multiple cell extensions. Some of the extensions were long, thin and had bulbous tips suggesting cytoskeleton reorganization similarly to pro-platelet structures. Such extensions were hardly observed in cells expressing WT-αIIbβ3.

Conclusions: The thrombocytopenia and platelet size variation in GT-like patients can be explained by the presence of proplatelet-like extensions formed on immobilized fibrinogen which results in constitutively active αIIbβ3. These data and the macrothrombocytopenia in the patients with GT-like syndrome suggest that integrin β3 is involved in platelet formation in addition to its well known role in platelet function.

OC 34.4

Treatment modalities and outcomes in 204 surgical procedures in 96 Glanzmann thrombasthenia (GT) patients: the International Prospective Glanzmann's Thrombasthenia Registry (GTR)

Poon M-C[1], D'Oiron R[2], Zotz R[3] and Di Minno G[4]

[1]*University of Calgary Foothills Hospital, Calgary, Canada;* [2]*Bicêtre Hospital AP-HP, University Paris XI, Paris, France;* [3]*Hemostasis Institute, Düsseldorf, Germany;* [4]*Federico II University, Napoli, Italy*

Background: Standard treatment for GT, a severe autosomal recessive bleeding disorder with defective platelet $\alpha_{IIb}\beta_3$, is platelet transfusion.

Recombinant FVIIa (rFVIIa) has been effective in GT with platelet antibodies and/or platelet refractoriness.

Aims: To assess the efficacy of rFVIIa, compared to other systemic hemostatics in GT with or without antibodies and/or refractoriness for surgical prophylaxis.

Methods: Analysis of data from GTR, an international multicenter observational study on the efficacy and safety of rFVIIa and other treatment modalities for bleeding and surgery in GT patients.

Results: From 2004-2011, GTR enrolled 218 patients from 45 sites (15 countries, 4 continents) with 1073 admissions. Out of these, 96 patients (F/M: 52/44 [54%/46%]; age ≥ 18y, 69 [72%]) were treated for 204 surgical procedures (minor/major, 167/37 [82%/18%]). Out of 55 patients with known disease type, 48 (87%) had type 1 GT. History of antibodies were reported in 43 patients [45%], refractoriness in 23 [24%], and antibodies+refractoriness in 17 [18%], while 47 [49%] had no antibodies/refractoriness. Treatments analyzed include antifibrinolytics (AF), rFVIIa ± AF (r7), platelets ± AF (P) and rFVIIa+platelets ± AF (r7+P). The top minor procedures were dental (n = 132, 79%), endoscopy (n = 11, 6.6%) and nasal (n = 8, 4.8%). The top major procedures were GI (n = 9, 24.3%) and orthopedic (n = 9, 24.3%). Most frequent treatment for minor procedures was r7 (n = 120 [72%]); and for major procedures, r7 and r7+P (13 [35%] each). In GT with no antibodies/refractoriness, r7 was 100% efficacious for both minor (n = 41) and major procedures (n = 7), similar to or better than that for P (minor 11/11 = 100%; major 5/6 = 83%) and r7+P (minor 4/4 = 100%; major 6/9 = 67%). In GT with antibodies and/or refractoriness, the efficacy of r7 (minor procedures 69/79 = 87%; major 4/6 = 67%) was not inferior to that for P (minor 10/14 = 71%; major 2/2 = 100%) and r7+P (minor 7/9 = 78%; major 2/4 = 50%). A few patients were treated with AF alone, with an overall efficacy rate of 56% for nine minor procedures, but 100% for three major procedures. rFVIIa was generally given initially at a median of ~90 μg/kg at ~2 h intervals, for both minor (median 2–3 doses) and major (number of doses: higher and variable) procedures. The median (mean ± SD) number of platelet units used in patients with no antibodies and/or refractoriness, was 1 (2 ± 1) for minor and 5 (8 ± 7) for major procedures. In patients with antibodies and/or refractoriness, the median platelet use was higher and variable, up to 60 U for one major procedure. Only one thromboembolic event occurred in an adult female with refractoriness treated with r7+P for a major procedure. One additional allergic reaction was attributed to platelets.

Summary/Conclusions: (1) The GTR provides the largest experience to date on surgical procedures in GT. (2) GTR results show that the efficacy of rFVIIa ± AF was similar to platelets ± AF and rFVIIa+platelets ± AF in surgical procedures in GT patients, regardless of investigator-reported antibodies/refractoriness status. (3) rFVIIa ± AF was safe for surgical procedures. (4) Platelets were efficacious in GT patients with investigator-reported antibodies and/or refractoriness, but higher doses were reported. (5) The combined use of rFVIIa+platelets could be attributed to the insufficient efficacy of one or the other alone.

OC 34.5

The β-1 tubulin R307H single nucleotide polymorphism is associated with significantly worse thrombocytopenia and distinct platelet physiology in Bernard Soulier monoallelic 'Bolzano' mutation patients

Basciano P[1], Bozzi V[2], Civaschi E[2], Provini S[2], Matakas J[1], Giannakakou P[1], Bussel J[1], Balduini C[2] and Noris P[2]

[1]Weill Cornell Medical College, New York, USA; [2]University of Pavia and IRCCS Policlinico San Matteo Foundation, Pavia, Italy

Background: Single nucleotide polymorphisms (SNPs) in the hematopoietic-specific β-1 tubulin isotype have been correlated with alterations in platelet physiology. We previously showed that the β-1 R307H SNP identified ITP patients with more severe thrombocytopenia, increased risk of failure to immune-modulatory treatments, and unique platelet dynamics compared to non-SNP patients. The diversity of disease pathophysiology in ITP made interpreting these results difficult. Bernard Soulier monoallelic 'Bolzano' mutation (BSS-BM) patients are unique as they have a single mutation (c.515C>T in *GPIBA*) causing macrothrombocytopenia, but a variable clinical severity of unknown etiology. These unique disease characteristics made BSS-BM an ideal disorder to further examine the physiologic relevance of the β-1 R307H SNP.

Aim: To determine if the β-1 tubulin R307H SNP is associated with significant differences in clinical outcomes and platelet physiology in patients with BSS-BM.

Methods: After approval from regulatory boards and informed consent from patient was obtained, we genotyped 92 previously-reported BSS-BM patients for the presence of the β-1 tubulin R307H SNP (rs6070697G>A). Platelet count and mean platelet volume (MPV) were measured by impedance in 92 patients and by optical laser scanning in 20 patients; manual counts from peripheral blood smears were obtained in 23 patients. Platelet biomass was calculated as the product of manual platelet count and optical MPV in 20 patients, as impedance measurement of these parameters has been shown to be unreliable. Means of platelet count, MPV, and platelet biomass were compared between SNP and non-SNP patients; mean WHO bleeding scale scores were also compared. Pearson correlation coefficients for platelet count and MPV were calculated separately for SNP and non-SNP groups.

Results: β-1 R307H SNP carrier frequency (heterozygote SNP + homozygote SNP) was 36% in BSS-BM patients, similar to the general population. BSS-BM patients with the R307H SNP had significantly worse thrombocytopenia compared to non-SNP patients as measured by all three methods (impedance: 70 v 95, $P < 0.001$; optical: 71 v 119, $P = 0.01$; manual: 76 v 124, $P = 0.01$; all reported counts × 10^9/L). There was no significant difference in mean optical MPVs (SNP: 15 fL; non-SNP: 15.1 fL). Mean platelet biomass was 32% lower in the SNP group (0.13% of blood volume) versus the non-SNP group (0.19%; $P = 0.02$). Mean WHO bleeding scores did not significantly differ between the genotype groups. Platelet count and MPV were strongly and inversely correlated in the SNP group ($R = -0.9$, $P = 0.03$) but not the non-SNP group ($R = -0.24$, $P = 0.24$).

Summary/Conclusions: BSS-BM patients with the β-1 tubulin R307H SNP had significantly worse thrombocytopenia and lower platelet biomass compared to non-SNP patients; furthermore, a significant correlation between platelet count and MPV was detected for SNP patients but not non-SNP patients. These associations between the R307H SNP and changes in clinical parameters and platelet physiology are consistent with our findings in ITP. These similar findings in two distinct platelet disorders support a strong relevance for the R307H SNP in platelet physiology. Further investigations of the R307H SNP in more common platelet disorders may have clinical utility, and investigations into the mechanistic basis for our findings are underway.

OC 34.6

The BRIDGE bleeding and platelet disorders exome sequencing project: presentation and first discoveries

Freson K and on behalf of the BRIDGE Bleeding and Platelet Disorders (BPD) consortium

University of Leuven, Leuven, Belgium

Background: The purpose of the BRIDGE-BPD consortium (www.bridgestudy.org) is through international collaboration to identify the genetic basis of hitherto unresolved rare bleeding and platelet disorders (BPDs) by exome sequencing. Patients with an abnormal platelet count, volume, ultrastructure and/or function and/or a bleeding disorder of unknown etiology and of early onset are enrolled by 34 specialized referral centres in Belgium, France, Germany, the Netherlands, the UK and the USA. Cases with known inherited BPDs are enrolled in a parallel project overseen by the ISTH ThromboGenomics working

party. So far, 748 BPD cases of unknown etiology have been enrolled and clinical and laboratory information has been deposited in the central BRIDGE-BPD database. The challenge of homogenization of clinical phenotype information is supported by the coding of each patient with terms from the Human Phenome Ontology (HPO) application.

Methods: The DNA samples are quality-controlled and sequenced at Cambridge University in the UK on the Illumina HiSeq2000 platform following targeted enrichment with the Roche Nimblegen SeqCap EZ Human Exome v3.0 protocol. Variant calling makes use of the GATK software package together with the SAMtools and DinDel applications. Alleles are removed by filtering against the results of the 1000 Genomes and UK10K projects. The consequences of the variants are interpreted using standard consequence prediction algorithms, our recently developed protein-protein interaction network and ENCODE and BluePrint results on the experimentally-driven functional annotation of the non-coding fraction of the genome. As a next step toward understanding how newly discovered genes contribute to changes in haemostasis, we perform studies in model organisms and in *in vitro* differentiated megakaryocytes obtained from haematopoietic stem cells and patient-derived induced pluripotent stem cells.

Results: The initial analysis of the results of the first 50 cases identified four new genes. First *NBEAL2* and *RBM8A* were discovered as the causative genes for Grey Platelet and Thrombocytopenia with Absent Radius syndromes, respectively. Second in a patient with a rare platelet defect with abnormal alpha granules and severe bleeding, a compound heterozygous mutation was identified in a new gene on 15q15. Finally, homozygosity mapping revealed a homozygous 2-base pair deletion in a gene at 6q22.1 in a child born to healthy but consanguineous parentage and with symptoms of epilepsy, neurodegeneration, hypotonia, hypogonadotropic hypogonadism, and defective platelet secretion. As was the case for the first two, also the latter two genes were not known to be implicated in megakaryocyte and platelet biology. The genes on 15q15.1 and 6q22.1 regulate the structure of the extracellular matrix components dermatan sulphate and collagen and cell cycling, respectively.

Conclusion: The successful proof-of-principle studies prompted the sequencing of further cases and the results of the analysis will be shared. In conclusion, the hypothesis-free surveying of the 64 million bases of coding fraction of the genome results in the identification of novel genes, which are causative of rare inherited BPDs and point to novel biologically relevant molecular pathways in haemostasis.

OC 35 – Platelet Signaling – I

OC 35.1

A recombinant HPA-1a antibody with abrogated Fc? receptor binding for treatment of fetomaternal alloimmune thrombocytopenia: proof of principle in human studies

Ghevaert C[1], Herbert N[1], Cookson PH[2], Garner SF[2], Lloyd-Evans P[2], Ballan K[3], Ouwehand WH[1], Armour LK[4], Clark MR[4] and Williamson L[2]

[1]University of Cambridge and NHS Blood and Transplant, Cambridge; [2]NHS Blood and Transplant, Brentwood; [3]Addenbrookes University Hospitals, Cambridge; [4]University of Cambridge, Cambridge, UK

Background: Fetomaternal alloimmune thrombocytopenia (FMAIT) caused by the maternal generation of antibodies against the Human Platelet Antigen-1a (HPA-1a) carried by fetal platelets can result in intracranial haemorrhage and intrauterine death. Current treatment options for FMAIT during pregnancy involve either administration to the mother of IV immunoglobulins with or without corticosteroids or intrauterine transfusions of HPA-1a negative platelets which carries a 15% risk of fetal death. We have developed a therapeutic human recombinant high affinity HPA-1a antibody (B2G1Dnab) that competes for binding to the HPA-1a epitope but which carries a modified constant region that does not bind to Fc gamma receptors. Previous *in vitro* competition studies with a range of clinical anti-HPA-1a sera have shown that B2G1Dnab blocks monocyte chemiluminescence by > 75%. Studies in chimaeric mice have confirmed that a non-destructive HPA-1a blocking antibody can prevent *in vivo* platelet destruction by polyclonal HPA-1a antibodies.

Aims: In this first-in-man study we aim to answer two questions. First does the therapeutic B2G1Dnab antibody affect platelet survival in circulation. Second, in competition studies with a destructive anti-HPA-1a does B2G1Dnab demonstrate a gain in platelet survival *in vivo*.

Method: Eighteen HPA-1a1b (matching fetal platelet group) volunteers were recruited and *in vivo* platelet survival studies carried out by means of dual radiolabelling. Two aliquots of autologous platelets were generated from each volunteer and sensitized *ex vivo* with combinations of antibodies. After re-injection to the volunteers, platelet survival was observed by means of serial sampling and gammacounting. In a first phase, we compared survival of unsensitised platelets and platelet sensitized with either B2G1Dnab or the destructive equivalent IgG1 antibody B2G1. In a second phase we looked at platelet survival after sensitization with a combination of B2G1 (as an exemplar of destructive HPA-1a antibody) and B2G1Dnab (as would be the case in fetuses receiving B2G1Dnab as therapy) in proportions shown previously to reduce monocyte response by 50% and 80%. Permission for the study was granted by the Local Research Ethics Committee (LREC), the Administration of Radioactive Substances Advisory Committee (ARSAC) and the Medicines and Healthcare devices Regulatory Agency (MHRA).

Results: Platelets sensitized with B2G1Dnab were shown to have parallel survival kinetic compared to unsensitised platelets (calculated survival 196 vs 189 h respectively) whilst platelets sensitized B2G1 completely disappeared from circulation within the first 2 h (calculated survival 18 min). Platelets sensitized with a combination of B2G1 25%/B2G1Dnab 75% and B2G1 10%/B2G1Dnab 90% had calculated survivals of 44 and 58 min respectively. This two to three-fold gain compared to platelets sensitized with B2G1 alone would translate to a platelet count 2–3 times higher than baseline in the fetus, conferring a major reduction in the risk of intracranial haemorrhage.

Conclusions: in this first in man set of studies we demonstrate the therapeutic potential of B2G1Dnab for treatment of pregnancies affected by HPA-1a antibodies paving the way for further clinical studies. In addition, the efficient clearance of platelets sensitized with B2G1 also opens up the opportunity to carry out studies of prophylaxis to prevent alloimmunisation in HPA-1a negative mothers.

OC 35.2

The P2X1 receptor antagonist NF449 protects mice from experimental transfusion related acute lung injury

Maitre B, Leguay C, De La Salle H, Hechler B and Gachet C

UMR_S949, Inserm, Université de Strasbourg, EFS-Alsace, Strasbourg, France

Background: Transfusion Related Acute Lung Injury (TRALI) is one of the first causes of transfusion related mortality. It is defined as a non-cardiogenic pulmonary edema during or within 6 h after blood transfusion. In most cases, two sequential events contribute to the appearance of this syndrome. The first hit is the inflammatory condition of the patient causing sequestration and priming of neutrophils in the pulmonary compartment. The second hit is the transfusion of a blood product containing antibodies that activate the primed neutrophils of the recipient and lead to lung injury. Neutrophils are thus key players in this pathology through their migration into the lungs and their subsequent activation. Among the various signals involved in neutrophil chemotaxis, ATP was reported to play an essential role through activation of the ATP-gated $P2X_1$ cation channel.

Objectives: Our aim was to evaluate the role of the $P2X_1$ receptor in an experimental model of TRALI.
Methodology: TRALI was induced using a 2-hit model in which Balb/C mice are primed with i.p. injection of LPS (0.1 mg/kg) 24 h before i.v. challenge with a cognate MHC I antibody (0.5 mg/kg). TRALI was estimated by: (i) the rate of mortality of mice after 2 h, (ii) the measure of the lung edema assessed by protein content in bronchoalveolar fluids and (iii) the lung inflammation by evaluating the presence of neutrophils using immunohistological analysis. The role of the $P2X_1$ receptor was evaluated using the NF449 $P2X_1$ antagonist (10 mg/kg) administered i.v. either before LPS, or before the MHC I antibody injection, or at both steps.
Results: Within 2 h after MHC I injection, 70% of control mice died, whereas only 30% of NF449-treated mice died ($P < 0.01$, $n = 20$). Accordingly, lung edema was reduced in mice receiving NF449 (1367 ± 971 mg/mL) as compared to control mice (3537 ± 971 mg/mL) ($P < 0.05$, $n = 6$). Immunohistological analysis of lung sections with an anti-neutrophil antibody revealed a lesser amount of neutrophils infiltrated into pulmonary tissues of NF449-treated mice (65311 ± 5614 pixels) as compared to control mice (171253 ± 20264 pixels) ($n = 3$, $P < 0.001$). To delineate the role of the $P2X_1$ receptor in each event leading to TRALI, NF449 was administered either only before LPS sensitization or only before MHC I injection. In both cases, the rate of mortality was only slightly decreased in NF449-treated mice suggesting that the $P2X_1$ receptor is involved both in the recruitment of neutrophils and in their activation.
Conclusion: Our data indicate that the $P2X_1$ receptor plays a key role in TRALI and suggest that its pharmacological inhibition could represent a novel therapeutic approach.

OC 35.3

The mechanical regulation of VWF GPIba dependent platelet triggering on a single cell

Ju L[1], Chen Y[1], Cruz MA[2] and Zhu C[1]
[1]Georgia Institute of Technology, Atlanta, GA; [2]Baylor College of Medicine, Houston, TX, USA

Background: Binding of platelet membrane receptor GPIbα to von Willebrand factor (VWF) A1 domain tethers platelets to disrupted vascular surface during the haemostatic process. The VWF-A1-GPIbα interaction under flow can trigger outside-in signaling cascade, characterized by distinct elevations of cytosolic calcium concentration. GPIbα is hypothesized as an mechano-sensor of platelet, however, its mechano-sensing mechanism still remains obscure.
Aim: Using the single-molecule accumulative force clamp assay with a biomembrane force probe (BFP), we studied force-induced signal initiation by repeated brief contacts of a single platelet with a glass bead coated with VWF-A1 domain in a precisely controlled fashion.
Materials and Methods: Recombinant proteins including wild-type (WT) VWF A1 domain, gain-of-function A1 mutant (R1450E), loss-of-function A1 mutant (G1324S) were prepared. The washed platelets were purified and kept discoid after the venous blood draw. In BFP experiment, VWF-A1 was also covalently linked to the probe bead aspired by a micropipette, which was opposed by another micropipette aspiring a discoid platelet. The force was calculated from the deformation of the red blood cell (RBC). The epi-fluorescence channel was added to allow the simultaneous measurements of force regulation and calcium signals.
Results: Contacting a single platelet with a bead coated VWF-A1 of low density resulted in adhesion kinetics on the single bond level. We observed a catch-bond for the VWF-A1-GPIbα interaction, in which the bond lifetime increased with force to a maximum (~25pN) and then decreased with force. The von Willebrand disease (VWD) mutations in A1 shifted this biphasic pattern either toward higher force (40pN for G1324S, type 2M) or to lower force (10pN for R1450E type 2B). On the other hand, we found that single bond of WT A1-GPIbα interaction could trigger the calcium flux but not enough to induce platelet activation. However, force and accumulative lifetime threshold existed, above which the A1-GPIbα bond could trigger calcium mobilization within ~30 s. The stronger calcium triggering was observed at 40pN than 25pN for WT and G1324S A1. In contrast, the R1450E, described as the gain-of-function mutant, showed little calcium triggering effect while the G1324S, known as the loss-of-function mutant, showed stronger calcium triggering than WT.
Summary: Coupling of force and bond lifetime was both necessary and sufficient for platelet calcium triggering. The structural variation in ligand altered the triggering energy barrier. With the single molecule method, we provided new understandings on the mechano-sensing mechanism of the VWF-A1-GPIbα interaction.

OC 35.4

The Rap guanine nucleotide exchange factor CalDAG-GEFI is phosphorylated and regulated by protein kinase A

Guidetti GF, Manganaro D, Consonni A, Canobbio I, Balduini C and Torti M
University of Pavia, Pavia, Italy

Background: In circulating platelets, the guanine nucleotide exchange factors CalDAG-GEFI mediates the Ca^{2+}-dependent activation of the small GTPase Rap1b, which is required for integrin $\alpha_{IIb}\beta_3$ inside-out activation and platelet aggregation. cAMP is the major intracellular inhibitor of platelet function, and the cAMP-activated protein kinase A (PKA) antagonizes both Rap1b and integrin $\alpha_{IIb}\beta_3$ stimulation. PKA directly phosphorylates Rap1b, but this event regulates subcellular localization of Rap1b, rather than its activation. Therefore, the precise mechanisms for the prevention of agonist-induced Rap1b stimulation by cAMP in platelets remains unclear.
Aims: To investigate whether CalDAG-GEFI is a target for PKA to mediate cAMP-promoted inhibition of Rap1b.
Methods: The phosphorylation of CalDAG-GEFI was investigated *in vitro* and in intact cells as incorporation of radiolabelled phosphate and by immunoblotting. The effect of PKA-mediated phosphorylation on CalDAG-GEFI activity was established both in platelets, and in HEK293 cells transfected with specific serine to alanine mutants of CalDAG-GEFI.
Results: In this work we demonstrate that CalDAG-GEFI is phosphorylated by PKA *in vitro*, as well as in transfected cells treated with the cAMP-increasing agent forskolin. cAMP increase triggers CalDAG-GEFI phosphorylation also in intact platelets, and this effect is associated to the inhibition of Ca^{2+}-induced Rap1b activation and platelet aggregation. By computational sequence analysis and site-directed mutagenesis, the serine residues 116 and 586 have been identified as the PKA phosphorylation sites. The substitution of these two serine residues with alanine was sufficient to completely abolish PKA-mediated CalDAG-GEFI phosphorylation in transfected cells. Two additional potential PKA phosphorylation sites were found to be present on CalDAG-GEFI, serine 117 and serine 147, however these residues did not contribute to CalDAG-GEFI phosphorylation. Forskolin-induced phosphorylation of CalDAG-GEFI also occurred in transfected HEK293, and was associated to the prevention of Rap1b activation by intracellular Ca^{2+} elevation. Moreover, cAMP-mediated inhibition of Rap1b activation was lost in HEK293 cell transfected with a double mutant of CalDAG-GEFI (S116A and S586A), that failed to be phosphorylated by PKA.
Conclusions: These results demonstrate that phosphorylation of CalDAG-GEFI by PKA affects its activity on Rap1b, and represents a novel mechanism for cAMP-mediated inhibition of Rap1b in platelets.

OC 35.5

Genetic deletion of Vaccinia H1-related (VHR) phosphatase inhibits collagen-induced platelet activation and thrombus formation without affecting bleeding time in mice

Rahmouni S[1], Musumeci L[1], Maurissen L[1], Kuijpers MJE[2], Senis YA[3], Mustelin T[4] and Heemskerk JWM[2]

[1]University of Liege, Liege, Belgium; [2]Maastricht University, Maastricht, the Netherlands; [3]University of Birmingham, Birmingham, UK; [4]Sanford-Burnham Medical Research Institute, La Jolla, CA, USA

Background: A critical limitation of current antiplatelet therapies is their inability to separate a reduction in thrombotic events from an increase in bleeding occurrences. Vaccinia H1-related (VHR) phosphatase is a dual-specific protein phosphatase, the physiological role of which is not known. We used genetic manipulations to generate mice lacking VHR and found that this phosphatase plays a critical role in platelet function and in arterial thrombosis.

Aims: The goal of this project is to investigate the role of VHR in thrombosis and hemostasis, using transgenic mouse model, with a specific focus on deciphering the function of this phosphatase in platelet biology and GPVI signaling pathways.

Methods: VHR deficient mice were generated by homologous recombination. Platelet adhesion, aggregation and secretion assays were performed using VHR deficient and wild type platelets. Intracellular calcium fluxes were studied in fura-2 loaded platelets. Aggregate formation on collagen surface was analyzed under flow conditions. Arterial thrombosis was assessed in a model of pulmonary embolism and upon ferric chloride induced carotid artery injury. Tail bleeding times were measured.

Results: VHR-deficient platelets display impaired collagen-related peptide (CRP) and collagen-induced aggregation and granule secretion compared to platelets from wild-type mice. However, Thrombin- and ADP-induced platelet aggregations were not affected by VHR deficiency. Consistently, aggregate formation and phosphatidylserine exposure of VHR-deficient platelets on collagen under flow was reduced. In addition, VHR-deficient mice were more resistant to collagen- and epinephrine-induced thromboembolism, compared to wild-type mice, and showed impaired thrombus formation upon carotid artery injury. Intriguingly, VHR deficiency did not affect bleeding times compared to wild-type mice. At the molecular levels, we found that VHR deficiency leads to a decrease of Src family kinase activatory phosphorylation upon GPVI triggering with CRP. In addition, convulxin-induced Ca^{2+} flux was greatly reduced (50%) in VHR-deficient platelets compared to wild-type platelets.

Conclusions: All together, our data suggest that VHR plays a selective and essential role in collagen-induced platelet activation and in arterial thrombus formation *in vivo*. Given that VHR-deficient mice remain healthy and do not exhibit any spontaneous phenotype, inhibition of VHR may prove effective as an alternative and safe antiplatelet strategy in the treatment of arterial thrombosis.

OC 35.6

SHIP1 deficiency affects platelet internal contraction and integrin dynamics during the first steps of platelet activation

Severin S[1], Consonni A[2], Chicanne G[1], Allart S[3], Payrastre B[1] and Gratacap M-P[1]

[1]Inserm U1048 I2MC, Toulouse cedex 4, France; [2]University of Pavia, Pavia, Italy; [3]Inserm U1043/CNRS UMR 5282/Université Toulouse III, Toulouse, France

SHIP1 is a lipid phosphatase capable to dephosphorylate the PI3-kinase product phosphatidylinositol 3,4,5-trisphosphate (PtdIns(3,4,5)P_3) into PtdIns(3,4)P_2, and to interact with several signalling proteins as a docking protein. In platelets, previous studies suggest dual effects of this phosphatase as it may negatively regulate platelet adhesion and spreading on a fibrinogen surface and positively regulate thrombus growth *ex vivo* and *in vivo*.

Little is known about its implication during the early phase of platelet activation in suspension, before aggregation. Using SHIP1 knock-out mice we show that the absence of this phosphatase has no significant impact on Akt, ERK or Src family kinases activation following thrombin stimulation in the absence of aggregation. However, using a confocal-based morphometric analysis we found that SHIP1 is involved in the regulation of cytoskeleton organization and platelet internal contractile activity when platelets are stimulated by thrombin in suspension, independently of integrin engagement. Both the RhoA/Rho-kinase pathway activation and myosin IIA relocalization are affected in the absence of SHIP1. Interestingly, SHIP1 interacts with the membrane skeleton and its absence impacts on the maintenance of the association of integrins to this network following thrombin activation. Using super resolution microscopy we show that the SHIP1-regulated contractile cytoskeleton controls $\alpha_{IIb}\beta_3$ integrin dynamics.

Altogether, our data reveal a lipid-independent function for SHIP1 in the regulation of the contractile cytoskeleton and integrin dynamics in the absence of platelet aggregation.

This study complies with the Declaration of Helsinki.

OC 36 – Reversal of Anticoagulant Agents

OC 36.1

Early reversal with prothrombin complex concentrate in vitamin K antagonist-treated patients with severe haemorrhage is associated with decreased mortality

Vigué B[1], Riou B[2], Tremey B[3], Samama CM[4], Vicaut E[5] and Tazarourte K[6]

[1]CHU de Bicêtre, Le Kremlin Bicêtre; [2]CHU de Pitié-Salpétrière, Paris; [3]CMC Ambroise Paré, Neuilly; [4]CHU de Cochin-Hôtel Dieu; [5]CHU Lariboisiere, Paris; [6]SAMU 77, Melun, France

Background: Vitamin K antagonist (VKA) therapy is associated with a high rate of mortality in patients with severe haemorrhage, in particularly those with intracranial bleeding. French guidelines recommend prothrombin complex concentrate (PCC) and vitamin K infusion for complete reversal of VKA therapy in case of severe haemorrhage.

Aim: This observational cohort study was set-up to test the hypothesis that early appropriate VKA reversal decreases 7-day mortality rate.

Methods: Prospective data from patients on VKA therapy admitted in 44 emergency departments with life-threatening haemorrhage were analysed, with particular attention given to intracranial haemorrhage (ICH), gastrointestinal, thoracic, or deep muscles bleeding. In addition to the type of haemorrhage, the International Normalized Ratio, the treatment and 7-day mortality were recorded. Early reversal was considered appropriate when the guidelines (reversal perfusion of prothrombin complex concentrate (PCC) at a dose superior or equal to 20 IU/kg in equivalent-IX factor associated to, at least, 5 mg of vitamin K) were followed in a predefined delay of 8 h after admission. A multivariate analysis was used to assess the role of early and appropriate reversal in 7-day mortality in all patients and in the ICH group.

Results: Over a 14-month period, data from 822 vitamin K antagonist-treated patients with severe haemorrhage were collected. The following bleeding rates were seen: gastrointestinal (32%), intracranial (32%), muscular (13%), and 'other' (23%). The 7-day mortality was 13% (n = 110) in the whole cohort and 33% (n = 86) in patients with ICH. Appropriate reversal was performed in 38% of all patients and 44% of ICH patients. Multivariate analysis showed a significant two-fold decrease in the 7-day mortality rate in patients with early reversal

(OR = 2·15 [1·20–3·88]; P = 0·011); this mortality reduction was also observed when only ICH was considered (OR = 3·23 [1·53–6·79]; P = 0·002).

Conclusion: When guidelines on VKA reversal are followed, the management of major haemorrhages with PCC and vitamin K infusion within 8 h after hospital admission, is associated with a significant two-fold decrease in the 7-day mortality rate.

OC 36.2

In vitro characterization, pharmacokinetics and reversal of supratherapeutic doses of dabigatran-induced bleeding in rats by a specific antibody fragment antidote to dabigatran

Van Ryn J, Schiele F, Litzenburger T, Schurer J and Nar H
Boehringer Ingelheim Pharma GmbH & Co KG, Biberach, Germany

Background: The new oral anticoagulants have demonstrated efficacy and safety in preventing stroke in patients with atrial fibrillation; however, one feature they all share is the lack of a specific antidote in cases of emergency, such as excess bleeding. A fully humanized monoclonal antibody fragment (Fab) against dabigatran has been shown to effectively reverse anticoagulation and bleeding effects of dabigatran in animal models. Structural studies have also shown the similarity of the Fab binding site for dabigatran to thrombin.

Aim: This study investigated if the structural similarities of the Fab binding site had any enzymatic activity and influenced coagulation by binding to and activating other thrombin substrates.

Methods: The dissociation constant (K_D) and on-rate (k_{on}) of Fab binding to dabigatran were determined experimentally; the off-rate (k_{off}) was calculated. Potential off target binding to other thrombin substrates such as vWf, factors V, VIII and XIII, PAR-1, protein C (both activation peptides and purified compounds) and S-2238 substrate was also tested using surface plasmon resonance (SPR) binding to immobilized Fab. Any prothrombotic activity of the Fab was determined by testing the ability to induce coagulation in various assays in human plasma including endogenous thrombin potential (ETP) and ecarin chromogenic assay (ECA). Human platelet aggregation studies were performed with Fab and specific PAR-1 agonist, SFLLRN, using light transmission aggregometry.

Results: The X-ray crystal structure of dabigatran in complex with the antidote reveals many structural similarities of dabigatran recognition to thrombin. The Fab has a tight binding affinity to dabigatran, with a K_D of 2.1 ± 0.6 pM, ~350-fold more potent than the 0.7 nM K_D of dabigatran binding to thrombin, this is achieved by a tighter network of interactions and a larger buried surface area. This binding has a rapid k_{on} ($3.4 \pm 0.4 \times 10^5$/M/s) and a slow k_{off} ($0.7 \pm 0.2 \times 10^{-6}$/s), resulting in a calculated complex half life of ~275 h. Due to structural similarities to thrombin active site, potential enzymatic activity was investigated. There was no effect on thrombin generation with 3 mg/mL Fab added to plasma (ETP, 0.89-fold of control), in contrast, FEIBA (0.8 U/mL), resulted in 2.06 increase of ETP. ECA was also not changed vs control when adding up to 3 mg/mL Fab. Further studies investigated the binding of Fab to other substrates of thrombin, such as vWf, factors V, VIII and XIII, PAR-1, protein C using SPR. There was no binding seen at substrate concentrations relevant physiologically. The only specific binding of the immobilized Fab was to dabigatran. Platelet aggregation studies showed that conc up to 3 mg/mL Fab did not induce platelet aggregation, while the PAR-1 agonist, SFLLRN, induced maximal platelet aggregation with 2 μM, final concentration. The Fab did not potentiate or antagonise submaximal aggregation induced by PAR-1 activation.

Conclusions: These data show the specificity and selectivity of the Fab for dabigatran, and that despite structural similarities to thrombin in the binding site to dabigatran, there are no direct interactions with fibrinogen or other thrombin substrates. Thus, this agent holds promise for specifically reversing dabigatran-induced anticoagulation and bleeding effects.

OC 36.3

Active site-mutated thrombin S195A but not active site-blocked thrombin counteracts the anticoagulant activity of dabigatran in plasma

Sheffield WP[1], Lambourne MD[2], Bhakta V[2], Eltringham-Smith LJ[1], Arnold MD[1] and Crowther M[1]
[1]McMaster University; [2]Canadian Blood Services, Hamilton, ON, Canada

Background: Dabigatran etexilate (DE) is an oral anticoagulant in clinical use. DE is activated to its active form, dabigatran, after administration and dabigatran inhibits thrombin by active-site binding. No specific antidote for DE is currently available, if reversal becomes necessary. We previously found no ability of candidate reversal agents such as prothrombin complex concentrates or recombinant VIIa in a mouse model of DE-associated coagulopathy and bleeding diathesis (Lambourne MD et al., J Thromb Haemostasis 2012; 10: 1830–40).

Aim: To test the hypothesis that forms of thrombin with mutationally or chemically modified active sites would antagonize dabigatran in plasma, sparing active thrombin from inhibition.

Methods: Recombinant prethrombin-1 S195A was activated to S195A thrombin using prothrombinase and purified to homogeneity using SP-Sepharose, and further processed to γ_T-S195A thrombin using immobilized trypsin. Active (α-) thrombin was reacted with FPR-chloromethylketone, yielding FPR-thrombin. Restoration of endogenous thrombin function by these exogenous thrombin derivatives was measured using diluted thrombin times (TTs) of human plasma samples containing dabigatran (provided as controls in the HemoClot assay) or murine plasma samples from CD1 mice treated with 60 mg/kg DE by oral gavage 90 min prior to blood collection. Mice were separately injected intravenously with 0.2 mg γ_T-S195A thrombin 75 min following DE administration, tails were transected, shed blood quantified, and plasma obtained from blood collected by cardiac puncture 105 min post-DE. ^{125}I-labelled S195A thrombin was separately injected into untreated mice and acid-precipitable plasma radioactivity was followed over time.

Results: Introducing 0.1 mg/mL S195 A or γ_T-S195A thrombin into human plasma containing 0.11 μg dabigatran/mL was equally effective at reducing the TT (from 78 ± 13 to 20 ± 1 s in both cases, mean ± SD, n = 3–12). At 0.4 mg/mL S195 A but not γ_T-S195A thrombin showed reduced ability to antagonize dabigatran (TT values of 56 ± 3 and 17 ± 1 s, respectively). In mouse plasma containing 0.14 μg dabigatran/mL, 0.1 mg/mL γ_T-S195A thrombin reduced the TT from 67 ± 1 to 20.1 ± 0.3 s (mean ± SD, n = 3–6); in contrast, adding 0.1 mg/mL S195A thrombin or FPR-thrombin elevated the TT (to 79 ± 5 and 111 ± 22 s, respectively). In mice injected with both DE and γ_T-S195A thrombin, TT values declined by 40 ± 10% (mean ± SD, n = 3) after γ_T-S195A thrombin administration compared to post-DE, pre-thrombin values. No difference in blood loss between DE-treated mice was noted with or without γ_T-S195A thrombin injection. One hour post-injection, only 1.2% of the total dose of radiolabeled S195A thrombin remained in the murine circulation.

Summary/Conclusions: γ_T-S195A thrombin partially restored coagulation in murine and human plasma samples containing dabigatran, and in plasma samples from mice treated with DE and γ_T-S195A thrombin. The superior dabigatran antagonism of γ_T-S195A thrombin over other thrombin derivatives may relate to its not competing with thrombin for exosite 1 ligands. S195A thrombin seems to maintain a minimally modified active site capable of binding dabigatran. Further modifications to γ_T-S195A thrombin to slow its clearance may enhance its antagonism of DE *in vivo*.

OC 36.4

Reversal of direct factor Xa inhibitors using factor Xa zymogen-like variants

Thalji N[1], Patel-Hett S[2], Fruebis J[2], Pittman D[2] and Camire RM[1]
[1]*The Children's Hospital of Philadelphia, Philadelphia, PA;* [2]*Pfizer, Cambridge, MA, USA*

Oral direct factor Xa (FXa) inhibitors are emerging anticoagulants that have the potential to simplify dosing schemes and hemostatic monitoring in patients with prothrombotic diseases when compared to warfarin. The lack of a specific countermeasure to their effects, however, is a critical unmet clinical need that could limit the widespread adoption of these agents due to fears of unmanageable bleeding. We hypothesized that the effects of these inhibitors could be overcome by increasing the effective concentration of the inhibited enzyme, FXa. Administration of wild type FXa to achieve this is theoretically problematic due to its short half-life in plasma and the potential for thrombosis. Through mutagenesis to alter the equilibrium of the zymogen-to-protease transition, our group has developed long half-life variants of FXa that exist in a zymogen-like (inactive) conformation. These variants can be thermodynamically rescued to the protease (active) conformation by binding to the cofactor FVa. We have shown that these variants are potent, effective procoagulant agents in the setting of hemophilia. We evaluated whether one of these variants, FXa^{I16L}, could overcome the effects of rivaroxaban, a direct FXa inhibitor, in thrombin generation assays (TGA) and whole blood rotational thromboelastography (ROTEM). In TGAs, 500 nM rivaroxaban, the typical therapeutic plasma concentration, decreased peak thrombin generation to 22.5% of that observed in pooled normal human plasma (NHP). Addition of 1 nM or 3 nM FXa^{I16L} to 500 nM rivaroxaban-inhibited plasma restored peak thrombin generation to 84.1% and 102.1% of NHP, respectively. Endogenous thrombin potential (ETP) was also reduced by this dose of rivaroxaban to 49.8% of NHP, and addition 1 nM or 3 nM FXa^{I16L} yielded ETP values of 90.1% and 94.3%, respectively. At a higher concentration of rivaroxaban, 7.5 μM, peak thrombin was 5.2% of NHP and 3 nM FXa^{I16L} restored this value to 67.8% of NHP. In ROTEM experiments, 500 nM rivaroxaban prolonged clotting time to 154% of that of untreated blood. 0.3 nM and 3 nM FXa^{I16L} shortened clot time to 122% and 70% of normal blood, respectively. 2.5 μM rivaroxaban lengthened clot time to 263% of untreated blood, and addition of 0.3 nM and 3 nM FXa^{I16L} shortened clotting time to 156% and 86% of normal. These data suggest that a FXa zymogen-like variant can effectively reverse the anticoagulant effect of a direct FXa inhibitor in plasma-based and whole-blood coagulation assays at both therapeutic and supratherapeutic concentrations of the inhibitor. A thorough *in vivo* hemostasis study is necessary to determine the full potential of this variant as an emergency procoagulant to reverse bleeding due to overanticoagulation.

OC 36.5

Effects of three-factor and four-factor prothrombin complex concentrates on the pharmacodynamics of rivaroxaban

Levi M[1], Moore T[2], Castillejos CF[2], Berkowitz S[3], Kubitza D[3], Goldhaber SZ[4], Weitz JI[5] and Levy J[6]
[1]*University of Amsterdam, Amsterdam, the Netherlands;* [2]*Janssen Pharmaceutical Research & Development, Titusville;* [3]*Bayer Healthcare, Montville, NJ;* [4]*Brigham and Women's Hospital Harvard Medical School, Boston, MA, USA;* [5]*McMaster University School of Medicine, Hamilton, ON, Canada;* [6]*Duke University Hospital, Durham, NC, USA*

Background: Rivaroxaban is an oral Factor Xa inhibitor that has been developed as an alternative to warfarin. Although there is no specific antidote for rivaroxaban, four-factor prothrombin complex concentrate (PCC) rapidly corrects the effect of rivaroxaban on prothrombin time (PT) and thrombin generation in healthy adults. However, the specific constituent inPCCthat drives this effect is unknown, and this may be clinically important because differentPCCformulations have different concentrations of coagulation factors.

Aims: The aim of this study was to examine the effects of Beriplex P/N, a four-factorPCC, and Profilnine SD, a three-factorPCCthat lacks FactorVII, on PT and thrombin generation in adult volunteers receiving rivaroxaban.

Methods: In this open-label, single-centre, parallel-group study, 35 healthy adults were treated with supra-therapeutic doses of rivaroxaban 20 mg twice daily for 4 days to attain steady-state concentrations. On Day 5, 4 h after rivaroxaban administration, subjects were randomized to receive either: three-factor PCC (Profilnine SD) single bolus dose of 50 IU/kg, four-factor PCC (Beriplex P/N) single bolus dose of 50 IU/kg or a control saline single bolus dose of 100 mL. The PT and endogenous thrombin potential were measured before and serially afterPCCor saline administration. The two PT reagents used were Neoplastin Plus and Thromborel S.

Results: Thirty-four subjects (mean age 46 years, mean body mass index 25.8 kg/m^2) completed the study. Mean pharmacokinetic parameters for rivaroxaban were consistent across all three treatment groups. PT prolongation with rivaroxaban varied depending on the PT reagent; however, the effects of the PCCs were consistent regardless of the reagent used. Within 30 min, four-factor PCC reduced the mean PT by 2.5–3.5 s, whereas three-factor PCC produced only a 0.6–1.0 s reduction. In contrast to their effects on the PT, three-factor PCC more effectively reversed rivaroxaban-induced changes in endogenous thrombin generation (area under the concentration-time curve, peak and time-to-peak values) than four-factor PCC. Changes in lag-time values did not differ greatly.

Treatment-emergent adverse events (TEAEs) occurred in 51.4% of subjects. The most common TEAEs were abdominal discomfort, gingival bleeding, back pain and headache (8.6% each). Most TEAEs occurred during the rivaroxaban 20 mg twice-daily lead-in period. There were no clinically evident thromboembolic events, nor were there any significant changes in clinical laboratory values or vital signs.

Summary/Conclusions: Although four- and three-factor PCCs shorten the PT in rivaroxaban-treated subjects, four-factorPCChas a greater effect on reducing the mean PT than three-factorPCC. In contrast, three-factorPCChad a greater effect on reversing rivaroxaban-induced changes in endogenous thrombin potential than four-factorPCC. The explanation for the discrepant results on PT and thrombin generation are unclear but may reflect the absence of Factor VII in three-factor PCC Profilnine and the presence of heparin in four-factor PCC Beriplex. Ongoing studies will address these possibilities. Administration of PCCs in the presence of rivaroxaban was reported as safe and well tolerated, with no signs of prothrombotic response.

OC 36.6

Reversal of dabigatran effects by factor VIIa in a cell-based model of coagulation

Hoffman M[1], Volovyk Z[1] and Monroe D[2]
[1]*Duke University, Durham;* [2]*University of North Carolina, Chapel Hill, NC, USA*

Background: Dabigatran etexilate (Pradaxa®) is a prodrug that is metabolized to a small molecule direct thrombin inhibitor. As with all of the new oral anticoagulants, there is no specific reversal agent available. Several studies have suggested that recombinant factor VIIa (FVIIa), or prothrombin complex concentrates (PCCs) might reverse the effects of dabigatran on laboratory assays. Both have been used to reverse the effects of dabigatran in isolated patient case reports, though with mixed results. A better understanding of reversal strategies is badly needed.

Aims: We have previously reported that a 4-component PCC reverses some, but not all, of the effects of dabigatran on thrombin generation

in a physiologically relevant cell-based model. The goal of the current study was to similarly assess the effects of rFVIIa on parameters of thrombin generation.

Methods: We employed a modification of our well-characterised, cell-based model for these studies. We used adherent LPS-treated human monocytes as the tissue factor source (1 pM). Freshly isolated human platelets and different concentrations of dabigatran were added to citrated normal pooled plasma. Thrombin generation was monitored continuously in a fluorometric plate reader using the fluorogenic thrombin substrate from the calibrated automated thrombogram assay (CAT®; Stago). rFVIIa (NovoSeven®) was purchased from the hospital pharmacy.

Results: As others have reported for conventional CAT® assays, we found that dabigatran prolonged the lag before onset of thrombin generation. It also progressively depressed the rate and peak level of thrombin production. rFVIIa shortened the lag, but did not return it to normal. rFVIIa also increased the rate and peak level of thrombin generated, though it did not chnge the total amount of thrombin generated (AUC). Strikingly, the effectiveness of rFVIIa in improving parameters of thrombin generation was highly dependent on the level of dabigatran present. At dabigatran approximating therapeutic levels rFVIIa was effective, but at supratherapeutic dabigatran levels rFVIIa was not able to overcome its effects on rate or peak thrombin. This was true even at levels of rFVIIa above those used clinically. The magnitude of the response to FVIIa varied somewhat depending on the blood donor. However, the pattern of response to FVIIa was similar with all donors.

Conclusion: Our results suggest that rFVIIa can reverse the effects of dabigatran on the rate of thrombin generation and peak thrombin level, but this is restricted to levels of dabigatran approximating the therapeutic range. At higher levels of dabigatran rFVIIa did not reverse its effects on thrombin generation. The dependence of rFVIIa effects on the dabigatran level may explain, at least in part, its inconsistent ability to reverse dabigatran in clinical practice.

OC 37 – Therapy in Haemophilia A

OC 37.1

Targeting factor VIII expression to platelets by intraosseous delivery of lentiviral vectors into bone marrow corrects murine hemophilia A with and without pre-existing inhibitors

Wang X[1], Shin S[1], Pan D[2], Rawlings DJ[1] and Miao CH[1]

[1]Seattle Children's Research Institute, Seattle, USA; [2]Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

Platelets may comprise an ideal vehicle for delivering factor VIII (FVIII) in hemophilia A (Hem A) as FVIII stored in platelet α-granules is protected from neutralization by inhibitory antibodies and, during bleeding, activated platelets locally excrete their contents to promote clot formation. Previous reports showed platelet-stored FVIII (in transgenic mice or following *ex vivo* gene therapy) can partially correct the HemA phenotype. In order to avoid specific challenges posed by *ex vivo* gene delivery including, in particular, the requirement to pre-condition the subject, we aimed at limiting transgene expression to the megakaryocyte lineages using intraosseous (IO) delivery of 20 μL self-inactivating lentiviral vectors (LV) containing either GFP (G-GFP-LV) or a B-domain deleted FVIII (G-FVIII-LV) gene under the control of glycoprotein 1bα promoter. Firstly, we evaluated IO delivery of LV for *in situ* gene transfer into bone marrow (BM) cells. we confirmed that GFP expressed in 6.4% of hematopoietic stem cells (HSCs), 3.4% of $B220^+$, and 9.0% of $CD11c^+$ BM cells on day 29 after IO administration of 20 μL M-GFP-LV driven by a MND promoter. Secondly, in G-GFP-LV (6.0E+08 TU/mL) treated mice, GFP was undetectable in BM HSC or B220+, CD11c+ or CD11b+ cells, but was detectable in a small population of CD42d+ platelets, consistent with previous observations that only limited amounts of GFP can be stored in platelet α-granules during thrombopoiesis. The percentage of GFP^+CD42d^+ platelets was highest on day 7 after treatment (0.119%) and then decreased to 0.025% by day 35 and stabilized thereafter (0.025% on day 91 and 0.028% on day 161), suggesting that platelets containing the transgene products did not elicit transgene-specific immune responses. In G-FVIII-LV (6.0 E+07 TU/mL) treated HemA mice, FVIII was also undetectable by intracellular flow cytometry in BM HSCs, or B220+, CD11c+ or CD11b+ cells on day 92, whereas up to 2% of CD42d+ platelets were FVIII positive in recipients. Next, we induced anti-FVIII inhibitors in HemA mice by IP infusion of FVIII (2U/mouse, three times per week for 3 weeks) and then treated these mice with G-FVIII-LV. FVIII was detected in 0.32% of CD42d+ platelets ($n = 4$) on day 56 and more platelets (0.60%) contained FVIII in repeated LV-treated mice ($n = 4$). Finally, we evaluated the treated HemA animals with high (20 μL) vs. low dose (2 μL LV) G-FVIII-LV for phenotypic correction of bleeding diathesis by tail clip assay. In the high dosage group, the blood loss was 41% ($n = 7$), 48% ($n = 5$) and 33% ($n = 5$) on days 35, 118 and 160, respectively compared with control HemA (normalized to 100%) and wild-type (2.5%) mice. In the low dosage group, the percentage of the blood loss was 43% ($n = 7$), 54% ($n = 4$) and 42% ($n = 4$) on days 35, 118 and 160, respectively. Partial phenotypic correction of HemA was achieved over a 5 month experimental period following single-dose IO delivery of G-FVIII-LV without pre-conditioning. These results indicate that direct transduction of bone marrow cells targeting platelet-specific FVIII expression may provide an effective therapy to treat hemophilia A in the absence and presence of pre-existing inhibitors.

OC 37.2

A-LONG: results from a Phase 3 study of safety, efficacy, and pharmacokinetics of long-lasting recombinant factor VIII Fc fusion protein (rFVIIIFc)

Background: Prophylaxis is the standard of care for prevention of bleeding episodes and arthropathy in severe haemophilia A. However, frequent injections (3–4 times/week) are required, potentially impacting adherence, quality of life, leading to increased morbidity. To reduce frequent injections, a long-lasting recombinant FVIII Fc fusion protein (rFVIIIFc), consisting of a single molecule of recombinant FVIII covalently linked to the Fc domain of immunoglobulin G1 with no intervening sequence, was engineered. Fc fusion is an established

technology that utilises the endogenous IgG cycling pathway to prolong the half-life of therapeutic proteins.

Aims: This phase 3 study evaluated the safety, efficacy, and PK of rFVIIIFc given as prophylaxis, for treatment of acute bleeding, and for perioperative management in previously-treated patients (PTPs) with severe haemophilia A.

Methods: Eligible male subjects ≥ 12 years old, with severe haemophilia A (< 1 IU/dL [1%] endogenous FVIII), ≥ 150 prior exposure days (ED) to FVIII, and no history of FVIII inhibitor, received individualised prophylaxis (Arm 1; 25–65 IU/kg every 3–5 days), weekly prophylaxis (Arm 2; 65 IU/kg), or episodic (Arm 3; 10–50 IU/kg) treatment. Subjects from each arm were eligible to enter a surgery subgroup. PK properties of rFVIIIFc were compared with rFVIII (Advate®; sequential PK subgroup). Overall study duration was ≤ 75 weeks. The primary efficacy endpoint was annualised bleeding rate (ABR; Arm 1 vs. Arm 3). ABR in Arm 2 vs. Arm 3, prophylaxis dose and interval, number of injections required for treatment of bleeding episodes, and perioperative haemostasis were evaluated. The primary safety endpoints included the incidence of adverse events (AEs) and inhibitor development.

Results: One hundred and sixty-five subjects were enrolled at 60 centres; 93% completed the study. Median age was 30 years (range, 12–65). Geometric mean (95% CI) terminal half-life was 19.0 (17.0–21.1) hours for rFVIIIFc vs. 12.4 (11.1–13.9) hours for rFVIII. Geometric mean time to 1% FVIII activity following 50 IU/kg of rFVIIIFc was approximately 5 days. Additionally, area under the concentration curve, geometric mean residence time, and time to 1% and 3% FVIII activity were significantly increased with a decrease in clearance for rFVIIIFc versus rFVIII, $P < 0.001$. Comparable PK profiles of rFVIIIFc were observed at Week 14. Median ABR for individualised and weekly prophylaxis were 1.6 and 3.6, respectively, vs. 33.6 for episodic treatment. The median dose and dosing interval with individualised prophylaxis were 78 IU/kg and 3.5 days, respectively; approximately 30% of subjects achieved a mean dosing interval of 5 days over the last 3 months on study. Ninety-eight percent of bleeding episodes were controlled with 1–2 injections. Perioperative haemostasis with rFVIIIFc was rated as excellent or good for all nine major surgeries. rFVIIIFc was well tolerated. No rFVIIIFc-related serious adverse events were reported. No inhibitors were detected.

Summary/Conclusions: Current data from A-LONG, the largest registrational study in haemophilia A, demonstrate that rFVIIIFc was efficacious, safe, and well-tolerated showing an improved PK profile vs. rFVIII concentrate. These data suggest that rFVIIIFc may significantly reduce injection frequency for prevention and treatment of bleeding in severe haemophilia A, potentially improving adherence and patient outcomes.

OC 37.3

A novel bispecific antibody (ACE910) against coagulation factors IXa and X improves procoagulant activity of patients with hemophilia A *ex vivo* to hemostatic level

Ogiwara K[1], Nogami K[1], Yada K[1], Furukawa S[1], Minami H[1], Haku J[1], Kitazawa T[2], Hattori K[2] and Shima M[1]

[1]*Nara Medical University, Kashihara-shi, Nara;* [2]*Chugai Pharmaceutical Co., Ltd., Gotemba, Shizuoka, Japan*

Background/Aims: Requirement of frequent infusions of factor VIII (FVIII) concentrates for patients with hemophilia A (HA) and bleeding control in the patients with anti-FVIII inhibitor are the critical issues. Recently, we generated a novel bispecific antibody against FIXa and FX, ACE910, which mimics the cofactor function of FVIII to exert *in vivo* hemostatic activity (Nat Med 2012, ASH2012), and started a phase I clinical study. Since ACE910 possesses a different antigenicity from FVIII, it can improve the intrinsic pathway coagulation even in the presence of inhibitor. Therefore, ACE910 will be used for the HA patients without fear of developing inhibitor, as well as for the patients who have already developed the inhibitor. Other important advantage in HA treatment is that subcutaneous infusion is possible and long-acting over 1–2 weeks can be expected. In the present study, we examined the *ex vivo* hemostatic effect of ACE910 on HA patients.

Methods: Twelve HA patients (3 without inhibitor and 9 with inhibitor) were enrolled. The effect of ACE910 on the parameters of ROTEM [clotting time (CT), clot formation time (CFT)], which was triggered by recalcification, was examined. Next, we compared the effect of ACE910 with that of FVIII concentrates on commercially available FVIII-deficient plasma by using APTT-clot waveform analysis (CWA). Each value of CWA parameters (APTT, maximum velocity and acceleration) was converted to FVIII activity (IU/dL).

Results: In ROTEM, when ACE910 were added to the whole blood at 0, 1, 5, 10, 20 μg/mL, the median values of CT were 4714*, 2048*, 1119, 1056, 792 s, respectively [*P < 0.01 vs normal control, 936 s (761–1128)], showing normalized value at 5 μg/mL or more dose. CFT [2896*, 432, 326, 216, 151 s at respective dose, *P < 0.01 vs normal control, 313 s (202–514)] were also normalized at 1 μg/mL or more dose. The presence of inhibitor showed no significant difference. In CWA, APTT was normalized (FVIII activity > 30 IU/dL) by addition of 1.25 μg/mL or more ACE910. However, the maximum velocity and acceleration were just improved equally to mild HA (FVIII activity 5–30 IU/dL) by addition of 5–40 μg/mL ACE910. When the FVIII-deficient plasma was mixed with anti-FVIII inhibitor (10 BU), the effect of ACE910 was quite similar. We also confirmed the activity of ACE910 in plasma taken from the HA patients.

Discussion: It is noteworthy that FVIII requires additional time to be activated by thrombin, while ACE910 does not require the process. Therefore, in the mode of action, ACE910 is different from wild type FVIII. Our findings indicated that improvement of parameters such as coagulation velocity and acceleration seemed to be useful for assessment and monitoring of the effect of the antibody on FVIII function *in vivo*. Nevertheless, we concluded that spiked ACE910 exerted its cofactor activity in the blood of HA patients dose-dependently even in the presence of inhibitor.

Conclusion: Our findings strongly suggested that clinically-achievable concentration of ACE910 could exert hemostatic effect for HA patients regardless of the presence of inhibitor.

OC 37.4

An RNAi therapeutic targeting antithrombin increases thrombin generation and improves hemostasis in hemophilia mice

Akinc A[1]

[1]*Alnylam Pharmaceuticals, Cambridge, MA, USA*

Background: The hemostatic system balances the need to control blood loss with the need to prevent thrombosis. In hemophilia, the loss of certain procoagulant factors (Factor VIII (FVIII) and Factor IX (FIX), in the case of hemophilia A and B, respectively) results in an imbalance of the hemostatic system toward a bleeding phenotype. Interestingly, there have been reports suggesting that coinheritance of prothrombotic mutations (e.g. Factor V Leiden, protein C deficiency, protein S deficiency, antithrombin deficiency, prothrombin G20210A) may ameliorate the clinical phenotype in hemophilia. We are currently investigating the use of RNA interference (RNAi) to target the natural anticoagulant antithrombin (AT) as strategy to rebalance the hemostatic system and improve thrombin generation, and therefore hemostasis, in hemophilia. Previously, a short interfering RNA (siRNA), ALN-AT3, was developed against AT and demonstrated potent activity in both wild-type and hemophilia mice after single subcutaneous (SC) administration (ED50 ~ 1 mg/kg).

Aims: There are two main aims in this work. First, we investigate the ability of ALN-AT3 to silence AT, and consequently, increase throm-

bin generation in a dose-dependent manner in hemophilia mice. Second, we explore whether AT reduction is able to improve hemostasis in a dose-dependent manner in hemophilia mice.
Methods: Hemophilia mice (HA and HB) received single subcutaneous injections of ALN-AT3 at doses ranging from 1 to 30 mg/kg. Plasma samples were collected from animals and analyzed from thrombin generation using a Calibrated Automated Thrombinoscope (CAT). Hemostasis was assessed using intravital microscopy in a laser injury model of the microvasculature of the cremaster muscle.
Results: Dose-dependent increases in thrombin generation were observed, with full normalization of thrombin generation back to wild-type control levels in hemophilia mice treated with the highest dose of ALN-AT3. Similarly, improvement in hemostasis was observed after laser injury, with dose-dependent increases in platelet accumulation and fibrin deposition rates. While no stable clot formation was observed after laser injury in hemophilia mice treated control vehicle, a stable clot was observed at all laser injury sites in the ALN-AT3 treated groups.
Conclusions: These data suggest that the use of a novel RNAi therapeutic targeting AT is a promising approach for the treatment of hemophilia, and potentially, other bleeding disorders. Further, the SC route of administration, long duration of action, and applicability to persons with hemophilia who have inhibitors, make this a particularly

OC 37.5

Engineering a novel rFVIII-VWF D'D3 fusion protein to enhance stability and improve pharmacokinetic properties of FVIII

Seth Chhabra E, Liu T, Kulman J, Patarroyo-White S, Zhu L, Pape B, Pierce GF, Mei B, Jiang H and Peters RT
Biogen Idec, Waltham, MA, USA

Background: More than 95% of circulating FVIII exists in a non-covalent complex with von Willebrand Factor (VWF). While VWF stabilizes and protects FVIII from clearance, it also subjects FVIII to VWF-dependent clearance, thus imposing a limit on the magnitude of half-life extension of rFVIII that is achievable by current technologies, which correlates with an approximately two-fold half-life extension compared to rFVIII in animal models. Engineering a stabilized FVIII molecule that does not bind to circulating VWF may enable circumvention of this VWF clearance pathway and provide a strategy for further extending the half-life of rFVIII molecules.
Aims: Develop a novel fusion protein consisting of FVIII and VWF domains that provides the protection and stability of endogenous VWF while evading the limitation imposed by VWF.
Methods: Truncated VWF variants were screened by hydrodynamic injection in VWF-deficient mice to identify the minimal domains that could stabilize endogenous FVIII. Selected VWF domains were then fused to FVIII using Fc as a scaffold. A thrombin-cleavable linker was inserted in between the VWF and Fc domain to facilitate the release of the VWF domains upon FVIII activation. The *in vitro* plasma stability of fusion proteins were determined by FVIII activity assay. The molecular integrity and circulating half-lives of rFVIII-VWF domain fusion proteins were evaluated in FVIII deficient (HemA) and FVIII/VWF deficient (DKO) mice.
Results: The 477 amino acid D'D3 domain of VWF (linked to the Fc monomer through a 98 amino acid thrombin cleavable linker) was identified as the optimal configuration for providing maximum stabilization and protection to the FVIII molecule. To prevent multimerization, two cysteine residues in the D'D3 domain that lead to covalent dimerization of native VWF were mutated in the fusion protein. VWF D1D2 region was required for proper function of the D'D3 domains produced in the cell culture. rFVIII-VWF D'D3 fusion proteins displayed enhanced plasma stability compared to rFVIIIFc and stability was further enhanced by substituting the FVIII moiety with a single chain FVIII isoform. *In vitro* the D'D3 domain prevented association of rFVIII with endogenous VWF, a finding that was corroborated by similar pharmacokinetic profiles for the rFVIII-VWF D'D3 fusion protein in both HemA and DKO mice. A terminal half-life of 13 h in DKO mice was achieved by the lead rFVIII-VWF D'D3 fusion protein, representing an approximately 54-fold improvement over that of BDD-FVIII.
Summary/Conclusions: We have developed a rFVIII-VWF fusion protein with a prolonged *in vivo* half-life that is uncoupled from the fate of VWF but retains the stability ordinarily conferred by endogenous VWF. Liberation of FVIII from VWF represents the fundamental difference between rFVIII-VWF D'D3 fusion protein and other rFVIII molecules that are currently under clinical investigation. This approach provides a platform for incorporation of additional half-life extension technologies that can ultimately surmount the half-life extension ceiling imposed by endogenous VWF.

OC 37.6

Results of haemostatic efficacy, safety, and pharmacokinetics/pharmacodynamics of a plasma-derived factor VIIa and factor X (MC710) in haemophilia patients with inhibitors: phase II clinical trial

Amano K[1], Shirahata A[2], Fukutake K[1], Takamatsu J[3], Shima M[4], Higasa S[5], Fujii T[6], Migita M[7], Kawakami K[8] and Saito H[9]
[1]Tokyo Medical University, Tokyo; [2]Kitakyushu Yahata Higashi Hospital, Kitakyusyu; [3]Japanese Red Cross Aichi Blood Center, Nagoya; [4]Nara Medical University, Kashihara; [5]Hyogo College of Medicine, Nishinomiya; [6]Hiroshima University Hospital, Hiroshima; [7]Kumamoto Red Cross Hospital, Kumamoto; [8]Kagoshima City Hospital, Kagoshima; [9]National Hospital Organization Nagoya Medical Center, Nagoya, Japan

Background: MC710, a mixture of plasma-derived activated factor VII (FVIIa) and factor X (FX) at a protein weight ratio of 1:10, is a novel bypassing agent for haemostasis in haemophilia patients with inhibitors. MC710 is designed to administer FVIIa and its substrate FX concomitantly for greater potency than rFVIIa, and is long acting due to the long half-life of FX. We have already reported the results of a clinical pharmacological study (Phase I trial) wherein MC710 was intravenously administered at a single dose to haemophilia patients with inhibitors in non-bleeding state and the dose-dependency of pharmacokinetic (PK), pharmacodynamic (PD) parameters, and safety from 20 to 120 μg/kg (as FVIIa dose) were confirmed [1, 2].
Aims: In a Phase II trial, we evaluated the haemostatic efficacy and safety of single doses of MC710, and investigated PK and PD parameters in joint bleeding episodes in male haemophilia patients with inhibitors.
Methods: This trial was a multi-centre, open-label, non-randomized study of two doses (60 and 120 μg/kg), allowing for re-administration of different MC710 dosages to the same subjects. All subjects provided written informed consent. This trial was approved by the institutional review board of each participating institute. MC710 was intravenously administered at a single dose to the patients within 3.5 h after the onset of joint bleeding (shoulder, elbow, knee, or ankle) to evaluate haemostatic efficacy, safety, and PK (FVII:C, FX:C, FVII:Ag, and FX:Ag) and PD (APTT clot waveform analysis, PT, and thrombin generation test) in bleeding state. Haemostatic efficacy was determined for each treatment by investigator's evaluation using changes in visual analogue scale (VAS) for pain reduction, girth of joint (only for knee) for decrease in swelling, and range of motion (ROM) of the bleeding joint for improvement of joint mobility.
Results: In this trial, 19 subjects (nine haemophilia A (HA) patients with inhibitors and 10 haemophilia B (HB) patients with inhibitors) were enrolled. MC710 was given to six subjects including two HA patients with inhibitors and four HB patients with inhibitors. The

results of the study showed that in nine bleeding episodes, seven treatments were rated as 'excellent' or 'effective' in haemostatic efficacy at 8 h after administration. PK parameter values were close to those of the non-bleeding state. PD parameters changed drastically after administration and those changes were maintained for up to 24 h. No serious or severe adverse events were observed after administration; furthermore, measurement of several diagnostic markers revealed no signs or symptoms of disseminated intravascular coagulation (DIC).

Summary/Conclusion: The haemostatic potential of MC710 was confirmed at doses of 60 and 120 μg/kg in this trial. MC710 is thus expected to be a safe and efficacious novel bypassing agent for controlling bleeding in haemophilia patients with inhibitors. An expanded study (Phase III trial) in haemophilia patients with inhibitors and haemorrhage is ongoing to investigate the duration of MC710 efficacy, and the safety of repeated administration.

OC 38 – Tissue Factor

OC 38.1

Heme-induced vascular permeability leads to the extravascular TF-dependent activation of coagulation

Sparkenbaugh EM[1], Chantrathammachart P[2], Chen J[3], Kirchhofer D[4], López JA[3], Key NS[1], Mackman N[1] and Pawlinski R[1]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; [2]Mahidol University, Ramathibodi Hospital, Bangkok, Thailand; [3]Puget Sound Blood Center, Seattle, WA; [4]Genentech, San Francisco, CA, USA

During hemolytic anemia, an excess of free heme in the blood leads to oxidative stress, vascular inflammation, activation of coagulation and thrombosis. Heme has been reported to increase tissue factor (TF) expression on endothelial cells (EC) and macrophages *in vitro*. In this study we investigated the mechanism of heme-induced activation of coagulation *in vivo*. C57Bl/6 mice were given a bolus intravenous injection of 0–35 μmol/kg heme or vehicle. Plasma was collected at 0–6 h after injection. Coagulation activation and inflammation were assessed by plasma thrombin anti-thrombin (TAT) complexes and plasma interleukin (IL)-6 levels, respectively. Administration of 17.5 and 35 μmol/kg of heme resulted in 1.8 ($P < 0.001$) and 2.6 ($P < 0.001$) fold increases, respectively, in plasma TAT levels 6 h after injection. In time course experiment (35 μmol/kg heme), plasma TAT levels increased rapidly at 1 h (2.2-fold, $P < 0.001$) and remained elevated at 3 (1.9-fold, $P < 0.001$) and 6 h (2.5-fold, $P < 0.001$).

Heme induces a rapid release of P-selectin and von Willebrand Factor (vWF) from EC Weibel-Palade bodies. P-selectin anchors ultralarge vWF strings to the endothelium and creates a thrombogenic surface. We observed significant increase in total plasma vWF ($P < 0.05$) and the amount of ultra large vWF multimers 1 h after heme injection (35 μmol/kg). However, inhibition of P-selectin with anti-P-selectin antibody (50 μg/kg) did not attenuate heme-induced activation of coagulation.

Next, we determined the role of TF in heme-induced activation of coagulation and inflammation. Thirty minutes before heme injection, C57Bl/6 mice were pretreated with the rat anti-mouse TF antibody 1H1 (25 mg/kg, single i.p. injection) or rat IgG. Heme (35 μmols/kg) induced leukocytosis (2.3-fold, $P < 0.001$) and increased plasma levels of interleukin-6 (8.5-fold, $P < 0.01$). However, inhibition of TF with 1H1 antibody did not affect any of these parameters. Heme increased plasma TAT levels from 4.6 ± 1.3 to 9.6 ± 1.3 ng/mL ($P < 0.001$); this increase was significantly attenuated by 1H1 treatment (6.8 ± 0.4 ng/L, $P < 0.01$). Importantly, TAT levels were also reduced by 40% ($P < 0.01$) in heme injected low TF mice (expressing 1–2% of normal TF levels) compared to control mice. Interestingly, the total number of phosphatidylserine-positive microparticles (MP) was not increased and there was no detectable TF-positive MP activity in the plasma after heme treatment, suggesting that MPs are not involved in heme-mediated coagulation activation.

To determine the cellular source of TF that contributes to the activation of coagulation, we used $TF^{flox/flox}$, Tie-2 Cre mice (TF deficiency in hematopoietic and ECs). Deletion of TF from these cells did not affect plasma TAT levels in heme injected mice, indicating that some other cellular source of TF activates coagulation. Importantly, we demonstrated that heme rapidly increased vascular permeability in the lung (2.7-fold increase in Evans Blue content compared to controls, $P < 0.05$), indicating EC damage and exposure of the extravascular TF.

Our data indicate that heme-induced activation of coagulation, but not inflammation, is TF-dependent. In contrast to *in vitro* data, TF expressed by extravascular cells rather than leukocytes or ECs is the likely source of TF contributing to heme-mediated activation of coagulation in mice.

OC 38.2

The insulin-like growth factor 1 receptor mediates tissue factor/FVIIa-induced cell survival

Åberg M, Eriksson O, Mokhtari D and Siegbahn A

Uppsala University, Uppsala, Sweden

Background: The binding of factor VIIa (FVIIa) to tissue factor (TF) initiates blood coagulation and activates various intracellular signalling pathways. Solid tumors often have high expression of TF and recently, we showed that TF/FVIIa-complex formation protects cancer cells from TNF-related apoptosis inducing ligand (TRAIL)-induced apoptosis. The anti-apoptotic signalling did not involve the engagement of TF co-receptors PAR1 or PAR2 but possibly another cell surface component. The receptor tyrosine kinase (RTK) insulin-like growth factor 1 receptor (IGF-1R) is a major regulator of cell survival, and is implicated in the pathogenesis of several disease states, including cardiovascular disorders and cancer. Although we and others have described transactivation of RTKs by the TF/FVIIa complex, there are no published reports concerning TF and the IGF-1R.

Aim: The aim of the current study was to investigate the involvement of the IGF-1R in TF/FVIIa-mediated protection against TRAIL-induced apoptosis in breast and prostate cancer cells.

Methods: MDA-MB-231 breast and PC3 prostate cancer cells were incubated with 100 ng/mL TRAIL and 100 nM FVIIa, either alone or in combination, while the IGF-1R was blocked using specific inhibitors (PPP; AG1024) or siRNA. The caspase-8 and -3 levels, nuclear alterations, and cellular size were then monitored for 6 h by the ArrayScan VTI microscope. Human monocytes were isolated from whole blood and induced to express TF by stimulation with 10 ng/mL LPS for 3 h. The phosphorylation status of the IGF-1R and its associations to the 14-3-3 family of adaptor proteins were determined using the Duolink *In Situ* proximity ligation assay. The phosphorylation of AKT was determined by western blot.

Results: Both in the IGF-1R inhibitor-treated and in the gene silenced MDA-MB-231 cells, the antiapoptotic signalling mediated by TF/FVIIa was significantly reduced to levels comparable to TRAIL-treatment alone. The phosphorylation of AKT, whose activation is mandatory for the survival signalling of TF/FVIIa, was also sensitive to IGF-1R inhibition. Our findings were verified in PC3 cells and the possibility that AG1024, PPP, and the siRNA treatment evoke apoptosis on their own was clearly ruled out.

TF/FVIIa furthermore induced a tyrosine phosphorylation of the IGF-1R in MDA-MB-231 cells as well as in human monocytes. This led to an association of the IGF-1R and members of the 14-3-3-family, an event previously known to initiate pro-survival signalling pathways.

Summary/Conclusions: We propose that the IGF-1R is a key mediator of TF/FVIIa antiapoptotic effects. We also demonstrate, for the first time, that FVIIa-treatment leads to IGF-1R transactivation in several

cell types, and association of the IGF-1R to the 14-3-3 family of adaptor proteins. Our novel findings thus couple the coagulation system to the IGF-system, and shed new light on both TF/FVIIa and IGF-1R signalling.

OC 38.3

Red blood cells enhance LPS-induced tissue factor and TNFalpha in monocytes

Osterud B and Olsen JO
University of Tromso, Tromso, Norway

Introduction: We have previously shown that the expression of tissue factor (TF) activity in LPS-stimulated human monocytes is enhanced two fold by blood platelets in a granulocyte dependent reaction. Although red blood cells (RBCs) have been reported to accelerate thrombin generation by their surfaces, a possible interaction between RBCs and monocytes in the expression of TF has not been shown. RBC transfusion has been demonstrated to increase platelet activation and aggregation *in vitro* in healthy individuals. In some old data not reported we found a positive correlation between RBC and LPS-induced in whole blood and TNFα, IL-6 and P-selectin when screening a large population. This prompted a further search for a possible interaction between RBC and activated monocytes.

Methods: Whole blood was collected from healthy individuals with Fragmin as anticoagulant. RBC, granulocytes and mononuclear cells were isolated by centrifugation of the blood on top of Lymphoprep/Polymorphprep as described earlier. The granulocytes, mononuclear cells and platelets were after washing re-suspended in plasma (Fragmin) and added increasing volumes of RBC and correcting volume by adding saline.

Test aliquots were prepared by combining mononuclear cells, granulocytes and platelets from 1 mL blood that was re-suspended in 0.5 mL plasma (Fragmin) and RBCs as indicated below. These samples were added 5 ng/mL LPS and incubated for 2 h at 37 °C in a rotary incubator. EDTA was added to stop the reaction and mononuclear cells isolated and frozen and thawed before measurements of TF in a specific TF activity assay. In separate experiments the incubation samples were centrifuged for collection of plasma to quantify TNFα that was measured in an ELISA assay.

Results: RBC enhanced LPS-induced TF activity in a dose dependent manner with an optimal effect of 8.8×10^9/mL (final concentration) RBCs in the sample (49.7 ± 19.0 mU/10^6 to 80.4×8.6 mU/10^6, $n = 6$). At higher concentration of RBCs, there was a less effect of them.

TNFα was measured in plasma samples, and a significant rise was observed between 1.1×10^9/mL (1.53 ± 0.40 ng/mL) and 17.6×10^9/mL (2.74 ± 0.75 ng/mL, $n = 8$) RBCs added to the white cells and platelets.

When screening blood of healthy individuals ($n = 143$), it was found a positive correlation coefficient between RBCs and LPS-induced TNFα, IL-6 and P-selectin of respectively 0.22 ($P < 0.01$), 0.19 ($P < 0.05$) and 0.33 ($P < 0.001$).

Discussion: The enhancement of LPS-induced TF activity as well as TNFα in monocytes by RBCs shows that RBCs has a pro-coagulant and a pro-inflammatory effect. This is in agreement with our observation that P-selectin and the production of TNFα in LPS-stimulated blood of a large population correlated positively with RBCs. Our results may at least partially account for the higher risk of thrombosis at high RBC counts.

OC 38.4

Endothelial cells uptake and recycle microparticle-derived tissue factor to the cell surface with augmented procoagulant activity

Ettelaie C, Mei PM, Collier MEW, Xiao Y and Maraveyas A
University of Hull, Hull, UK

Background: Endothelial cells may express TF in response to inflammatory cytokines. However, there is also *in vitro* and *in vivo* evidence that TF-positive microparticles transfer TF to vascular endothelial cells. Recent evidence suggests that microparticles bind to the surface of cells and are then internalised by endocytosis. However, it is not known whether TF associated with microparticles is internalised by an endocytotic process and whether this TF is then recycled back to the cell surface or degraded.

Aims: In this study, we have demonstrated the uptake of TF from microparticles by microvascular endothelial cells and have examined the mechanisms involved in the recycling of TF together with the exposure of phosphatidylserine, resulting in increased TF activity on the surface of endothelial cells.

Methods: Human dermal blood endothelial cells (HDBEC) were incubated with TF-positive and TF-negative microparticles isolated from the media of MDA-MB-231 and MCF-7 cell lines respectively. Cell surface TF antigen and activity were measured over 6 h using an anti-TF antibody, and a thrombin generation assay, respectively. The exposure of phosphatidylserine was also analysed by annexin V-labelling. TF expression was also monitored using quantitative RT-PCR. In addition, samples of cells were incubated with cyclohexamide to prevent protein synthesis, or a dynamin inhibitor (Dynasore) to prevent endocytosis, prior to incubating with microparticles. Finally, microparticles were isolated from the media of MDA-MB-231 cells expressing a TF-tGFP hybrid protein. Endothelial cells were incubated with the microparticles and the co-localisation of TF with the Rab family of proteins analysed by confocal microscopy.

Results: Measurement of TF antigen on the surface of HDBEC revealed two distinct peaks at 30 and 180–240 min post-incubation of the cells with TF-positive, but not TF-deficient microparticles. However, only the second peak was concurrent with high TF activity as determined by a chromogenic thrombin-generation assay. Annexin V-labelling of the HDBEC-surface showed the exposure of phosphatidylserine following 90 min incubation with microparticles, which explains the high TF activity associated with the second antigen peak. Analysis of TF mRNA levels revealed no *de novo* expression of TF mRNA in response to microparticles, and pre-incubation of the cells with cyclohexamide did not prevent the appearance of TF. In contrast, blocking endocytosis with Dynasore prolonged the disappearance and prevented the re-appearance of TF antigen on the cell surface. Incubation of HDBEC with microparticles containing TF-tGFP revealed the early co-localisation of TF with Rab4 and Rab5, which was followed by co-localisation with the late endosomal/trans-Golgi network marker Rab9, and the recycling endosome marker Rab11.

Conclusions: These data suggest a mechanism by which TF-containing microparticles are internalised by endothelial cells and the TF moiety recycled to the cell surface. Together with the exposure of phosphatidylserine, this is capable of inducing a substantial increase in the procoagulant potential of the surface of endothelial cells.

OC 38.5

Tissue factor expression and signalling in aortic valve interstitial cells: insights into fibro-calcific aortic valve disease

Susen S[1], Elkalioubie A[2], Arbesu Y Mar A[2], Corseaux D[2], Dupont A[2], Zawadzki C[2], Juthier F[2], Smadja D[3], Chinetti G[4] and Van Belle E[5]

[1]Haematology Transfusion Department; [2]Univ Lille Nord de France, UDSL, IFR114, EA2693, Faculté de Médecine, Lille; [3]Inserm UMR-S 765, Université Paris V, Paris; [4]Inserm UMR-1011, Institut Pasteur de Lille; [5]CHRU, Pôle de Chirurgie Cardiovasculaire et de Cardiologie, Lille, France

Background: Aortic valve stenosis (AVS) is an atherosclerosis-like process characterized by valve interstitial cell (VIC) proliferation and commitment to fibrocalcification and pro-inflammatory cytokines. To date, no effective medical treatment is able to improve the clinical course of the disease. Tissue factor (TF) and thrombin expressions were previously shown to be significantly associated with fibrocalcification in human stenotic aortic valves.
Aims: We investigated differential TF expression in normal and pathological valves and VIC and further describe its downstream signalling pathways in normal VIC and its role in their profibrotic commitment.
Methods: Fibrocalcific and normal human aortic valves were collected ($n = 50$ and $n = 6$ respectively) from which tissue lysates and valve interstitial cells (VIC) were isolated. VIC phenotype was analysed by flow cytometry. VIC obtained from normal aortic valves were stimulated or not with IL-1beta (major inflammatory cytokine involved in AVS at 1 ng/mL). In valve lysates and in VIC, TF and PAR-2 were quantified by qPCR for relative mRNA expression, and by flow cytometry/ELISA for protein and activity quantification.
Downstream signalling pathways ERK (cell activation and proliferation) and Smad2 (pro-fibrosis transcription factor) of VIIa/TF in stimulated VIC were assessed by westernblotting after incubation of TF-overexpressing VIC with VIIa (50 ng/mL for 30 min) in the presence or in the absence of anti-TF antibody. Results are expressed as median (interquartile range).
Results: VIC were defined by flow cytometry as being CD31 and CD68 negative and and stemness marker (CD90). Relative mRNA expressions of TF and PAR-2 were significantly higher in fibrocalcific vs normal valve lysates (3.2 (1.5-.8) vs 0.18 (0.02–0.29), $P < 0.05$; 1.15 (0.48–1.62) vs 0.16 (0.02–0.22), $P < 0.05$; respectively). Normal VIC constitutively expressed active TF mRNA and protein (relative mRNA 4.1 (2.1–21.2); activity 36.2 (13.2–101.3) pg/mL) as well as PAR-2 receptor (mRNA and protein by flow cytometry). TF expression was significantly increased in fibrocalcific VIC (relative mRNA 22.8 (9.8–33.8), $P = 0.05$; activity 153 (71.5–247.0) pg/mL, $P < 0.05$) when compared to normal VIC. Following IL-1beta stimulation of VIC, TF expression was significantly upregulated when compared to unstimulated cells (relative mRNA 15.4 (12.9–28.2) fold increase, $P < 0.05$) and was associated with an increase of TF activity (2.7 (2.2–5.5) fold increase, $P < 0.05$). The VIIa stimulation of TF-overexpressing VIC entailed an upregulation of ERK and Smad2 signalling pathways (pERK/ERK activation ratio 3.5 (2.9–4.8) fold increase; pSmad2/Smad2/3 activation ratio 1.8 (1.2–1.8) fold increase). This upregulation was blunted by preincubation of VIC with a specific anti-TF antibody.
Summary/Conclusions: Our results demonstrate the implication of TF/VIIa/PAR-2 axis in VIC commitment to fibrocalcific aortic valve disease. Thus, modulation of this pathway may represent a new therapeutic target for the early medical treatment of AVS.

OC 38.6

Increased expression of tissue factor in intra-abdominal adipose tissue in a metabolic syndrome model: a new insight ?

Corseaux D[1], Pasquesoone L[1], Elkalioubie A[1], Ung A[2], Vaast B[2], Chinetti G[3], Staels B[3], Jude B[2], Van Belle E[2] and Susen S[2]

[1]Université Lille 2; [2]CHRU; [3]Inserm UMR 1011, Lille, France

Background: Tissue factor (TF), the principal initiator of blood coagulation, plays an important role in atherosclerosis. TF is considered to be the main contributor to plaque instability by favoring thrombogenicity and angiogenesis. Metabolic syndrome (MetS), a major risk factor of atherosclerotic cardiovascular diseases, is characterized by the accumulation of dysfunctional intra-abdominal adipose tissue secreting adipokines and other proinflammatory factors.
Aims: We aimed at studying adipose tissue TF expression and its modulation in relation to MetS.
Methods: Eighty five male Sprague Dawley rats were placed on a fructose-enriched (60%) diet or a normal diet during 6 weeks. Development of MetS was confirmed via blood pressure measurement, blood sampling and MRI study of fat distribution. TF expression (antigen, activity and mRNA) was assessed in adipose tissue (subcutaneous, intra-abdominal and perivascular), adipose tissue conditioned medium and in cultured pre-and mature adipocytes.
Results: We confirmed that a fructose-enriched diet induced an early stage of MetS with arterial hypertension, insulin resistance, increased plasma cholesterol and triglycerides levels, and body fat redistribution, as identified by MRI ($P < 0.01$). TF expression occurred in all adipose tissues in both groups of rats (activity, antigen and mRNA), significantly more so in the MetS group. In particular, TF expression was significantly higher in intra-abdominal adipose tissue of MetS rats compared to control rats (activity: 1286 versus 812 mU/g of protein respectively, $P < 0.01$) with similar results regarding TF antigen. Cultured fat cells (adipocytes and stromal fraction which contains pre-adipocytes) produced TF which activity increased with the degree of cell differentiation, more in the MetS group compared to control rats (5424 versus 2570 mU/g of protein respectively, $P < 0.005$). When cultured, intra-abdominal adipose tissue secreted functionally active TF (69 mU/mg protein).
Conclusions: This study shows for the first time the expression of functionally active TF in various adipose tissues of an early nutritional acquired MetS rat model. TF expression was significantly higher in intra-abdominal adipose tissue and could accordingly, via a paracrine effect, contribute to MetS related atherosclerotic complications.

OC 39 – Von Willebrand Disease – Basic Aspects

OC 39.1

The type 2B p.R1306W von Willebrand factor mutant shows a large enhancement of sensitivity to shear stress that favors its interaction with the platelet receptor

De Cristofaro R[1], Lancellotti S[2], Scaglione GL[2], Papi M[3], De Spirito M[3], Baronciani L[4], Pagliari MT[4], Arcovito A[5], Di Stasio E[5] and Peyvandi F[6]

[1]*Catholic University School of Medicine;* [2]*Department of Medical Sciences, Catholic University School of Medicine;* [3]*Instituto of Physics, center of Microscopy, Catholic Univ School of Medicine, Roma;* [4]*Fondazione I.R.C.C.S. Ca' Granda Ospedale Maggiore Policlinico, Univ of Milano, Milano;* [5]*Institute of Biochemistry, Catholic Univ School of Medicine, Roma;* [6]*Fondazione IRCCS Maggiore Hospital Foundation, Milano, Italy*

Background: Shear stress triggers conformational changes of von Willebrand factor (VWF) from a globular to a stretched status, responsible for both exposure of the binding site for the platelet receptor GpIb and its self-association. This mechanism supports the formation of platelet plug under high shear stress in flowing blood. Natural VWF mutants of type 2B VW disease (2B-VWD) are generally considered having an increased affinity for platelet GpIb, in turn responsible also for accelerated hydrolysis by ADAMTS-13.

Aims: This study was aimed at assessing whether the type 2B p.R1306W mutant has an intrinsic higher affinity in the minimal binding domain for GpIb present in the A1-A2-A3 domain or rather the increased interaction with the platelet receptors stems from an increased sensitivity to shear stress that exposes the interaction sites for GpIb upon the conformational changes induced by shear forces.

Methods: Surface plasmon resonance spectroscopy was used to measure the interaction between WT and mutant p.R1306W A1-A2-A3 domain with the recombinant GpIb part containing the VWF binding domain. The analysis of VWF self-association was performed under controlled shear stress conditions ranging from 0 to 60 dyn/cm^2 by atomic force microscopy and dynamic light scattering spectroscopy. The pro-aggregating properties of full length recombinant WT and p.R1306W VWF forms were studied by light aggregation and platelet adhesion studies in flow chamber.

Results: Measurements on the interaction between WT and mutant p.R1306W A1-A2-A3 domain with GpIb, showed that binding to GpIb is characterized by similar K_d values equal to about 20 nM. On the other hand, full length WT-VWF does not significantly interact with GpIb under static conditions, whereas the p.R1306W mutant at 1.9 μg/mL already showed a significant interaction with the receptor. At values of shear stress < 10 dyn/cm^2, the full length p.R1306W mutant already unfolds and undergoes an initial self-aggregation with formation of a network characterized by increased roughness compared to WT-VWF. Dynamic light scattering spectroscopy showed that the hydrodynamic radius of WT VWF in the absence of shear is about 2.5-fold lower than that of the 2B VWF mutant (87 ± 22 nm vs 210 ± 60 nm). Mechanical stretching experiments showed that full length p.R1306W mutant needs 30% less energy to be reversibly strained compared to WT protein. The difference of ~ 30% is related to the energy/length ratio and in the simplest picture of a homogeneous solid subject to a shear stress, the work done per unit length during the strain (equal to the strain energy stored per unit length) depends on the square of the average shear stress applied. Hence, even little differences in energy can reflect much bigger differences in shear stress to be applied.

Summary/Conclusion: These findings showed that then p.R1306W mutation enhances the avidity of this type 2B VWF mostly by increasing the sensitivity to shear stress that facilitates exposure of GpIb binding sites and proteolytic attack by ADAMTS-13. This effect contributes to loss of high molecular weight VWF multimers and to platelet consumption, often observed in this disease

OC 39.2

The von Willebrand disease type 2B p.V1316M mutation inhibits platelet functions by interfering with Ca^{2+} mobilization and integrin αIIbβ3 activation pathways

Casari C[1], Berrou E[1], Lebret M[1], Bobe R[1], Desconclois C[2], Christophe OD[1], Rosa J-P[1], Lenting PJ[1], Denis CV[3] and Bryckaert M[1]

[1]*Inserm;* [2]*Sérvice Hématologie Biologique AP-HP;* [3]*Inserm U 770, Le Kremlin-Bicêtre, France*

Background: Von Willebrand disease type 2B (VWD2B) is characterized by gain-of-function mutations in von Willebrand factor (VWF) which exhibits increased binding to platelet glycoprotein (GP)Ibα. The bleeding tendency observed in VWD2B is currently explained by the absence of high molecular weight-VWF multimers and by thrombocytopenia.

Aims: We postulate that constitutive binding of VWF may alter platelet functions, and thus participate in the bleeding tendency of VWD2B patients. To test this hypothesis we analyzed platelet functions using three models: (i) a murine model of VWD2B due to p.V1316M mVWF expression and associated with a severe phenotype; (ii) human control platelets pretreated with recombinant hVWF/p.V1316M and (iii) platelets from a VWD2B patient with the severe hVWF/p.V1316M mutation.

Methods: Spreading, aggregation, secretion, and αIIbβ3 activation were examined in static conditions in washed platelets stimulated with various agonists. Thrombus formation was performed on collagen under flow at 300/s and 1500/s. Platelet signaling including Rap1 activity, calcium release induced by G-proteins-coupled receptors (GPCRs) or by collagen receptors and GPVI signaling was examined.

Results: Platelets from mice expressing mVWF/p.V1316M or from a VWD2B patient bearing the hVWF p.V1316M mutation exhibited inhibition of integrin αIIbβ3 activation and platelet aggregation, secretion, or spreading, as induced by various agonists (collagen, convulxin, ADP and PAR4-AP). Consistent with inhibition of integrin αIIbβ3 activation, alteration of thrombus growth under flow on collagen, was also noted in both cases. Interestingly, Rap1 activation and calcium signaling as induced by various agonists were markedly diminished both in human control platelets pretreated with recombinant hVWF/p.V1316M and in platelets from the patient exhibiting the p.V1316M hVWF mutation. Interestingly, upon stimulation of GPVI signaling by convulxin, Ca^{2+} influx was drastically diminished, but Ca^{2+} store release and phospholipase (PLC)γ activation were normal (or slightly increased). This suggests a block between Ca^{2+} store release and Store Operated Calcium Entry (SOCE), possibly at the level of the SOC channel Orai1-Stim1 complex. In contrast, PLCβ-dependent Ca^{2+} store release triggered by GPCRs signaling pathways (P2Y and PAR receptors for ADP and thrombin, respectively) and Ca^{2+} influx were both reduced to comparable levels. This suggests a block upstream Ca^{2+} store release and SOCE, thus pointing to the GPCR-Gq-PLCβ pathway.

Conclusion: We conclude that V1316M VWF alters platelet aggregation, spreading and thrombus growth, via inhibition of αIIbβ3 activation, by interfering with Rap1 activation and with the cytosolic Ca^{2+} rise, by an upstream or downstream block of Ca^{2+} store release depending on agonists. While the mechanism by which VWF/p.V1316M acts still remains to be elucidated, our data strongly argue in favor of a role for thrombopathy in the bleeding tendency of V1316M VWD2B patients.

Von Willebrand factor (VWF) mediates platelet adhesion to damaged endothelium and stabilises coagulation factor VIII. VWF is stored within and directs the formation of Weibel-Palade bodies (WPB) in endothelial cells (EC). WPB contain many proteins including the angiogenic regulator Angiopoietin-2 (Ang-2). Von Willebrand disease (VWD) is the most common inherited bleeding disorder caused by decrease or dysfunction of VWF. The cellular basis of VWD is poorly understood. VWD can be associated with angiodyplasia, describing the presence of vascular lesions which can cause intractable bleeding. We demonstrated a role for VWF in angiogenesis and hypothesized that angiodysplasia might be linked to dysregulated angiogenesis through several pathways. We have used Blood Outgrowth EC (BOEC) to study the cellular basis of VWD and angiogenesis. Mononuclear cells were isolated from peripheral blood of four type 1, four type 2 VWD patients and nine healthy controls and cultured to obtain BOEC. Various EC markers confirmed the identity of the BOEC. In this study confocal microscopy confirmed VWF and Ang-2 co-staining within BOEC WPB. We discovered a heterogeneous basal release of Ang-2 from patient and control cells over a 75 min time-course with no significant difference between the groups. We previously demonstrated decreased VWF levels in type 1 VWD patients' BOEC. mRNA levels were predictive of plasma VWF levels in these patients confirming a defect in VWF synthesis (Pearson $R = 0.9976$, $P = 0.024$, $r^2 = 0.9952$). BOEC from type 1 VWD patients also showed defects in processing, storage and/or secretion of VWF with reduced VWF staining of WPB by confocal microscopy. Two patients with type 1 VWD showed increased levels of pro-peptide containing VWF. In this study we discovered that three type 1 patients showed no Ang-2 release post-cellular stimulation, consistent with the inability of these BOEC to correctly package WPB. One patient showed significant release of Ang-2 ($P < 0.05$); interestingly this patient showed the highest levels of VWF within the type 1 group with more WPB and VWF strings released upon stimulation. Our previous study showed that levels of VWF were normal in BOEC from three type 2 VWD patients, supporting the dysfunctional VWF model. However, one type two patient showed decreased VWF synthesis and storage and increased levels of pro-peptide containing VWF, indicating a complex cellular defect. We now show that all type two patients' BOEC show a significant release of Ang-2 upon stimulation, confirming correct packaging of WPB. Together our data suggests that the angiogenesis defect in type 1 VWD patients is due to dysregulation of Ang-2 storage and release, but that other mechanisms may be more relevant in type 2 VWD. Ongoing studies will define Ang-2 mRNA expression and long-term constitutive release from EC from VWD patients. These results demonstrate that isolation of endothelial cells from VWD patients provides novel insight into the cellular mechanisms of the disease and may aid in developing treatment for this common inherited bleeding disorder.

OC 39.4

Applying *in silico* analysis to the historically reported VWF exon 42 deletion reveals a probable L1 non-autonomous retrotransposition mediated deletion pathomechanism

Cartwright A, Peake IR and Goodeve AC

The University of Sheffield, Sheffield, UK

Introduction: Partial deletions of the von Willebrand factor gene (*VWF*) have been recognised as contributing to the pathogenesis of types 1, 2 and 3 von Willebrand disease (VWD). Peake et al (1990):75 654 reported an out-of-frame homozygous deletion of exon 42 (ex42del) in a type 3 VWD patient, proposed to introduce a premature stop codon into the *VWF* sequence within exon 43. A novel 182 bp insertion at the breakpoint junction was shown to be derived from an unknown site within the genome. Aim

To undertake *in silico* analysis to derive the full sequence around the breakpoints and determine the mechanism by which the deletion arose.

Methods: To assess the extent of repetitive element involvement at the breakpoint junctions and of the genomic insert, RepeatMasker was used. Nucleotide BLAST was used to find information on the genomic insertion and DNA sequence motif analysis was performed based on published information.

Results: Peake et al. could not identify repetitive sequences directly adjacent to the breakpoints and this remains the case with current methods. Nucleotide BLAST of the 182 bp insert against the human genome revealed that sequence matched *VWF* intron 38, with 96% homology (MegaBLAST). Analysis of 5′ and 3′ breakpoint regions identified topoisomerase cleavage sites directly adjacent to the breakpoints. Repetitive element analysis of the insert using RepeatMasker revealed presence of a 3′ truncated long interspersed nuclear element (LINE, L1 class) in the first 124 bp with the remainder comprising non-repetitive sequence, derived from intron 38. The mutation can be described as c.7081+86_7287+1044delins182; p.Ala2361Gly*fs*45*.

Conclusion: Previously reported L1 retrotransposition events within *F8* and *F9* contain inserts larger than reported here. These L1 inserts are associated with transposition of L1 DNA only and contain long poly A tails, capable of integrating into the genome at complementary sites, through target-site primed reverse transcription, whereby L1 endonucleases nick complementary sites and integrate reverse transcribed L1 DNA into the genome. The L1 insertion causes the disease phenotype, disrupting the reading frame and reducing gene expression. In this instance, the likely mechanism of ex42del is through a non-classical L1 retrotransposition mediated deletion event; with disease phenotype resulting from the out-of-frame ex42del. In the proposed mechanism, the 182 bp sequence is copied from intron 38 of *VWF* by another full length L1 element (non-autonomously). Topoisomerase cleavage at the sites directly adjacent to the breakpoints result in a DNA strand break, removing exon 42 sequence and flanking intron. Breakpoints are processed and the 182 bp mRNA template anneals to microhomologous sites at the 3' breakpoint. Finally, mRNA is converted to cDNA via reverse transcription and the strand break repaired by DNA synthesis. The reason for not finding 100% homology with the intron 38 inserted sequence was possibly due to the differences between the historical *VWF* sequence data and reference sequence information now available. This first report of a possible *VWF* deletion arising through non-classical L1-retrotransposition extends understanding of mechanisms responsible for *VWF* deletion mutations.

OC 39.5

Investigation of the contribution of von Willebrand factor (VWF) propeptide mutations to type 3 VWD using *in vitro* cellular studies and patient-derived blood outgrowth endothelial cells (BOEC)

Bowman ML[1], Casey L[1], Morrison L[1], Tuttle A[1], Walker I[2], Silva M[1], Jacobi PM[3], Haberichter SL[3], Lillicrap D[1] and James PD[1]

[1]*Queen's University, Kingston;* [2]*McMaster University, Hamilton, ON, Canada;* [3]*Blood Center of Wisconsin, Milwaukee, WI, USA*

Background: In the Canadian type 3 VWD study, 42% of mutations identified were found in the VWF propeptide, and index cases (IC) with mutations in this region had higher bleeding scores (BS) than IC with mutations elsewhere in VWF (median BS = 22 vs.13, $P = 0.012$).

Aims: To investigate the molecular pathogenesis of VWF propeptide (VWFpp) mutations identified in the Canadian type 3 VWD population using a heterologous mammalian cell system and patient-derived blood outgrowth endothelial cells (BOEC). As well, to investigate the potential to restore normal VWF biosynthesis by co-transfections with VWFpp.

Methods: Two mutations located in the VWFpp were investigated; the recurrent in-frame deletion of exons 4 and 5 (ex4-5del), and a novel missense mutation in exon 15, c.1897T>C (p.Cys633Arg). VWF secretion, multimerization, storage, stimulated release, and confocal immunofluorescence (IF) microscopy were examined *in vitro* in HEK293T cells and in BOEC. To investigate the potential to restore normal VWF function, HEK293T cells were co-transfected with each mutation and a human wild-type (WT) VWFpp plasmid. VWF secretion, and multimerization were investigated.

Results: Previous *in vitro* expression of homozygous ex4-5del showed markedly reduced secretion (2% of WT), levels of VWF in the cell lysates comparable to WT, loss of multimerization and absence of pseudo-Weibel-Palade bodies (WPBs). Heterozygous ex4-5del expression (1:1 WT:variant) resulted in reduced VWF secretion (14% of WT), cellular VWF comparable to WT, and normal multimers. Homozygous expression of p.Cys633Arg in HEK293T cells showed markedly reduced secretion (< 1%), intracellular retention (20% more than WT), loss of multimerization and absence of pseudo-WPBs. Heterozygous expression of p.Cys633Arg resulted in reduced VWF secretion (21% of WT), a 10% increase in the cell lysates compared to WT, and normal multimerization.

BOEC were obtained from a homozygous and heterozygous ex4-5del patient and from two homozygous and one heterozygous p.Cys633Arg patient. Compared to normal BOEC, both heterozygotes showed quantitative abnormalities in WPB formation with 50% and 62% fewer WPBs in the ex4-5del and p.Cys633Arg patients, respectively. WPBs were qualitatively different in the heterzoygotes, being more round than the typical cigar-shaped observed in normal BOEC. Associated with these WPB defects, heterozygous ex4-5del showed a minimal response to stimulation with PMA (increase in%VWF secretion was 55% that of normal) whereas the increase in p.Cys633Arg BOEC was comparable to normal (93%). A complete absence of WPBs in the three homozygotes was observed, with only diffuse VWF staining. This diffuse VWF staining co-localized with the ER marker, calnexin, indicating ER retention. Other proteins found in WPBs – P-selectin, IL-8 and CD63 did not co-localize with the diffuse VWF staining. Co-transfections of the mutant plasmids with the WT VWFpp did not restore VWF secretion, or multimerization.

Summary/Conclusions: We have shown that two different *VWF* mutations, a complete in-frame deletion of two exons and a missense mutation, which are both located in the VWF propeptide have similar effects on VWF biosynthesis and secretion. This further highlights the importance of VWF propeptide mutations in regulating VWF production and highlights the value of continued work using BOEC to study VWD.

OC 39.6

Novel variations in platelet GPCRs identified in patients with a historical diagnosis of Type 1 von Willebrand disease

Stockley J[1], Nisar SP[2], Leo V[1], Goodeve AC[1], Mundell S[2], Mumford AD[2], Watson SP[3], Daly ME[1] and MCMDM-1VWD Study group[1]

[1]*Haemostasis Research Group, Sheffield;* [2]*University of Bristol, Bristol;* [3]*University of Birmingham, Birmingham, UK*

Background: Data from the Molecular and Clinical Markers for the Diagnosis and Management of Type 1 von Willebrand Disease (MCMDM-1VWD), and other studies support a role for genes outside of the von Willebrand factor locus in contributing to the expression of type 1 von Willebrand disease (VWD). We recently identified two mutations in the platelet $P2Y_{12}$ ADP receptor gene (*P2RY12*) in patients with type 1 VWD recruited through the MCMDM-1VWD study and showed that they could contribute to the bleeding phenotype of these patients (Blood 2009;113:4110–4113, Blood. 2011;118:5641–5651).

Aims: To investigate whether variations in platelet G-protein coupled receptor (GPCR) genes other than *P2RY12* contribute to the bleeding tendency in type-1 VWD patients.

Methods: The exonic and flanking intronic sequences of the platelet GPCR genes *P2RY1, F2R, F2RL3, TBXA2R* and *PTGIR* were amplified from the genomic DNA of 146 index cases diagnosed with type 1 VWD and recruited through the MCMDM-1VWD study, and then sequenced on an automated ABI 3730 DNA capillary sequencer.

Results: Seven candidate heterozygous GPCR gene single nucleotide variations (SNVs) were identified in eight index cases. Two *F2R* SNVs were detected in two index cases, a missense mutation in the 7th transmembrane domain of PAR-1 (c.1063 C>T, p.L355F) and a single nucleotide transition in the 5' UTR (c.-67 G>C). One index case was heterozygous for a missense *F2RL3* SNV (c.65 C>A) predicting a p.T22N substitution in the PAR-4 propeptide which was co-inherited with a synonymous SNV (c.6680C>T, p.S218=) in *TBXA2R* which encodes the Thromboxane A2 receptor. Two synonymous *F2RL3* mutations were identified in two further index cases (c.402 C>G, p.A134=; c.1028 G>C p.V343=). None of these SNVs were present among at least 80 control subjects recruited through the same centres as the cases. A missense mutation in the gene encoding the prostacyclin receptor *PTGIR* (c.44 T>C, p.V15A), was identified in three index cases from two centres. However this SNV also occurred in two control subjects (two alleles of 326 examined). None of the candidate mutations that were identified had previously been reported on dbSNP.

Conclusions: We have identified seven novel GPCR mutations in patients with a historical diagnosis of type 1 VWD, comprising three non-synonymous and three synonymous SNVs and 1 promoter change. Therefore, of the 146 index cases examined, 10 are heterozygous for candidate mutations in platelet GPCR genes (6.8%). These results further support the potential contribution of other loci to the bleeding phenotype of patients with type 1 VWD, highlighting the heterogeneity of the disease.

OC 40 – Angiogenesis and Arteriogenesis – II

OC 40.1

The ability of cleaved high molecular weight kininogen (HKa) to induce endothelial cell apoptosis and inhibit angiogenesis is not dependent on the urokinase-type plasminogen activator receptor (uPAR)

McCrae KR[1] and Betapudi V[2]

[1]*Cleveland Clinic;* [2]*Case Western Reserve University School of Medicine, Cleveland, OH, USA*

Background: Endogenous anti-angiogenic polypeptides derived from proteolysis of parent proteins play an important role in regulating angiogenesis in normal and pathological conditions. High molecular weight kininogen (HK), a plasma protein and an important member of intrinsic coagulation pathway, undergoes proteolysis by kallikrein and other proteases to release the mitogenic nonapeptide bradykinin, leaving behind cleaved high molecular weight kininogen (HKa), which expresses potent antiangiogenic activity. Previous studies from our laboratory and others have demonstrated that HKa induces DNA fragmentation and selective apoptosis of proliferating endothelial cells, and inhibits angiogenesis *in vivo*; however, the mechanisms by which HKa inhibits angiogenesis remain controversial as does the role of the urokinase receptor (uPAR), which has been reported in several studies to mediate the antiangiogenic effects of HKa.
Aims: The goal of this study was to directly determine the role of the urokinase receptor in the anti-endothelial and anti-angiogenic activity of HKa.
Methods: We directly examined the role of uPAR in HKa-induced endothelial cell apoptosis by examining the effects of HKa on endothelial cells treated with control or uPAR siRNA. The role of uPAR in inhibition of angiogenesis by HKa *in vivo* was determined by comparing the effects of HKa on angiogenesis in Matrigel plugs in wild type and uPAR-deficient mice. Matrigel plugs that did or did not contain HKa were prepared in uPAR deficient mice and wild-type littermates, and angiogenesis in the Matrigel measured after 9 days.
Results: Cells treated with uPAR siRNA retained full viability and proliferative potential, as well as complete susceptibility to HKa-induced apoptosis as measured by morphology (cell contraction), nuclear fragmentation, chromatin condensation and chromosomal DNA fragmentation. A similar pattern of activation of caspases 3 and 7 was also observed in uPAR and control siRNA treated endothelial cells. *In vivo*, angiogenesis was inhibited equally well in HKa containing plugs that were placed in wild-type or uPAR deficient mice.
Summary/Conclusion: Though HKa binds to uPAR and may influence some uPAR-dependent activities, uPAR is not essential for the anti-endothelial cell effects of HKa *in vitro* or *in vivo*. The antiangiogenic mechanism(s) of HKa remain uncertain.

OC 40.2

Thrombin receptor PAR-1 activation on endothelial progenitor cells enhances chemotaxis associated gene expression and leukocytes recruitment by a COX-2 dependant mechanism

D'Audigier C[1], Cochain C[2], Bièche I[3], Mauge L[1], Marsac B[1], Vidaud M[3], Silvestre JS[2], Gaussem P[1] and Smadja D[1]

[1]*Inserm UMR-S 765;* [2]*Inserm UMR-S 970, Paris Cardiovascular Research Center – PARCC;* [3]*Inserm UMR-S 745, Paris, France*

Background: Endothelial progenitor cells (EPC), and especially endothelial colony forming cells (ECFC), play an important role in neovasculogenesis and could promote therapeutic endothelial repair in patients with cardiovascular disease. However, little is known about their proinflammatory potential. We previously found that *in vitro* PAR-1 activation enhances ECFC angiogenic properties, suggesting the interest of ECFC preconditioning with the hexapeptide SFLLRN for future therapeutic use. We also showed that PAR-1 activation triggers IL-8 synthesis and release by ECFC, acting thus with a paracrine effect to enhance circulating angiogenic cells (CAC, the second EPC population) recruitment *in situ* and cell cooperation during neovascularization. Within an inflammatory context, COX-2 pathway has been also shown to regulate IL-8 in cancer cells.
Aims: To explore inflammation effects on ECFC through PAR-1 activation, and whether these effects modify ECFC angiogenic properties and chemotaxis/recruitment capacity.
Methods and Results: We first screened in ECFC, by real-time qPCR (Taqman® and SyBR Green® chemistry) on the ABI Prism 7900 HT (Applied Biosystems, Courtaboeuf, France), expression of genes known to be associated to inflammation and chemotaxis. Among them, 32 are expressed at a basal level, including CXCL, CCL, CSF, CXCR, CCR, CSF-R, Cell Adhesion Molecule and Interleukin families. Then ECFC PAR-1 was activated with the SFLLRN peptide and we found a significant increase in nine genes associated to chemotaxis expression, including CCL2 and CCL3. PAR-1 was next silenced using a specific small interfering RNA (siRNA, sc-36663, Santa Cruz Biotechnology, Santa Cruz, CA, USA) and expression of those nine genes was abrogated. Furthermore, COX-2 expression was found to be dramatically up-regulated consequently to PAR-1 activation. COX-2 silencing with the specific COX-2-siRNA (sc-29279, Santa Cruz Biotechnology, Santa Cruz, CA, USA) also triggered the nine previous genes down-regulation. CCL2 and CCL3 were afterward tested on ECFC through classical angiogenic *in vitro* assays, and were found to stimulate ECFC migration and tubulogenesis. Conditioned media (c.m.) from control-siRNA- (Allstars Neg. control siRNA, Qiagen, Cambridge, MA, USA) and COX-2-siRNA-transfected ECFC, stimulated or not with SFLLRN, were produced to explore ECFC paracrine recruitment toward leukocytes with the hindlimb ischeamia model. Analysis with either flow cytometry for muscles lysates or Laser Doppler Perfusion Imaging, showed that the capacity to recruit leucocytes of the c.m. from ECFCs stimulated with SFLLRN, was abrogated when COX-2 was silenced.
Conclusions: ECFC PAR-1 activation induces CCL2 and CCL3 mRNA expression. Those chemotactic ligands enhance ECFC angiogenic properties and could increase leukocytes recruitment and cell cooperation through a COX-2 dependant mechanism.

OC 40.3

Peritoneal fluid reduces angiogenesis-related microRNA expression in cell cultures of endometrial and endometriotic tissues from women with endometriosis

Braza-Boils A[1], Gilabert-Estellés J[2], Marí-Alexandre J[1], Gilabert J[3], España F[4] and Estellés A[4]

[1]*IIS La Fe;* [2]*Hospital General Universitario;* [3]*Hospital Arnau de Vilanova;* [4]*Hospital Universitario y Politécnico La Fe, Valencia, Spain*

Background: Endometriosis, defined as the presence of endometrium outside the uterus, is one of the most frequent gynecological diseases. It has been suggested that modifications of both endometrial and peritoneal factors could be implicated in this disease. Endometriosis is a multifactorial disease in which angiogenesis and proteolysis are dysregulated. microRNAs (miRNAs) are small non-coding RNAs that regulate the protein expression and may be the main regulators of angiogenesis. Our hypothesis is that peritoneal fluid from women with endometriosis could modify the expression of miRNAs that regulate angiogenesis and proteolysis in the endometriosis development.
Aim: The aim of this study was to evaluate the influence of peritoneal fluid from patients on the miRNA expression profile and to correlate

this profile with several angiogenic and proteolytic factors in endometrial and endometriotic cell cultures from women with endometriosis compared with women without endometriosis.
Methods: Endometrial and endometriotic cell cultures were treated with peritoneal fluid pools from patients and controls. miRNAs expression arrays were performed in Affymetrix platform. Results were analyzed with Partek Genomic Suite software. To validate results from arrays, we studied the expression of six miRNAs by RT-PCR as well as protein and mRNA levels of vascular endothelial growth factor-A (VEGF-A), thrombospondin-1 (TSP-1), urokinase plasminogen activator (uPA) and plasminogen activator inhibitor-1 (PAI-1) by ELISA and qRT-PCR respectively. Informed consent was obtained from all subjects of the study and it was approved by the medical ethics committee of our Institution.
Results: GeneChip miRNA 2.0 Array contains 1105 human probes for mature miRNAs. Profiling of these miRNAs was completed for control endometrial and patient endometrial and endometriotic cell cultures treated with peritoneal fluids from patients and controls. Pathological peritoneal fluids induced a significant dysregulation of miRNAs profile: 85 mature miRNAs were differentially expressed ($P < 0.05$) (75 down-regulated and 10 up-regulated) in patient endometrial cell cultures in comparison to cell cultures from the same patient samples without peritoneal fluid exposition. After the 'in silico' study of the target genes for those miRNAs differentially expressed we selected three miRNAs related to angiogenesis (miR-17-5p, -20a, -221). Additionally, we selected three miRNAs that did not show significant differential expression but are related to angiogenesis and endometriosis (miR-16, -125a, -222). Patient peritoneal fluid pools induced a significant reduction of all studied miRNAs levels in endometrial and endometriotic cell cultures. Moreover, both peritoneal fluids induced a significant increase in VEGF-A, uPA and PAI-1 protein levels in all cell cultures without significant increase in mRNA levels. Endometrial cell cultures from patients treated with patient peritoneal fluid showed lower expression of miRNAs ($P < 0.05$) and higher expression of VEGF-A protein ($P < 0.01$) than cultures from controls ($P < 0.01$). Furthermore, a significant inverse correlation was observed between changes in VEGF-A protein and miR-17-5p ($r = -0.739$, $P = 0.001$), miR -20a ($r = -0.676$, $P = 0.001$), miR-125 ($r = -0.567$, $P = 0.01$) and miR-222 ($r = -0.494$, $P = 0.037$) levels in endometriotic cell cultures after treatment with peritoneal fluid.
Conclusion: In conclusion, this '*in vitro*' study indicates that peritoneal fluid from women with endometriosis modulates the expression of miRNAs that could contribute to the angiogenic and proteolytic disequilibrium observed in this disease.

OC 40.4
MicroRNAs expression profile in endometriosis: its relation with angiogenesis and fibrinolytic factors

Braza-Boils A[1], Marí-Alexandre J[1], Gilabert J[2], Sánchez-Izquierdo D[3], España F[4], Estellés A[4] and Gilabert-Estellés J[5]
[1]IIS La Fe; [2]Hospital Arnau de Vilanova; [3]IIS Hospital La Fe; [4]Hospital Universitario y Politécnico La Fe; [5]Hospital General Universitario, Valencia, Spain

Background: Endometriosis, one of the most frequent gynecological diseases, is defined as the presence of endometrial tissue in extrauterine locations. It is a multifactorial disease in which the angiogenesis may be involved. Similarly to tumor metastases, endometriotic implants require neovascularization to proliferate, invade the extracellular matrix and establish an endometriotic lesion. microRNAs (miRNAs) are non-coding RNAs that regulate the translation of their mRNAs target. Recently, miRNAs have been described as the main regulators of angiogenesis and different expression of several miRNAs has been found in endometriosis.
Aim: The aim of this study was to analyze the miRNA expression profile in endometriosis and to correlate this profile with several angiogenesis (VEGF-A, TSP-1) and fibrinolytic factors (uPA, PAI-1) in endometriotic lesions in comparison with control and patient endometrium.
Material and Methods: miRNAs expression arrays were performed in Affymetrix platform and results were analyzed with Partek Genomic Suite software. To validate results from arrays, nine miRNAs were validated employing miRCURY LNA Universal RT microRNA PCR from EXIQON. VEGF-A, TSP-1, uPA and PAI-1 protein levels were quantified by ELISA. Fifty-three women with endometriosis and thirty-eight women without the disease (controls) were studied. Informed consent was obtained from all subjects of the study and it was approved by the medical ethics committee of our Institution.
Results: GeneChip miRNA 2.0 Array contains 1105 human probes for mature miRNAs. Profiling of these non-coding RNAs was completed in control and patient endometrium and endometriotic lesions (ovarian endometrioma, peritoneal implants and rectovaginal nodules). The PCA of the results obtained from Affymetrix GeneChip miRNA 2.0 arrays confirmed that endometriotic tissues clustered separately from control endometrial tissues. When the endometriotic tissue samples were compared to the endometrial control samples, 145 mature miRNAs were found to be differentially expressed ($P < 0.05$) (69 up-regulated and 76 down-regulated). The 'in silico' study of the target genes for those miRNAs differentially expressed enabled us to select nine miRNAs related to angiogenesis and proteolysis (miR-16, -29c, -202, -411, -411*, -424, -449b, -636, 935) with a significant different expression ($P < 0.05$) in endometriotic tissues in comparison with the control endometrial tissue. Patient endometrium showed higher VEGF-A levels ($P < 0.01$) and lower expression of miR-202 and miR-449b ($P < 0.05$) in comparison to control endometrium. However, ovarian endometrioma showed significantly higher expression of the angiogenic inhibitor TSP-1 ($P < 0.01$) and higher expression of miR-29c and miR-202 than control and patient endometrium ($P < 0.05$). A significant inverse correlation between miR-449b and VEGF-A protein levels ($r = -335$, $P < 0.05$) was obtained in patient endometrium and a direct correlation between miR-202 and TSP-1 protein levels was observed in ovarian endometrioma ($r = -380$, $P < 0.05$). Peritoneal implants showed a significant increase in VEGF-A in comparison to ovarian endometrioma ($P < 0.01$).
Conclusions: The higher angiogenic activity observed in patient endometrium might contribute to the capability of implantation of endometrial cells at ectopic sites. The different expression of miRNAs could modulate the expression of angiogenic factors which may play an important role in the pathogenesis of endometriosis. Functional studies are needed to confirm the VEGF-A targeting by the miRNAs found in the present study.

OC 41 – Animal Models of Antiphospholipid Syndrome

OC 41.1
Adenosine generation protects in a murine model of antiphospholipid antibody-induced miscarriages

Nandurkar H[1], Samudra A[1], Sharma A[2], Zhang XM[3], Selan C[1], Dwyer K[1], Robson S[4], D'Apice A[1] and Cowan P[1]
[1]University of Melbourne and St. Vincent's Hospital, Fitzroy, Australia; [2]Johns Hopkins Medical Institute, Baltimore, MD, USA; [3]Third Hospital, Wuhan, China; [4]Beth Israel Deaconess Medical Center, Boston, MA, USA

Background: Autoantibodies (aPL-ab) generated in Antiphospholipid Syndrome (APS) cause arterial and venous thrombosis, and miscarriages. Antiphospholipid antibodies stimulate cytokine release leading to tissue factor (TF) expression, inflammation and complement activation, all of which have been implicated in the pathogenesis of APS-related foetal loss. ATP and ADP are extracellular purines and important signaling molecules that activate inflammation and thrombosis,

respectively. ATP and ADP are hydrolysed by the cell surface enzyme CD39 (NTPDase) to AMP and AMP in turn is subsequently hydrolysed to adenosine by the action of another enzyme, CD73. In contrast to the effect of ATP and ADP, adenosine signals via A2 receptors to inhibit inflammation and suppress TF expression on endothelial cells and monocytes. We have previously shown that CD39 over expression is antithrombotic and protective against complement-mediated endothelial activation (Dwyer et al., J Clin Invest 2004; 113: 1440–46) and suppresses TF expression on pancreatic islet cells (Dwyer et al, Transplantation 2006; 82 (3):428–32). Moreover, we have also shown that adenosine generated by the action of CD39 is vascular-protective in a model of ischaemia reperfusion injury (Crikis et al., Am J Trans-plant 2010; 10: 2586–95).

Aims: To analyse the role of purineregic nucleotides in APS miscarriages.

Methods: We have established an aPL-ab-induced model of miscarriages by administration of aPL-ab (purified from patients with APS) to pregnant mice (10 mg on day 8 and 12 of pregnancy followed by analysis on day 15).

Results: We applied this model to mice with modifications of several of the purinergic pathway enzymes:

1 CD39-Transgenic (CD39-TG on a BALB/c strain) mice with increased hydrolysis of ATP and ADP to AMP and adenosine: demonstrate reduction in aPL-ab-induced miscarriages. Resorption frequency in wild-type (WT-BALB/c) treated with non-immune IgG, 21% ±6 (SEM); WT treated with aPL-ab, 40% ±5; CD39-TG treated with aPL-ab, 14% ± 3; ($P = 0.0008, n = 7$/group).
2 CD39-null (CD39−/−, on a C57Bl/6 strain, which is more resistant to miscarriages than BALB/c) mice with decreased hydrolysis of ATP and ADP: demonstrate higher frequency of miscarriages. Resorption frequency with aPL-ab: 3 ± 2% in WT-C57BL/6 and 15 ± 4% in CD39−/−, $P = 0.036, n = 7$/group).
3 CD73−/− (C57BL/6 strain) mice cannot hydrolyse AMP further to adenosine: demonstrate higher frequency of miscarriages. Resorption frequency with aPL-ab: 2 ± 2% in WT-C57BL/6 and 11 ± 2% in CD73−/−, $P < 0.05, n = 7$/group).
4 Adenosine receptor $A_2AR-/-$ show an increased trend to miscarriages (P = ns, as yet).

We have initiated studies to discriminate between the effects of CD39 on the uterus versus placenta.

We further demonstrated that TF mRNA expression is more (> 2-fold, $P < 0.05$) in cohorts with increased miscarriages. Also, complement activation (detected by immunohistochemistry) and TNF expression (TNF mRNA as a marker of inflammatory cytokine release) is reduced in the placentae of CD39-TG mice that have fewer miscarriages as compared with WT after aPL-ab administration.

Conclusions: Hydrolysis of ATP and ADP and adenosine generation is protective in APS miscarriages by reducing inflammation, TF expression and complement activation.

OC 41.2

In vivo thrombus formation fostered by a human cofactor independent monoclonal anticardiolipin antibody

Manukyan D[1], Jäckel S[1], Prinz N[2], Walter U[1], Reinhardt C[1] and Lackner KJ[3]

[1]Center for Thrombosis and Hemostasis (CTH), Johannes-Gutenberg-University of Mainz; [2]Institute of Clinical Chemistry and Laboratory Medicine, JGU of Mainz; [3]Institute of Clinical Chemistry and Laboratory Medicine, University Hospital, Mainz, Germany

Background: Antiphospholipid syndrome (APS) is an autoimmune disease characterized by arterial and/or venous thrombosis and thromboembolic events associated with the presence of antiphospholipid antibodies (aPL). APLs are a heterogeneous family of autoantibodies that bind negatively charged phospholipids such as cardiolipin, phosphatidylserine, and lysobisphosphatidic acid and phospholipid binding proteins such as β2-glycoprotein I (β2GPI). Currently, it is postulated that only aPL binding to β2GPI are able to induce thrombosis *in vivo*. We have previously cloned monoclonal aPL IgG from patients with the APS. One of them, HL5B, binds to cardiolipin and phosphatidylserine in a cofactor independent manner. It does not bind to β2GPI. *In vitro* HL5B induces prothrombotic and proinflammatory pathways in monocytes and endothelial cells.

Aim: We intended to investigate the potential of HL5B to induce thrombus formation *in vivo*.

Methods: Thrombus formation in living mice has been estimated using high speed real-time intravital fluorescence microscopy. In anesthetized mice a median laparotomy was performed and the inferior vena cava (IVC) was exposed by atraumatic surgery. A space holder was placed on the outside of the vessel and a permanent narrowing ligature was performed exactly below the left renal vein. Subsequently, the wire was removed to avoid complete vessel occlusion. Thus, flow reduction was induced in IVC. Platelets and leukocytes were visualised by labelling them respectively with rhodamine B and acridine orange. Fibrin was visualised with labelled anti-fibrin antibody. Rotem thrombelastography has been performed to evaluate the fibrin formation in whole blood at physiological temperatures (37 °C). To estimate tissue factor (TF) dependent fibrin formation corn trypsin inhibitor (CTI) was added to inhibit FXIIa and thus to block the contact pathway of blood coagulation.

Results: In IVC of anesthetized mice thrombus formation was dramatically enhanced 3 h after intravenous injection of HL5B but not by control IgG. Thrombus formation was abolished by preincubation of HL5B with a synthetic peptide which blocks the antigen binding site of HL5B and prevents binding of HL5B to cardiolipin and other phospholipids. Moreover, an inhibitory anti-TF antibody prevented thrombus formation induced by HL5B. In addition, HL5B increased fibrin formation in mouse carotid artery model of thrombosis. Clotting time of whole blood drawn from mice injected with HL5B was shortened in comparison to mice injected with IgG. A similar observation was made with human blood preincubated with HL5B.

Conclusions: Our results show that the human monoclonal aPL HL5B promotes arterial and venous thrombus and fibrin formation via TF pathway in living mice. To our knowledge, this is the first description of *in vivo* thrombus induction by a cofactor independent anticardiolipin aPL which has significant implications for our understanding of the APS.

OC 41.3

IgA anti-β2glycoprotein I antibodies are pathogenic in a mouse model of antiphospholipid syndrome

Willis RA, Ruiz-Limon P, Romay-Penabad Z, Papalardo E, Carrera-Marin AL and Pierangeli S

University of Texas Medical Branch, Galveston, TX, USA

Background: Recently exclusive IgA anti-β_2GlycoproteinI ($a\beta_2GPI$) seropositivity – in the absence of any other antiphospholipid (aPL) antibodies- has been reported, particularly in SLE patients. A significant proportion of those patients (70–80%) were found to have Antiphospholipid Syndrome (APS)-clinical manifestations (e.g. thrombosis and/or pregnancy losses). APL antibodies of the IgG and IgM isotypes have been shown to be pathogenic *in vivo*, but there is limited data demonstrating the thrombogenicity of IgA $a\beta_2GPI$ antibodies *in vivo*.

Aims: Here we examined the effects of affinity purified IgA $a\beta_2GPI$ antibodies isolated from patients with exclusive IgA $a\beta_2GPI$ positivity on thrombus formation and tissue factor (TF) upregulation in mice.

Methods: IgA was isolated from pooled sera of four APS patients (IgA-APS) with isolated IgA $a\beta_2GPI$ titers (≥ 80 SAU) – two had strokes, one had a confirmed deep vein thrombosis and one had two pregnancy losses – and from normal human serum (IgA-NHS) using

an Immobilized Jacalin column (Pierce Biotechnology). IgA aβ_2GPI in the IgA-APS and in the IgA-NHS preparations was determined by ELISA (INOVA Diagnostics), the protein concentration by the Bradford method and the lupus anticoagulant by using a modified silica clotting time (SCT) assay. CD1 mice were inoculated with 500 μg of either IgA-APS or IgA-NHS on two occasions at a 48 h interval. Seventy-two hours after the first injection, the size of induced thrombi in the femoral vein was determined as described previously (Circulation 1996; 94: 1746–1751). Tissue factor activity was determined in homogenates of pooled carotid arteries and in peritoneal macrophages using a chromogenic assay. Student's t test was used to determine differences between IgA-APS and IgA-NHS treated mice.

Results: IgA-APS and IgA-NHS were rendered endotoxin free by the Limulus amebocyte lysate assay, and did not have detectable levels of IgG or IgM. The IgA-APS preparation but not the IgA-NHS was positive for IgA aβ_2GPI (103.7 SAU) and LA [SCT ratio IgA-APS/IgA-NHS = 2; normal < 1.2]. Thrombus size (1.7-fold increase, $P = 0.02$), TF activity in carotids (2.9-fold increase, $P = 0.004$) and TF activity in peritoneal macrophages (3.5-fold increase, $P = 0.0003$) were significantly elevated in IgA-APS treated mice when compared to mice treated with IgA-NHS.

Conclusion: These data show for the first time that IgA aβ_2GPI antibodies are thrombogenic and upregulate TF in mice. Detection of IgA aβ_2GPI antibodies – currently not included in the classification criteria for APS – may further identify a group of patients with APS-associated clinical manifestations that otherwise would have been missed with tests used routinely in the clinical laboratory to confirm APS.

OC 41.4

Affinity purified antibodies directed against domain I of β2GPI are pathogenic in a mouse model of thrombosis

Willis RA[1], Pericleous C[2], Ruiz-Limon P[1], Romay-Penabad Z[1], Garza-Garcia A[3], Murfitt L[3], Giles I[2], Ioannou Y[2], Rahman AV[2] and Pierangeli S[1]

[1]University of Texas Medical Branch, Galveston, TX, USA; [2]University College London; [3]MRC National Institute of Medical Research, London, UK

Background: Circulating IgG antiphospholipid antibodies (aPL) against β2glycoprotein I (a2GPI) are a serological hallmark for diagnosis of the antiphospholipid syndrome (APS). We and other groups have shown that aPL targeting domain I (DI) of β2GPI (aDI) are APS-specific, predominantly correlating with (venous) thrombosis. We have also demonstrated that recombinant DI inhibits aPL-induced thrombosis in a mouse microcirculation model. To date however, no study has confirmed a direct pathogenic link between aDI and features of the APS.

Aims: We have now employed the same mouse model to determine the thrombogenic potential of affinity purified polyclonal aDI IgG derived from APS sera.

Methods: Serum from one female APS patient was incubated with His-tagged DI coupled to nickel beads to adsorb aDI antibodies. The bead-serum mix was then centrifuged, serum re-collected and antibodies bound to DI-coupled beads were eluted. IgG from re-collected serum (aDI-poor) and eluted fractions (aDI-rich) was then obtained by protein G purification. Serum and IgG fractions (100 μg/mL) were tested for aCL (GPLU), aβ2GPI (GBU, in-house calibrator) and aDI (GDIU, in-house calibrator) activity. For *in vivo* experiments, CD1 mice were inoculated (on two occasions at a 48 h interval) with 100 μg/mL of either aDI-poor IgG, aDI-rich IgG, or IgG from healthy volunteers (NHS-IgG) as a control (five animals per group). Seventy-two hour after the first injection, the size (μm^2) of induced thrombi in the femoral vein was determined (Circulation 1996;94:1746–1751). Tissue factor (TF) activity (pM/mg/mL protein) was determined in homogenates of pooled carotid arteries and peritoneal macrophages using a chromogenic assay. Mouse serum was obtained on the day of surgery and tested for the presence of circulating whole human IgG.

Results: Purified aDI-rich IgG displayed high aCL (90GPLU), aβ2GPI (95GBU) and aDI (50GDIU) activity whilst aDI-poor IgG displayed high aCL (90GPLU) but reduced aβ2GPI (47GBU) and aDI (17GDIU) activity. NHS-IgG was negative in all assays. aDI-rich IgG induced significantly larger thrombi compared to aDI-poor and NHS-IgG ($P < 0.001$). In addition, aDI-rich IgG induced the greatest increase in TF activity in carotids (1.4-fold) and peritoneal macrophages (3.3-fold) compared to NHS-IgG. In contrast, aDI-poor IgG induced smaller thrombi and less macrophage TF activity compared to aDI-rich IgG and did not increase carotid TF activity above that of NHS-IgG

Conclusion: This is the first study to directly demonstrate the thrombogenic potential of affinity-purified aDI IgG *in vivo*. Despite aDI-poor IgG retaining aCL and, to a lesser extent, aβ2GPI activity, significantly larger thrombi and elevated TF activity were induced with aDI-rich IgG. Our findings support the concept that although circulating aPL recognizing different domains of β2GPI can be pathogenic, the major population that drive thrombosis are directed against DI.

OC 42 – Bleeding and Anticoagulants

OC 42.1

Comparison of four scores for the prediction of major bleeding in patients with acute venous thromboembolism. Findings from the RIETE registry

Piovella C[1], Dalla valle F[1], Trujillo-Santos J[2], Pesavento R[1], Monreal M[3] and Prandoni P[1]

[1]Department of Cardiothoracic and Vascular Sciences, University of Padua, Italy, Padova, Italy; [2]Ramón y Cajal Hospital, Instituto Ramón y Cajal de Investigación Sanitaria, Madrid; [3]Medicine Department, German Trias I Pujol Hospital, Badalona, Barcelona, Spain

Background: Stratification of the individual bleeding risk prior to initiation of anticoagulation in patients with acute venous thromboembolism (VTE) has the potential to assist clinicians for decisions about the proper intensity and duration of antithrombotic therapy. It is unclear which of the four properly validated and internationally accepted scores that have been recommended for the achievement of this important task has the best predictive value.

Aims: We sought to compare the predictive value of four scores (by Landefeld, Beyth, Kuijer and Ruiz-Gimenez, respectively) for the development of major bleeding complications (defined as widely accepted) occurring in the first 3 months in patients with acute VTE treated with conventional anticoagulation.

Methods: Based on patients demographics and baseline clinical characteristics available for the population of RIETE Registry (an ongoing international, multicenter, prospective registry of consecutive patients with VTE who were all followed-up for at least 3 months), we identified the subgroup of patients presenting all the prognostic variables required for the determination of the four predictive scores, and then calculated the ability of each score for predicting the bleeding risk.

Results: Of 40 265 patients enrolled in this registry, we identified 8717 patients (21.6% of RIETE population) meeting the eligibility criteria. Overall, 82 patients (0.9%) experienced at least one episode of major bleeding, which was fatal in 20 (24.4%), within 90 days of the index VTE event. The proportion of patients classified as having a low risk varied between 1.2 and 3.7%, that of patients having an intermediate risk between 76 and 93%, and that of patients classified as having a high risk between 6.1% for the Kuijer score and 18% for the Ruiz-Gimenez score. The area under the receiver operating characteristic

ranged between 0.55 and 0.60, the positive predictive value between 1.5 and 3.2, and the likelihood ratio between 0.72 and 1.59.
Conclusions: All the existing validated scores show a very low ability for prediction of the bleeding risk in patients with acute VTE undergoing conventional anticoagulation

OC 42.2

Recurrence of intracranial hemorrhage after resumption of anticoagulation in patients who had a first episode occurred during Vitamin K Antagonists anticoagulation. Results of a collaborative study

Daniela P[1], Antonucci E[2], Testa S[3], Erba N[4], Guazzaloca G[5], Tiraferri E[6], Ciardiello A[7], Lerede T[8], Nante G[9] and Palareti G[10]
[1]AOU Careggi; [2]University of Florence, Florence; [3]AO Istituti Ospitalieri di Cremona, Cremona; [4]Presidio Ospedaliero di Merate, Merate; [5]AOU Sant'Orsola-Malpighi Bologna, Bologna; [6]Civic Hospital Rimini, Rimini; [7]Ospedale Maria Vittoria, Torino; [8]Ospedali Riuniti di Bergamo, Bergamo; [9]University of Padova, Padova; [10]AOU Sant'Orsola-Malpighi, Bologna, Bologna, Italy

Background: Vitamin K antagonists (VKA) treatment is associated with an increased risk of intracranial hemorrhage (ICH). However, the risk of recurrent ICH after a first episode is still uncertain. Some patients carry a so high thromboembolic risk, requiring to start or restart VKA treatment after ICH.
Aim: Aim of our study was to evaluate the risk of recurrent ICH in patients on VKA after a first episode.
Methods: We collected data of patients eligible for the study from the database of 27 Centres affiliated to the Italian Federation of Anticoagulation Clinics.
Results: We enrolled 267 patients (males 163, 61%, median age 73.9 years). Eighty-eight patients (33%) were on treatment for mechanical heart valves, 121 (45.3%) for atrial fibrillation and 45 (16.8%) for venous thromboembolism. The index event was spontaneous in 99 patients (38.5%); the site was Intraparenchimal in 86 patients (32.8%), subdural hematoma in 131 (4a 9.0%) and subaracnoid in 45 (17.2%). The total period of follow-up after resumption of treatment was 778 pt-years. An ICH recurred in 20 patients (7.5%; rate 2.56 × 100 pt-years) at median time of 16.5 months and was fatal in five patients (25%; rate 0.4 × 100 pt-years). Male sex, hypertension, prosthetic valves, previous ischemic stroke, renal failure, cancer and spontaneous events were associated to the risk of recurrence, even if none of them reached the statistical significance.
Conclusions: In our study patients with history of ICH and who need anticoagulation carry a significant risk of recurrent ICH. These patients require a careful evaluation of thromboembolic risk to estimate the net clinical benefit of treatment.

OC 42.3

The predictive ability of bleeding risk stratification models in very old patients on VKA treatment for venous thromboembolism. Results of the prospective collaborative EPICA study

Daniela P[1], Antonucci E[2], Testa S[3], Cosmi B[4], Palareti G[4] and Ageno W[5]
[1]AOU Careggi; [2]University of Florence, Florence; [3]AO Istituti Ospitalieri di Cremona, Cremona; [4]AOU Sant'Orsola-Malpighi, Bologna, Bologna; [5]University of Insubria, Varese, Italy

Background: The optimal duration of anticoagulant treatment after venous thromboembolism (VTE) should be evaluated in relation to bleeding risk. This assessment is particularly difficult with elderly patients, because of their increased risk of both recurrences and hemorrhages. Bleeding risk stratification models have been proposed, but their predictive ability in very elderly patients is unknown.
Aim: We aimed to assess six bleeding stratification models in this setting, by using information available in our dataset.
Methods: Patients aged ≥ 80 years receiving vitamin K antagonists (VKA) for the secondary prevention of VTE were eligible for this prospective cohort study. All patients were followed at Italian Anticoagulation Clinics for the monitoring of VKA treatment. Risk factors for bleeding were collected and major bleeding events and mortality were documented during follow-up. The association of bleeding events with the available risk factors was tested by means of Cox regression analysis; the *c* statistic was used to quantify the predictive validity of the classification schemes.
Results: One thousand and seventy-eight patients (37.2% males, mean age 84 years) were enrolled in the study, for a total observation period of 1981 patient-years. The rate of major bleeding was 2.4 × 100 patient-years (47 events, 1 was fatal). Mortality rate was 5.2 per 100 patient-years. None of the considered risk factors resulted to be significantly associated with bleeding events. The predictive validity of the risk stratification models was low and the most accurate model was not specifically developed for VTE patients ($HEMORR_2HAGES$, c-statistic 0.60, 95% CI 0.49–0.70).
Conclusions: Bleeding risk stratification models appear to have little accuracy in very elderly VTE patients.

OC 42.4

Statin use and bleeding complications during treatment with vitamin K antagonists: a cohort study in 8188 patients with atrial fibrillation

Van Rein N, Willem LM, Cannegieter SC, Rosendaal FR, Reitsma PH and Van Der Meer JM
Leiden University Medical Center, Leiden, the Netherlands

Background: Statins decrease atherosclerosis which could lead to improved vessel wall health. Theoretically, this could result in fewer bleeding complications in patients who are treated with vitamin K antagonists (VKAs). Additionally, atherosclerosis is known to increase with age, possibly resulting in different effects of statins along strata of age.
Aims: To determine the effect of statins on bleeding complications during VKA treatment, overall and for different age categories.
Methods: All patients with atrial fibrillation who started treatment with VKAs at the Anticoagulation Clinic Leiden between 2003 and 2009 were selected. Information on medication use and bleeding complications were obtained from patient records. Hazard ratios (HRs) and 95% confidence intervals (95%CI) were calculated for minor and major bleeding by means of a Cox regression model with time-varying determinants. HRs were also computed for three strata of age: 50–65 years ('young'), 65–75 years ('middle aged'), > 75 years ('elderly') and adjusted for sex, INR-target range, diabetes, hypertension, and use of anti-platelet drugs. Analyses were stratified by incident (patients who started using statins during follow-up) and prevalent statin use (patients who used statins at baseline) compared with non-use. This avoids the overoptimistic effects obtained from analyses in prevalent users, as they have already 'survived' a period of statin treatment before starting VKA treatment (Danaei *et al*., Am J Epidemiol, 2012). Furthermore, they are generally healthier than subjects who started treatment but discontinued after some time. Neither informed consent nor approval by a medical ethics committee is, according to Dutch law, required for studies in which data are collected from the records by the treating physician.
Results: Eight thousand one hundred and eighty-eight Patients were treated with VKAs for a mean period of 2.1 years. Four hundred and fifty-two Major and 1787 minor bleeding complications occurred during the follow up of 18 105 patient-years. Statin use was associated with slightly reduced risks of minor bleeding (HR 0.88 95%CI 0.79–

0.98) and major bleeding (HR 0.83 95%CI 0.67–1.02). After stratification on age and restriction to incident statin use, all HRs in the various age-categories increased to estimates indicative of absence of effects or increased risks (above unity), ranging from 0.98 to 3.22. One exception occurred for major bleeding in the elderly where the HR in incident users remained below unity (HR 0.66 95%CI 0.40–1.07). Apart from chance variation as an explanation, this may also be the result of additional selection bias, since, according to the guidelines, statins should only be prescribed to elderly with a reasonable life expectancy.

Conclusions: In overall analyses, statins appear to protect against bleeding complications in patients receiving anticoagulant treatment. After stratification on age and restriction to incident use, in an effort to reduce selection bias, these protective effects largely disappeared. This bias giving overoptimistic views on the complementary effects of statins is similar to what was found in earlier studies on hormone replacement therapy – suggesting protection against coronary heart disease which was not borne out in randomised trials – and may also be present in other observational studies on statins.

OC 43 – Clinical Aspects of Atherosclerosis

OC 43.1

Reduced propagation of blood outgrowth endothelial cells in subjects with advanced subclinical atherosclerosis

Martin Ramirez J[1], Hofman M[2], Kok MG[3], Creemers E[3], Meijers JC[4], Voorberg J[2] and Pinto S-J[3]
[1]*Sanquin;* [2]*Sanquin-AMC Landsteiner Laboratory;* [3]*Amsterdam Medical Centre;* [4]*Academic Medical Center Amsterdam, Amsterdam, the Netherlands*

Background: Atherosclerotic coronary artery disease (CAD) represents one of the principal causes of mortality in developed countries. Clinical manifestations of CAD consist of acute or chronic myocardial damage induced by a decrease in supply of oxygen-rich blood. This sequel of events is due to the formation of atherosclerotic plaques resulting in the tightening of the lumen in the affected coronary vessels. Several cellular components, including endothelial cells from the arterial wall are involved in this process.

Aims: In order to better understand the pathophysiology of CAD, we have established cultures of blood outgrowth endothelial cells (BOECs) from peripheral blood of patients with premature cardiovascular disease (CVD) and their first degree relatives.

Methods: Patients with premature CVD (men < 51 year, women < 56 year) and their apparently healthy first degree relatives were included. From 70 patients and 157 first degree relatives, blood was drawn for cultures of blood outgrowth endothelial cells. Furthermore, all first degree relatives underwent multi-detector computed tomography to establish coronary calcification (CAC) as a marker of subclinical CVD. On average, from 14 to 21 days after isolation and establishment of cultures, BOEC colonies were observed. These cultures were further propagated, establishing their proliferative capacity and subsequently cryopreserved.

Results: As for the relatives: 99 (63%) had a CAC score of 0 and were considered relatives without subclinical CVD. The other 58 (37%) relatives displayed a positive CAC score, and were considered as subjects with subclinical CVD. We were able to isolate BOEC colonies in 52 (74%) of the patients, in 79 (80%) of the relatives without subclinical CVD and in 42 (72%) of the relatives with subclinical CVD. In relation to the ability of the isolated colonies to proliferate, we were capable to expand colonies in 43 (61%) of the patients, in 31 (53%) of the relatives with subclinical CVD and in 69 (70%) of the relatives without subclinical CVD. Differences between patients and relatives without subclinical CVD were not significant ($P = 0.272$). Differences between relatives with and without subclinical CVD were significant ($P = 0.039$; adjusted for age, sex and smoking).

Conclusion: These observations demonstrate that the number of circulating BOEC precursors in relatives with subclinical CVD is diminished when compared to relatives without subclinical CVD and patients. Additionally, the proliferative capacity of the isolated endothelial cells was similar between relatives without subclinical CVD and patients. However, it was significantly lower in relatives with subclinical CVD. The mechanism underlying the reduced frequency of BOEC precursors in the circulation of these subjects is currently under investigation.

This clinical study has been performed under patient's informed consent and approved by a recognised medical ethics committee, complying as well the Declaration of Helsinki .

OC 43.2

Plasma levels of matrix metalloproteinases and circulating endothelial cells in patients with peripheral arterial disease: relationship with disease severity and effect of treatment with prostanoids

Conti V[1], Falcinelli E[1], Fierro T[1], Lenti M[2] and Gresele P[1]
[1]*University of Perugia;* [2]*Hospital of Perugia, Perugia, Italy*

Background: Peripheral Arterial Disease (PAD) is one of the most common manifestations of atherosclerosis and is associated with inflammatory and endothelial changes. The presence of PAD is a powerful and independent predictor of cardiac and cerebral ischemic events. Matrix Metalloproteinases (MMPs), a family of zinc-dependent endopeptidases able to degrade the extracellular matrix, are involved in atherosclerosis development and complications. Iloprost, a stable prostacyclin analogue, promotes local perfusion and relieves symptoms in patients with Critical Limb Ischaemia (CLI), often with an effect lasting for weeks or months after the end of the infusion. Our aim was to investigate circulating MMPs plasma levels and CECs in patients with PAD, their association with disease severity and the effects of treatment with iloprost infusion.

Materials and Methods: Eighty-eight patients suffering from PAD were enrolled in the study. According to Leriche-Fontaine classification, seven patients were asymptomatic (class I); 28 patients had intermittent claudication (class II), 14 patients presented rest pain (class III) and 39 had trophic lesions (class IV). Forty-one age- and sex-matched healthy subjects were enrolled as controls. Patients with CLI (class III and IV) were treated with daily intravenous infusions of Iloprost for 14–28 days. Blood samples were collected immediately before and at the end of the daily iloprost infusion on the first and last day of treatment for the measurement of plasma MMPs by zymography (ng/mL), CECs (cells/microl) by flow cytometry. Plasma vWF (%-Ag), MPO (ng/mL) and elastase (ng/mL) were also measured by ELISA. Circulating endothelial cells (CECs) and von Willebrand Factor (vWF) represent markers of endothelial damage (ED). Mieloperoxidase is a marker of inflammation and leukocyte activation.

Results: Plasma levels of MMP-9, but not of MMP-2, were significantly higher in PAD patients compared with controls (583.9 ± 78.8 vs 164.3 ± 25.6 ng/mL, $P < 0.001$) and more precisely in stage II (475.3 ± 104.0 ng/mL, $P < 0.005$), stage III (835.6 ± 186.8 ng/mL, $P < 0.001$); stage IV (570.3 ± 123.4 ng/mL, $P < 0.001$).

CECs were also significantly higher in PAD patients than in controls (1.83 ± 0.23 vs 0.32 ± 0.05 cells/microl) and with a progressive increase with the advancement of the disease stage (stage I: 0.067 ± 0.11 cells/microl, $P < 0.05$; stage II 2.36 ± 0.55 cells/microl, $P < 0.001$; stage III 3.03 ± 1.89 cells/microl, $P < 0.001$; stage IV 3.08 ± 0.91 cells/microl, $P < 0.001$). vWF and MPO were also significantly increased in PAD patients (170.8 ± 7.59 vs 95.87 ± 4.20 Ag%, $P < 0.001$; 32.20 ± 4.22 vs 15.91 ± 2.98 ng/mL, $P < 0.005$, respectively). Treatment with iloprost decreased significantly plasma levels of MMP-9, both at the first and last day of infusion (day 1 pre =

699.6 ± 98.3 post = 407.9 ± 44.4 ng/mL, $P < 0.001$; day 21–28 pre = 566.2 ± 112 post = 406 ± 75.5 ng/mL, $P < 0.05$), while it decreased MMP-2 only after the last infusion (day 1 pre = 780.9 ± 66.1; day 21–28 post = 643.3 ± 55.0 ng/mL, $P < 0.05$). Moreover, Iloprost decreased CECs (day 1 pre = 2.71 ± 0.65 post = 1.78 ± 0.48, $P < 0.05$; day 21–28 pre = 1.33 ± 0.92 post = 1.08 ± 0.57 cell/microl).
Conclusions: MMP-9, CECs, vWF and MPO are significantly enhanced in PAD. Treatment with Iloprost significantly reduces MMPs and CECs but not vWF and MPO. The prognostic value of MMP-9 and CECs in CLI and of their changes induced by iloprost and the potential for pharmacologic targeting of MMPs in PAD deserve further evaluation.

OC 43.3

Human coronary thrombus formation is associated with degree of plaque disruption and expression of tissue factor and hexokinase II in atherosclerotic plaques

Matsuda S, Okuyama N, Yamashita A, Moriguchi S, Sato Y, Hatakeyama K, Marutsuka K and Asada Y
University of Miyazaki, Miyazaki, Japan

Background: Although coronary atherosclerotic plaque disruption is a trigger of acute myocardial infarction (AMI), it does not always result in complete luminal occlusion and AMI. Therefore, the formation of a large thrombus is critical to the onset of AMI, and determinants of the size of coronary thrombus after plaque disruption remain unknown.
Aims: This study of autopsy cases aimed to determine relationships between vascular factors and thrombus size in human coronary arteries in AMI and non-cardiac death.
Methods: We examined 43 coronary arteries with thrombi from autopsy cases of AMI (plaque rupture, $n = 15$; plaque erosion, $n = 8$) and non-cardiac death (plaque rupture, $n = 5$; plaque erosion, $n = 15$). Culprit lesions of coronary arteries were examined histologically and immunohistochemically using antibodies against CD68, CD163, smooth muscle actin, tissue factor (TF), glucose transporter (Glut)-1 and hexokinase (HK)-II. We used image-analysis software to measure thrombus size, ratio of thrombus area to luminal area, ratio of intima to media (I/M ratio), stenotic ratio, degree of plaque disruption and the numbers of nucleated cells that were immunopositive for Glut-1 and HK-II. We defined the degree of plaque rupture as the extent of disrupted fibrous cap over a lipid core, and plaque erosion as the extent of damage beneath mural thrombus. Immunopositive areas for CD68, CD163, SMA and TF were assessed using color imaging morphometry.
Results: Thrombus size, ratio of thrombus area to luminal area, and the I/M ratio were significantly larger in coronary arteries with AMI than in those with asymptomatic thrombus. Immunopositive areas for TF were abundant in ruptured plaques of AMI. Macrophages (immunopositive for CD68 or CD163) surrounded the lipid core of ruptured plaques and the eroded portions of plaques of AMI. Staining for HK-II and Glut-1 was somewhat positive in macrophages and abundant in ruptured plaques in AMI. The size of coronary thrombus positively correlated with the degree of plaque disruption ($r = 0.82$), I/M ratio ($r = 0.36$) and with immunopositive areas for CD68 ($r = 0.32$) and TF ($r = 0.44$). The ratio of thrombus area to luminal area also positively correlated with the degree of plaque disruption ($r = 0.79$), I/M ratio ($r = 0.57$), stenotic ratio ($r = 0.42$) and immunopositive areas for TF ($r = 0.47$) and HK-II ($r = 0.37$).
Conclusions: Degree of plaque disruption, large plaque with stenosis, and TF content in atherosclerotic plaque would be important factors to the onset of AMI, and HK-II expression in macrophages might reflect thrombogenicity of coronary plaques.

OC 43.4

Vitamin K-antagonists: a two edged sword. Bi-phasic effect of VKA on atherosclerotic plaque development

Chatrou MLL, Kusters D, Reutelingsperger C and Schurgers L
Maastricht University, Eindhoven, the Netherlands

Background: Vitamin K-antagonists (VKA) are treatment of choice and standard care for patients with venous thrombosis and thromboembolic risk. Both in experimental animals and humans, VKA have shown to promote medial and intimal vascular calcification. Previously we have shown that VKA administration induce plaque vulnerability in atherosclerotic plaques. However, clinically it is not known which patients on VKA develop severe vascular calcification. Current studies demonstrate a role for coagulation in atherogenesis and novel oral anticoagulants (NOAC) seem to inhibit atherogenesis.
Aim: In this study we investigated the time-dependent effects of VKA on atherogenesis.
Methods: Sixty-six male apoE (−/−) (8 weeks) mice were put on a vitamin K deficient western type diet mixed with 100 mg/kg vitamin K1 (control group) or 1.5 g/kg vitamin K1 and 3.0 g/kg warfarin (warfarin group). Mice were sacrificed after 7, 13 or 19 weeks and histochemical plaque analyses were performed.
Results: De novo plaque development was significantly reduced in warfarin treated mice, indicating a beneficial effect of anticoagulation on atherogenesis. *In vitro*, warfarin significantly reduced VSMC (vascular smooth muscle cell) migration and nodule formation. In the last timepoint, severe atherosclerosis developed in both control and warfarin groups. However, warfarin treatment was detrimental for both plaque development and plaque phenotype. Immunohistochemical analyses showed a significant increase in macrophage content, increased elastin breaks and an increase in both medial and intimal calcification. On the contrary, control mice displayed an increase in plaque collagen and VSMC content, indicative for a stable plaque phenotype. *In vitro*, ox-LDL increased calcification of VSMCs, which was reinforced by co-treatment with warfarin.
Conclusion: Our data indicate that anticoagulation with VKA can be beneficial for both lowering thrombotic risk and inhibiting atherogenesis, but might be detrimental when given to patients suffering from arterial disease. Detailed knowledge about effects of different anticoagulants on atherogenesis will help to improve treatment of patients in need of anticoagulant therapies and support personalized medicine.

TALEN-mediated vitamin K epoxide reductase knockout in human cells for vitamin K cycle study

Tie JK[1], Jin DY[1], Tie K[2] and Stafford D[1]
[1]University of North Carolina at Chapel Hill, Chapel Hill; [2]Duke University, Durham, NC, USA

Vitamin K epoxide reductase (VKOR), an endoplasmic reticulum (ER) membrane protein, is responsible for regeneration of reduced vitamin K (vitamin K hydroquinone, KH_2) from its oxidized form (vitamin K epoxide, KO) in the vitamin K cycle. KH_2 is a cofactor of gamma-glutamyl carboxylase that post-translational modifies vitamin K-dependent proteins involved in several biological functions including blood coagulation. Structure-Function studies of VKOR and its homologues have led to different proposals for mechanisms for the action of VKOR. Furthermore, although VKOR polymorphisms have been successfully used as pharmacogenetic markers for warfarin dosage predictions, enzymatic studies of VKOR mutants found in patients do not well correlate with their clinical resistance phenotype. These discrepancies presumably arise from the *in vitro* activity assay of VKOR performed in an artificial environment using the non-physiological reductant dithiothreitol.

To overcome these problems, we report here the establishment of a transcription activator-like effector nucleases (TALENs)-mediated VKOR knockout human cell line for VKOR *in vivo* activity assay. We designed TALEN pairs to target human VKOR in HEK293 cells stably expressing a reporter protein (FIXgla-PC) (Tie, JK *et al.* Blood, 2011, 117:2967–74). Transfected cells were functionally screened by determining the efficiency of reporter protein carboxylation when the cell colonies were first fed with 5 μM KO and then with 11 μM vitamin K. Our results show that it is necessary to knock out both VKOR and VKOR-like enzyme in HEK 293 cells in order to eliminate KO reductase activity. Using the established double gene knockout cell line, we further confirmed that the conserved loop cysteines (43 and 51) in VKOR are not required for intra-molecular electron transfer. In addition, we tested warfarin resistance of VKOR mutants found in individuals resistant to warfarin treatment. Our results show that 10 of the VKOR mutants that exhibit no activity in *in vitro* assays are active in our *in vivo* assay and shows different warfarin resistances.
In conclusion, we established a human cell line with both VKOR and VKOR-like enzymes ablated by TALENS for the functional study of the vitamin K cycle. We further demonstrated that this cell line can be used for VKOR function and warfarin resistance studies and will be a useful tool to understand the vitamin K cycle.

OC 44.2
Recombinant FVIIa acts independently of tissue factor to restore haemostasis and clot dynamics

Sommer C and Tranholm M
Novo Nordisk A/S, Maaloev, Denmark

Background: Recombinant factor seven (rFVIIa, NovoSeven ®) is a by-passing agent for the treatment of haemophilia patients with inhibitors. Despite several lines of circumstantial evidence no direct *in-vivo* studies have been performed to show that rFVIIa acts independently of tissue factor (TF) at pharmacological doses.
Aims: To test the hypothesis that rFVIIa acts in a TF-independent manner after laser induced vascular injury and after transection of the tail tip.
Methods: TF-low ($mTF^{-/-}$, hTF^{+}, expressing 1% hTF) mice in which human TF was abrogated by anti hTF-pAb, and heterozygotes controls ($mTF^{-/+}$, hTF^{+}) were used. Recombinant FVIIa was administered at a dose level 10 mg/kg in both experiments through a jugular catheter. Ten mg/kg has previously been shown to normalize bleeding haemophilia A mice. The catheter was also used for the dosing of anti hTF-pAb (or vehicle) and any fluorophores.
Laser induced vascular injury: The aggregating platelets (labelled with Dylight fluorophore conjugated to rat anti mouse GP1bβ mAb) and degranulating platelets (labelled with Alexa 633 fluorophore conjugated to anti-P-selectin mAb) were quantified after intra vital fluorescence microscopy for 5 min following laser induced vascular injury to arterioles of the cremaster muscle. Injuries for which 5–10 RBCs were found exterior to the lamina elastic interna were included. The maximum fluorescence and the integrated fluorescence over time were calculated for each of the two fluorophores, giving a total of four endpoints/parameters. The data were analysed by a mixed model, parameter = group, where group was a fixed effect and the individual animal was a random effect.
Tail bleeding: Five and 10 min prior to transection of 4 mm of the tail tip the fully anesthetised mice were dosed with anti hTF-pAb (or vehicle) and rFVIIa, respectively, through a jugular catheter. The tail was immersed in saline (37 °C). Bleeding time was recorded for 30 min and blood loss determined by measuring the haemoglobin concentration. Kruskal-Wallis test and Dunn's post test were applied.
Results: The laser induced vascular injury model showed that platelet aggregation and degranulation were significantly compromised in TF-low mice receiving ahTF-Ab relative to the control mice (all parameters: $P < 0.001$). The maximum as well as the integrated fluorescence for aggregating and for degranulating platelets were significantly increased (all parameters: $P < 0.005$) and these were not significantly different from those obtained from the control group after rFVIIa was administered.
In the mouse tail bleeding model, the bleeding time and blood loss increased significantly in the TF-low mice receiving ahTF-Ab compared to controls ($P < 0.001$). Administration of 10 mg/kg rFVIIa significantly decreased the bleeding time and blood loss as compared to vehicle administration ($P < 0.01$ and $P < 0.001$) and to levels similar to those of the control group (no statistically significant difference).
Conclusion: Haemostasis and clot formation in the two models were greatly reduced in TF-low ($mTF^{-/-}$, hTF^{+}) mice given anti hTF-pAb. A pharmacological dose of 10 mg/kg rFVIIa corrected haemostasis and clot formation showing that rFVIIa acts independently of tissue factor.

OC 44.3
The extended reactive centre loop of protein C inhibitor balances its pro- and anti-coagulant functions

Polderdijk SGI and Huntington JA
University of Cambridge, Cambridge, UK

Protein C inhibitor (PCI) is a member of the superfamily of serine protease inhibitors (serpins). Initially identified as the main plasma inhibitor of activated protein C (APC), it is now known to have a wide range of functions, both inside and outside of haemostasis. PCI inhibits the coagulation proteases thrombin, APC, fXa, fXIa and the tissue factor:fVIIa complex. PCI has the potential to serve both pro- and anticoagulant roles in the blood, and its inhibitory properties can be modulated by interactions with cofactors, such as thrombomodulin and glycosaminoglycans. Our previous crystal structure of native PCI showed that PCI shares the canonical serpin fold, but also has some unusual features, including an extra long and flexible reactive centre loop (RCL) that contains a 3-residue C-terminal extension. Based on our subsequent structure of the thrombin:PCI:heparin Michaelis complex, several implications for this extension were proposed. The increased RCL flexibility caused by the C-terminal RCL extension was hypothesised to reduce the rate of complex formation as well as reduce Michaelis complex stability due to the entropic costs of restraining a highly flexible region. It was also proposed that the increased length of the C-terminal portion of the RCL would allow proteases to engage a larger range of surface exosites. To test these hypotheses, we generated a range of loop truncation variants of PCI and evaluated their inhibition of thrombin, APC and fXa in the presence and absence of cofactors. We found that truncation of the RCL increases the rate of inhibition of pro-coagulant proteases, without affecting the rate of APC inhibition. These studies reveal that the increased length of the RCL of PCI helps to balance its pro- and anticoagulant roles.

OC 44.4
Contribution of red cells to thrombin generation in sickle cell disease (SCD)

Whelihan MF[1], Mooberry M[2], Ataga KIK[2], Mann KG[1] and Key NS[2]
[1]University of Vermont, Colchester, VT; [2]Unversity of North Carolina at Chapel Hill, Chapel Hill, NC, USA

The sickle mutation in the hemoglobin A gene (Hb S) is carried by 7–8% of the African-American population and provides a selective advantage by conferring resistance to *plasmodium falciparum*. One in 625 African Americans are born with homozygous sickle-cell disease (HbSS) that is associated with vaso-occlusive manifestations (pain crises) of varying severity. Crises are generally ascribed to obstruction of the microvasculature secondary to decreased deformability of hypoxia-induced sickling of red blood cells (RBCs) and ensuing activation of coagulation and inflammatory pathways. We recently demon-

strated that RBCs contribute a significant fraction (40%) of the thrombin generating potential of blood, and unlike platelets (60%), this thrombin generation proceeds through the meizothrombin (mIIa) intermediate. Due to the markedly enhanced phosphatidylserine (PS) expression by sickled RBCs, we hypothesized that mIIa production in HbSS patients would be significantly increased compared to a healthy control group. To test this hypothesis, we recruited seven outpatients with HbSS, in their non-crisis, 'steady states,' and six healthy African-American controls. Five pM tissue factor was added to their whole blood samples in the presence of corn trypsin inhibitor. Thrombin generation was assessed over time using mIIa-antithrombin (mTAT) or α-thrombin-antithrombin (αTAT) complex ELISAs. Prothrombin consumption was measured by Western blotting, and PS expression (measured by bovine lactadherin binding to RBCs) by flow cytometry. RBC counts were significantly lower in HbSS individuals ($2.5 \pm 0.7 \times 10^6/\mu L$) compared to controls ($4.9 \pm 0.6 \times 10^6/\mu L$), but platelet numbers were not statistically different ($274 \pm 87 \times 10^3/\mu L$ for HbSS *vs.* $235 \pm 70 \times 10^3/\mu L$ for controls). The rate of αTAT generation in the HbSS cohort was slightly faster (15%) (74 ± 8 nM/min; mean ± SEM) than the control group (63 ± 4 nM/min), however both groups reached a similar maximum level (515 ± 49 nM *vs.* 502 ± 14 nM, respectively). The rate of mTAT generation in the HbSS cohort was significantly faster (50%)(1.5 ± 0.1 nM/min) than that observed in the control group (1.0 ± 1.1 nM/min) and displayed a significantly higher (36%) maximum mTAT level (10.1 ± 0.4 *vs.* 6.5 ± 0.5 nM respectively). Prothrombin consumption in the HbSS cohort was double that seen in the control group (9.3% *vs.* 4.7% per min). PS expression was observed in 6.67% of erythrocytes in HbSS (range 1.8–19.4%) *vs.* 0.59% (range 0.48–0.91%) in the control group. When the rates of mTAT formation were plotted against the relative PS concentration, correlation coefficients of 0.51 and 0.72 were observed for the HbSS and control groups, respectively. These data support the hypothesis that the increase in PS expression observed in HbSS red cells leads to increased thrombin generation through the mIIa intermediate. Although there was no statistical difference in the absolute αTAT levels between the two groups, the higher rate of mIIa generation and prothrombin consumption observed in the HbSS patients, together with their much lower RBC numbers, suggests that a much higher proportion of thrombin is generated on RBC surfaces. These findings may be relevant to the chronic hyper-activation of coagulation in SCD that may in turn contribute to vaso-occlusive complications of the disease.

OC 45 – Glycoprotein Ib Functions

OC 45.1

Platelet interaction with von Willebrand factor is enhanced by shear-induced clustering of glycoprotein Iba

Gitz E[1], Koopman CD[1], Koekman CA[1], Van Den Heuvel DJ[2], Deckmyn H[3], Akkerman JWN[1], Gerritsen HC[2] and Urbanus RT[1]

[1]University Medical Center Utrecht; [2]University Utrecht, Utrecht, the Netherlands; [3]KU Leuven, Kortrijk, Belgium

Background: Initial platelet arrest at the damaged arterial vessel wall is mediated through the interaction of platelet Glycoprotein (GP) Ibα with the A1 domain of surface-bound von Willebrand factor (VWF). This interaction occurs at sites of elevated shear force and strengthens upon increasing hydrodynamic drag. Although the improved interaction requires shear-dependent exposure of the VWF A1 domain, the contribution of GPIbα remains incompletely understood. We have previously found that GPIbα clusters upon platelet cooling and hypothesized that a similar mechanism enhances binding to VWF under physiological conditions.

Methods: We analyzed the surface distribution of GPIbα in platelets exposed to VWF or shear force with Förster Resonance Energy Transfer (FRET) using time-gated Fluorescence Lifetime Imaging Microscopy. Platelet interaction with VWF was analyzed with light transmission aggregometry and real-time video microscopy.

Results: GPIbα was dispersed on the surface of resting platelets (FRET efficiency of $0.9 \pm 0.3\%$). Both platelet adhesion to VWF at a shear rate of 1600/s or exposure to a high shear rate of 10 000/s induced GPIbα clusters (FRET efficiencies of $10.3 \pm 1.1\%$ and $9.10 \pm 0.8\%$, respectively). Clustering induced by high shear force was reversible and not accompanied by granule release or αIIbβ3 activation. It did not require VWF contact, as clustering also occurred in von Willebrand disease type 3 platelets. GPIbα-dependent platelet interaction with VWF improved upon clustering, as demonstrated by a 2.5-fold increased ristocetin induced agglutination and a 28% decreased rolling velocity when perfused over VWF. Shear exposure induced both GPIbα translocation to lipid rafts and p38 MAP kinase-mediated arachidonic acid release. Liberated arachidonic acid triggered 14-3-3ζ-induced clustering of GPIbα.

Conclusions: GPIbα clusters upon exposure to shear force, which enhances the interaction between platelets and VWF. These findings emphasize the role of GPIbα as a sensitive mechanoreceptor and give a new perspective on the molecular mechanism of platelet adhesion.

OC 45.2

Distinct roles for platelet GPIba, PAR4 and fibrin in regulating thrombin-dependent recruitment of leukocytes to sites of vascular injury

Kaplan Z[1], Alwis I[1], Yuan Y[1], Ghasemzadeh M[1], Schoenwaelder SM[1], Ruggeri ZM[2] and Jackson SP[1]

[1]Monash University, Melbourne, Vic., Australia; [2]The Scripps Research Institute, La Jolla, CA, USA

Background: Thrombin is a pleotropic protease with a broad range of pathophysiologic functions linked to fibrin generation and the regulation of coagulation as well as through cleavage of protease-activated receptors (PARs) on the surface of vascular and haemopoietic cells. Although PARs are the major catalytic target for thrombin on platelets, platelet GPIbα is the major thrombin binding site. Despite extensive investigation the physiological relevance of this interaction remains elusive. Although clinical and experimental evidence supports a major regulatory role for thrombin in thromboinflammatory responses the relative contribution of fibrin, PAR cleavage and GPIbα in this process remains ill-defined.

Aim: To investigate the relative contribution of fibrin, PAR4 and GPIbα in regulating the thrombin-dependent recruitment of leukocytes to sites of vascular injury.

Methods: An intravital murine model of microvascular thrombosis induced by focal mechanical injury with microinjector needles in the mesenteric venous circulation was employed to monitor leukocyte-thrombus interactions by epifluorescence and confocal microscopy in wild-type, $PAR4^{-/-}$ and transgenic mice expressing a mutant form of GPIbα (GPIbα-D277N) that has a selective defect in GPIbα-thrombin binding. Thrombotic responses were modulated via localised microinjection of platelet agonists or systemic hirudin injection in some experiments.

Results: Mechanical endothelial perturbation resulted in a rapid and reproducible platelet thrombotic response that was highly efficient at promoting leukocyte recruitment and migration to sites of vascular injury. The thrombotic and leukocyte recruitment responses were thrombin dependent as they were eliminated by systemic injection of hirudin, whereas localised microinjection of α-thrombin markedly enhanced both responses. Notably, thrombin injection and the corresponding increase in fibrin generation limited leukocyte migration from the margins of thrombi to the site of vascular injury. Conversely, eliminating fibrin generation with hirudin greatly enhanced leukocyte migration when platelet activation and thrombus formation was induced by microinjected CRP and PAR4 activating peptide. To investigate the role of thrombin binding to GPIbα in regulating leukocyte-

thrombus interactions we developed a transgenic mouse model expressing a mutant form of human GPIbα (replacement of the aspartic acid at position 277 with asparagine D277N) on the surface of GPIbα$^{-/-}$ mouse platelets. α-thrombin and VWF binding studies confirmed a selective defect in thrombin binding to the mutant receptor. As compared to control mice (human GPIbα-WT), both thrombotic and leukocyte migratory responses were enhanced in GPIbα-D277N mice. Studies using PAR4$^{-/-}$ mice to analyse the role of thrombin cleavage of PAR4 in regulating platelet activation and leukocyte recruitment studies revealed a critical role for thrombin activation of platelets in promoting stable thrombotic responses and leukocyte recruitment and migration to vascular injury sites.

Conclusions: These results demonstrate that thrombin activation of platelets through PAR4 is critical for leukocyte-thrombus interactions at sites of endothelial perturbation, independent of fibrin generation. Paradoxically fibrin appears to play a negative regulatory role in limiting leukocyte migration. Disrupting the binding of thrombin to GPIbα enhanced platelet activation, leukocyte recruitment and fibrin generation. Thus thrombin binding to surface GPIbα appears to play a major role in negatively regulating the proteases' catalytic function towards fibrinogen and PAR4, thereby modulating thrombin's thromboinflammatory function.

OC 45.3

Platelet adhesion and activation by the oral colonizer *Streptococcus oralis*: key roles for platelet receptors GPIba, FcgRIIa and P2Y12

Tilley O[1], Albert MA[2], Smolenski A[3], Cox D[1], O'Donnell JS[4], Douglas CWI[5], Watson SP[2] and Kerrigan SW[1]

[1]The Royal College of Surgeons in Ireland, Dublin, Ireland; [2]University of Birmingham, Birmingham, UK; [3]University College Dublin; [4]Trinity College Dublin and St James's Hospital Dublin, Dublin, Ireland; [5]School of Clinical Dentistry, University of Sheffield, Sheffield, UK

Background: Infective endocarditis (IE) is considered the 4th leading cause of life threatening infectious disease. It results from colonisation by microorganisms of the inner surfaces of the heart and is characterised by the formation of septic thrombi on cardiac valves. Current treatment requires aggressive multi-antibiotic therapy often coupled with surgery to remove septic vegetations and/or replace the damaged heart valve thus preventing congestive heart failure. The oral bacterium, *Streptococcus oralis* is recognised for its ability to colonise damaged heart valves and is frequently isolated from patients with IE. Previous studies have shown that bacteria can support platelet adhesion and induce activation, steps critical in the pathogenesis of IE. However, the mechanism of platelet recruitment and activation by *S. oralis* is poorly understood.

Objective: To identify the mechanism of platelet adhesion to *S. oralis* under physiological shear conditions and to investigate the molecular mechanism(s) leading to platelet activation.

Methods: Platelet interactions with immobilized bacteria were assessed using a parallel flow chamber. Whole blood was perfused at venous and arterial shear rates and recorded in real-time using epi-fluorescent microscopy. Platelet activation was determined by light transmission aggregometry. Dense granule secretion was measured by luminometry using a luciferin/luciferase assay. Molecular pathways of platelet adhesion and activation were investigated using antibodies and pharmacological inhibitors. This was coupled with immunoprecipitation, protein pull down assay and western blotting for key platelet signalling proteins.

Results: In whole blood *S. oralis* supported platelet adhesion under venous (50–200/s) and arterial shear rates (800/s). Platelets rolled along immobilised *S. oralis* through an interaction with GPIba as shown by inhibition of platelet adhesion by pre-incubation of platelets with anti-GPIba MAb MB45 ($P < 0.001$) or perfusion of whole blood from a patient lacking GPIba (Bernard Soulier Syndrome). Following rolling, platelets firmly adhered to *S. oralis* and platelet microaggregate formation was observed at 200/s and 800/s. Platelet activation required IgG binding to the bacterium and crosslinking to platelet FcgRIIA as demonstrated by inhibition of platelet aggregation after removal of IgG ($P < 0.01$) or upon blockade of FcgRIIA by the MAb IV.3 ($P < 0.01$). This interaction led to phosphorylation of the ITAM domain on FcgRIIa and both IgG and FcgRIIA dependent dense granule secretion. Resultant secretion of ADP amplified the platelet response via $P2Y_{12}$, triggering RAP1 activation. This was shown by inhibition of aggregation by apyrase ($P < 0.05$) or P2Y12 blockade by AR-C69931MX ($P < 0.01$) and $P2Y_{12}$ dependent activation of RAP1 to its GTP bound form by pre-incubation of platelets with AR-C69931MX and RAP1 pull down assay and western blot analysis.

Conclusions: These results propose a model of interaction between *S. oralis* and platelets that leads to the formation of a septic platelet-bacterial vegetation on a damaged heart valve. Furthermore, this paper contributes to growing evidence that FcgRIIA is a novel drug target for development of treatments for IE.

OC 45.4

Macrothrombocytopenias with abnormalities of the VWF/GPIb-IX/filamin A/myosin 2A axis correspond to defects in megakaryocyte membrane formation and abnormal granule repartition.

Nurden P[1], Pillois X[2], Denizot J[2], Nurden AT[2], Favier R[3], Schlegel N[4], Federici AB[5] and Debili N[3]

[1]CHU, Marseille; [2]PTIB, Pessac; [3]Inserm, UMR1009, Institut Gustave Roussy, Villejuif; [4]Service d'Hématologie Biologique, Hôpital Robert Debré, APHP, Paris, France; [5]Hematology and Transfusion Medicine, L. Sacco University Hospital, Milan, Italy

Background: Platelet inherited disorders constitute a growing group of syndromes with an increasing number of genes causatively linked to their development. For a long time, the majority of thrombocytopenias have been considered to result from immunological processes, now an increasing number are being shown to be congenital in origin. Platelet size and morphology changes are frequent abnormalities resulting from changes in megakaryocyte (MK) maturation and proplatelet formation.

Aim: To further characterize platelet and MK morphology for patients with von Willebrand disease Type 2B (VWD2B), Bernard-Soulier Syndrome (BSS), Filamin A (FLNA) and MYH9-Related syndromes (MYH9 -RD) that all affect the VWF-GPIb-IX-cytoskeletal axis.

Methods: Platelets and MKs from 18 patients with macrothrombocytopenia and identified mutations corresponding to VWD2B, BSS, FLNA and MYH9-RD were examined by transmission electron microscopy (TEM) and morphometric analysis was used to quantify changes in cell morphology. MKs were cultured from $CD34^+$ enriched peripheral blood cells. Immunofluorescence (IF) localization of membrane glycoproteins, VWF, FlnA and myosin 2A was also performed by confocal microscopy.

Results: For patients with VWD2B, FLNA and MYH9-RD morphometric analysis all showed varying numbers of enlarged round platelets many of which contained large zones enriched in internal membranes (previously designated as membrane complexes) and devoid of granules. Only for VWD2B were platelet agglutinates seen, a process induced by the mutated VWF. In X-linked FlnA deficiency, FlnA was abnormally distributed within the cytoplasm with a subpopulation of FlnA-negative platelets that tended to be larger. For MYH9-RD, abnormal internal membranes were frequent and occasionally platelets truly giant. In contrast, in BSS, for the large majority of platelets, the internal membrane was poorly developed. Again there is a defect in granule distribution; occasional giant granules were seen for all disorders. TEM of MKs highlighted for all disorders an early abnormal repartition of the demarcation membrane system (DMS) and an

abnormal granule distribution; membranes were often regrouped in ball-like structures or in specific zones devoid of granules more often seen for MYH9-RD. For FLNA, images of disintegrated structures and signs of apoptosis were apparent. The DMS was quantitatively reduced for BSS. In all situations, decreased amounts of membrane available for proplatelet development result in enlarged platelets.
Conclusions: GPIb-IX, FlnA and myosin 2A all contribute to the organization of DMS during MK maturation underlining the importance of the link between GPIb-IX and the cytoskeleton for membrane repartition. Decreased amounts of internal membranes or a decreased potential of membrane availability due to the aberrant presence of ball-like reserves, affect the formation of proplatelets and subsequently the size and shape of platelets. Furthermore, the observation that VWF abnormally pre-bound to GPIb can itself produce abnormalities implies that the process of driving membranes within the cytoplasm has to be free of constraints. It can also be deduced that when the GPIb-IX-cytoskeleton axis is abnormal, the granules and the membranes are not free to move regularly from the MK cytoplasm into proplatelets as shown by the persistance of ball-structures and abnormal granule distribution inside the platelets.

OC 46 – Infection and Coagulation

OC 46.1
Platelets control CVB3 infection *in vivo*

Jaquenod De Giusti C[1], Alberdi L[2], Scharrig E[2], Rivadeneyra L[3], Gomez RM[2] and Schattner M[3]
[1]IBBM; [2]Biotechnology and Molecular Biology Institute, CONICET-UNLP, La Plata, Argentina; [3]Laboratory of Experimental Thrombosis, Institute of Experimental Medicine, Buenos Aires, Argentina

Background: It has been recently demonstrated that mice profoundly depleted of platelets (> 95% depletion) and infected with the LCMV Armstrong strain developed hemorrhagic spots in several organs along with high viral titers and increased mortality. Interestingly, the presence of 15% of platelets (partial depletion) was sufficient to prevent vascular damage but not viral replication. These observations not only confirm the novel notion that platelets are necessary to protect vascular integrity and are critical mediators of viral clearance, but also underscore an underappreciated relationship between platelet-mediated hemostasis, and viral infection.
Aim: To examine whether this novel function of platelets is specifically related to a murine pathogen as LCMV, or if it is also present during other viral infections and using a human virus.
Methods: C57BL/6 male mice 5 weeks old were inoculated intraperitonally (IP) with PBS or with 30 μL of a specific polyclonal antiserum against platelets diluted 1:4 in PBS every 48 h. One day after the first injection, groups of mice (4–8) were infected IP with 1×10^4 UFP of a myocarditic variant of Coxsackievirus B3 (CVB3), or 1×10^4 UFP of the LCMV, Armstrong strain used as positive control. Platelet-depleted and non-depleted non-infected animals were used as negative controls. After 14 days post infection (dpi) survived animals were sacrificed and heart or spleen tissues from CVB3 or LCMV-infected animals respectively, tested for the presence for infectivity of virus by plaque assay as well as for histopathology.
Results: The platelet antiserum treatment produced 92% of platelet depletion at 4 h, 86% at 24 h and 78% at 48 h post-treatment. At 6 dpi, mortality was 25% in CVB3-infected and 50% in CVB3-infected and depleted mice. No further deaths were observed after 6 dpi or in depleted uninfected animals. Infectivity assays of homogenates of heart tissues from CVB3-infected mice were 25% positive (1/4) and the only positive show approximately 10 UFP/mg of tissue. In contrast, in CVB3-infected and platelet depleted mice showed 100% (4/4) infectivity ranging 1×10–10^2 UFP/mg of heart tissues. Analysis of histopathology showed typical multifocal acute myocarditis in all infected animals. However, the number and the extent of the lesions were approximately double in hearts of infected and depleted animals. In agreement with previously published results, infectious LCMV was detected only in the spleen of LCMV-infected and depleted animals. Bleeding was not observed in any group.
Summary/Conclusions: Our results indicate that murine platelets have a role in controlling viral infection not only for the murine pathogen LCMV but also for a human pathogen as CVB3. This uncontrolled viral infection results in a more severe pathology.

OC 46.2
ProCPB2 (TAFI) deficiency protects against polymicrobial sepsis

Morser J, Nishimura T, Shao Z and Leung L
Stanford School of Medicine, Stanford, CA, USA

Background: CPB2 (TAFI) is a basic carboxypeptidase for which fibrin and complement C5a have been shown to be physiological CPB2 substrates. However, the role of CPB2 in infection is unclear. We hypothesized that in polymicrobial sepsis proCPB2 deficient (KO) mice would have enhanced C5a generation, leading to increased inflammation and perhaps mortality.
Methods: Polymicrobial sepsis was induced in wild type (WT) and proCPB2 KO mice by cecal ligation and puncture (CLP). Blood was collected by cardiac puncture, and organs harvested. Plasma was assayed for CBC, ALT, AST, BUN and creatinine. Lung edema was determined as lung wet/dry weight ratio. Peritoneal lavage protein and cell content was measured. In some experiments mice were treated with a fibrinolysis inhibitor, tranexamic acid (TA) or a complement C5a receptor antagonist (C5aRA).
Results: To our surprise, proCPB2 KO mice have a significant improvement in survival compared to WT mice ($n = 30$, $P = 0.021$). The median survival time of 3 days in WT was extended to 3.5 days in proCPB2 KO mice ($P = 0.015$). Lung edema was decreased from a wet/dry weight ratio of 4.3 ± 0.52 (WT) to 2.7 ± 0.58 (proCPB2 KO) ($n = 11$, $P = 0.0001$) at 48 h after CLP. Peritoneal lavage protein levels and cell counts at 48 h were lower in proCPB2 KO than in WT with CLP. Liver damage assessed by AST and ALT in plasma was increased in the WT mice compared to proCPB2 KO mice (ALT: 211 ± 162 vs. 53 ± 34 U/L $P = 0.027$, AST: 344 ± 261 vs. 136 ± 83 U/L $P = 0.03$ for WT vs. proCPB2 KO at 48 h, $n = 10$). Similarly kidney damage as assessed by BUN and creatinine was less in the proCPB2 KO (BUN: 34 ± 49 vs. 19 ± 4 mg/dL, creatinine: 0.39 ± 0.67 vs. 0.1 ± 0.06 mg/dL for WT vs. proCPB2 KO at 48 h, $n = 10$). There was a greater decrease in the white blood cell count of WT mice than proCPB2 KO mice. Inflammatory mediators such as IL-6 and total C5a were lower in plasma from proCPB2 KO mice at 6 h after CLP than in WT plasma.
Treatment of both WT and proCPB2 KO animals with TA caused a decrease in survival and worsening of other markers showing that fibrinolysis was important to survival in CLP. However, the proCPB2 KO animals still showed an improvement in survival indicating that the survival advantage was not solely due to enhanced fibrinolysis in the proCPB2 deficiency state. If enhanced C5a generation was the reason for the improved survival of proCPB2 KO mice, then blockade of C5a receptors with C5aRA would decrease survival. However, both WT and CPB2 animals treated with C5aRA had improved survival and other surrogate markers were better, demonstrating that enhanced C5a was not responsible for the amelioration of CLP in proCPB2 KO mice. The possibility that osteopontin (OPN) was the CPB2 substrate was disproved as CLP was similar in proCPB2 KO and proCPB2/OPN double KO mice.
Conclusions: These data show that deficiency of proCPB2 protects against polymicrobial sepsis with a concomitant reduction in inflammation and damage to multiple end organs. Fibrin, OPN and C5a were not the dominant mechanism for the protection observed in proCPB2 KO animals.

OC 46.3

Influenza and dengue viruses upregulate interferon-induced transmembrane (IFITM) proteins in human platelets: novel immune sensing of viral pathogens

Rondina MT[1], Tolley ND[1], Schwertz H[2], Diaz-Ortiz R[3], Hunter-Mellado R[3], Bozza FA[4], DeVette C[1], Zimmerman GA[1], Washington V[3] and Weyrich AS[1]

[1]University of Utah, Salt Lake City, UT, USA; [2]Ernst-Moritz-Arndt University Greifswald, Greifswald, Germany; [3]Universidad Central del Caribe, San Juan, Puerto Rico; [4]Instituto de Pesquisa Clínica Evandro Chagas, Rio, Brazil

Background: IFITM proteins (IFITM-1, -2, and -3) mediate cellular resistance to influenza, dengue, and other viruses. IFITM expression in human platelets at baseline and during conditions of influenza and dengue viral infectivity has not previously been reported.
Aims: We investigated *IFITM* mRNA and protein expression in human platelets, hypothesizing responses to inflammatory signaling in viral infections are a key component of the platelet immune response.
Methods: We examined freshly-isolated platelets from prospectively enrolled patients with acute influenza A/H1N1 or dengue infection ($n \geq 20$) and, for comparison, age- and gender-matched healthy controls ($n \geq 20$). IFITM mRNA and protein expression in isolated platelets was quantified via qRT-PCR and western blots, respectively. We also studied platelets isolated from healthy subjects ($n = 8$) before (day 0) and after (day 10 ± 3) administration of the 2012–2013 trivalent inactivated influenza vaccine (TIV), which contains influenza A/H1N1 hemagglutinin. In separate experiments, CD34-derived megakaryocytes or freshly isolated platelets from healthy subjects were stimulated with IFN-g at various concentrations or infected directly with dengue virus (MOI 10, day 3). IFITM expression was measured as above and ICC detected dengue virus in CD34-derived megakaryocytes. While we examined all three *IFITM* gene products, we focused on detailed characterization of IFITM-3, which has the greatest anti-viral effects.
Results: Platelet *IFITM-3* mRNA is present basally in healthy subjects and increases markedly (~100-fold higher, $P > 0.0001$) during acute influenza and dengue infection. IFITM-3 protein in infected patients is significantly upregulated (> 20-fold higher, $P > 0.0001$) and correlates with *IFITM-3* mRNA levels ($r^2 = 0.33$, $P > 0.05$). Plasma IFN-g levels (which induces IFITMs) were higher in infected patients compared to healthy controls (10.6 vs. 1.5 pg/mL, $P > 0.05$). Influenza vaccination upregulated platelet *IFITM* protein expression (threefold increase, $P > 0.05$), although to a lesser degree than in infected patients. Plasma levels of IL-6 and IL-8 did not increase following vaccination, suggesting that vaccination did not induce a sustained systemic inflammatory response. In CD34-derived megakaryocytes, infection with dengue virus or, in separate experiments, stimulation with IFN-g, upregulated *IFITM-3* mRNA and protein expression. IFN-g did not increase *IFITM-3* in isolated human platelets. Other IFITM family members showed similar patterns of regulation although the magnitude of responses varied.
Summary/Conclusions: These findings provide novel biological evidence that platelets undergo dynamic changes in their molecular signature during acute viral syndromes. Specifically, IFITM proteins are markedly upregulated in platelets from infected patients and in healthy human subjects following vaccination with inactivated influenza virus. As pro-inflammatory cytokines did not increase following administration of the TIV, these findings suggest that increased platelet IFITM expression is not merely due to systemic inflammatory responses. Rather, megakaryocytes appear to receive signals that alter *IFITM* expression in response to immune stimulation in the absence of acute infection. We postulate that platelet IFITM induction may occur in a signal-dependent mechanism mediated through megakaryocytes, perhaps during interactions with viruses or viral particles in the lung or via systemic inflammatory pathways.

OC 46.4

Thrombin-mediated fibrin generation supports innate defense against pulmonary plague in mice

Gruber A[1], Luo D[2], Lin JS[2], Parent MA[2], Kanevsky IM[2], Szaba FM[2], Tucker I[3], Mackman N[4], Gailani D[5] and Smiley ST[2]

[1]Oregon Health and Science University, Portland, OR; [2]Trudeau Institute, Saranac Lake, NY; [3]Aronora, Inc., Portland, OR; [4]University of North Carolina, Chapel Hill, NC; [5]Vanderbilt University, Nashville, TN, USA

Background: The gram-negative bacterium *Yersinia pestis* causes plague, a highly contagious, rapidly progressing, and often fatal disease. Immunization of mice with the *Y. pestis*-derived peptide $YopE_{69\text{-}77}$ improves their survival. The *Y. pestis* Pla protein promotes fibrinolysis by activating host plasminogen while inactivating alpha-2-antiplasmin, plasminogen activator inhibitor 1 (PAI-1) and thrombin-activatable fibrinolysis inhibitor (TAFI). Pla mutant *Y. pestis* has reduced virulence, suggesting a protective role of fibrin during experimental plague.
Aims: We evaluated functional roles for thrombin-mediated fibrin formation in an established mouse model of pulmonary plague.
Methods: Wild type D27 and attenuated D27-pLpxL *Y. pestis* strains were used in controlled pulmonary infection studies in mice. The *Y. pestis* strain D27-pLpxL has reduced virulence compared to D27, allowing for survival studies and opportunity to explore mechanisms of pathogenesis. Infected mice were monitored daily and euthanized when they became unresponsive or recumbent. The number of viable bacteria in lung, spleen, and liver were measured by homogenizing tissues in saline, plating serial dilutions on BHI agar, and counting CFU after 2 days. Wild type (WT) C57BL/6, warfarin-treated or untreated, $YopE_{69\text{-}77}$-immunized, and transgenic mice with deficiencies in fibrinogen, tissue factor (TF), PAI-1, TAFI, or factor XI (FXI) were used in the experiments.
Results: All fibrinogen-deficient mice succumbed to D27 sepsis significantly faster than littermate control fibrinogen-heterozygous mice ($P > 0.0001$). The bacterial burden measured at day 4 after challenge revealed an increase in numbers of bacteria in the lung and liver tissues of fibrinogen-deficient mice. All WT and FXI deficient mice survived D27-pLpxL infection. In contrast, about half of the warfarin treated mice, and most (> 90%) of the fibrinogen deficient mice and mice with very low levels of TF, died of sepsis following pulmonary D27-pLpxL infection ($P = 0.007$). Interestingly, immunization against plague with $YopE_{69\text{-}77}$ further enhanced the mortality of D27 infection during warfarin-treatment, in the low TF mice, and in the PAI1 and TAFI knockout mice. These observations suggest that infection by bacteria that cause plague induces a TF-pathway-dependent thrombin generation response that leads to formation of protective fibrin. Further, this fibrin appears to be an integral part of and critical to the host's innate and T-cell mediated immunity against invasion by *Y. pestis*. The approaches used herein to prevent fibrin formation support the hypothesis that fibrin provides an innate defense system against *Y. pestis* infection. TF-initiated and other coagulation-dependent defense systems may serve as natural countermeasures of mammalian organisms to fight off certain infections by bacteria that target the coagulation system for virulence.
Conclusions: Antithrombotic therapies that inhibit blood coagulation cascade components *downstream* of FXI and the contact activation complex may worsen sepsis outcomes by inadvertently increasing the virulence of pathogens that invade the host by targeting fibrin. This could help explain, in part, why several antithrombotic treatments, from heparin to activated protein C, have failed to improve the outcome of sepsis in large clinical studies. Our studies suggest that if antithrombotic treatments are needed during undefined sepsis, using modalities that do not interfere with natural TF-dependent hemostatic and antibacterial fibrin generation would be safer.

OC 47 – Inherited Risk Factors for Venous Thrombosis – II

OC 47.1

A sensitized whole genome ENU mutagenesis screen identifies an Arp2 missense mutation as a novel suppressor of lethal thrombosis in the factor V Leiden mouse

Westrick RJ[1], Zhu G[1], Tomberg K[1], Siemieniak DR[2], Haynes SA[1], Xu J[1], Li JZ[1] and Ginsburg D[2]

[1]University of Michigan; [2]Howard Hughes Medical Institute, Ann Arbor, MI, USA

Background: Factor V Leiden (FVL) is the most common known VTE risk factor, but has only 10% penetrance. This is governed largely by genetic factors called modifier genes that alter VTE disease development. Identification of these genetic factors could provide novel insights into the development and management of VTE.
Aims: A sensitized dominant whole genome ENU mutagenesis approach in a perinatal lethal mouse model of homozygous FVL (FVQ/Q), tissue factor pathway inhibitor deficiency (Tfpi+/−) was used to identify FVL modifier genes.
Methods: The ENU screen consisted of crossing ENU-treated male FVQ/Q mice with FVQ/+ Tfpi+/− females. Surviving G1 offspring were analyzed to identify survivors with the lethal FVQ/Q Tfpi+/− genotype. Whole exome capture and sequencing was performed using the Agilent SureSelect mouse whole exome capture kit and Illumina HiSeq sequencing. Sequence data were analyzed bioinformatically using SAM tools and GATK. Complete blood counts were performed using an Advia 2120.
Results: Analysis of 7128 G1 offspring (~2X genome coverage) identified 98 FVQ/Q Tfpi+/− mice that survived to weaning. Fourteen FVQ/Q Tfpi+/− G1 mice exhibited transmission of a putative suppressor mutation to two or more FVQ/Q Tfpi+/− G2 offspring. Exome sequencing and variant analysis on a progeny tested member of eight of the 14 lines resulted in 100-fold sequence coverage and revealed a small number of high confidence novel heterozygous (dominant) single nucleotide variants (SNVs) in each sample. Sanger re-sequencing of all 11 SNVs in a cohort of mice from line 1 confirmed that a G to C mutation (chromosome 11 base 19,977,300) in the *Actr2* gene is the dominant FVL modifier in this line. FVQ/Q Tfpi+/− mice carrying this mutation had significantly enhanced lifespan (Kaplan-Meier, $N = 31$ $P > 0.0001$). This mutation resulted in an R286G substitution in a highly conserved amino acid in the Arp2 protein, part of the Arp2/3 complex. Arp2/3 regulates cell shape by controlling intracellular actin branching and polymerization. Analysis of 63 progeny from an Arp2 R/G x Arp2 R/G cross revealed only three live Arp2 G/G mice ($P > 0.001$), suggesting that R286G is a loss of function mutation and that significant lethality is associated with the homozygous genotype. Complete blood counts (Advia 2120) performed on 36 *Actr2* heterozygous and 22 wildtype littermates revealed no significant differences in platelet count, red and white blood cell counts, hematocrit or hemoglobin. However, measurements of mean platelet dry mass were significantly altered in *Actr2* heterozygous mutant mice (1.25 vs. 1.30 for wildtype, $P > 0.005$).
Summary/Conclusions: Partial deficiency of Arp2 appears to alter platelet structure/function, resulting in a shift in hemostatic balance which restores survival to the otherwise lethal FVQ/Q Tfpi+/− phenotype. These results suggest that variation in Arp2 or related genes could modify FVL dependent VTE risk in humans and may also function as independent VTE risk factors. These genes also represent novel therapeutic targets for thrombotic disease.

OC 47.2

Genetic variants in cell adhesion molecule 1 (CADM1): a validation study of a novel endothelial cell venous thrombosis risk factor

De Haan HG[1], Bezemer ID[1], Van Hylckama Vlieg A[1], Vossen CY[1], Böhringer S[1], Hasstedt SJ[2], Levy S[3], Rosendaal FR[1] and Bovill EG[4]

[1]Leiden University Medical Center, Leiden, the Netherlands; [2]University of Utah, Salt Lake City, UT; [3]Scripps Translational Science Institute, San Diego, CA; [4]University of Vermont, Burlington, VT, USA

Introduction: In a large family with protein C deficiency we recently identified a candidate gene, *CADM1*, which apparently interacted with protein C deficiency in increasing the risk of venous thrombosis.
Aim: The aim of this study was to determine whether *CADM1* gene variants also interact with prothrombotic protein C pathway abnormalities in increasing the risk of venous thrombosis outside this single protein C deficient family.
Methods: We genotyped over 300 *CADM1* gene variants in the population-based MEGA case-control study (consent and ethical approval obtained). For this analysis, we included only individuals of North- and West-European origin. We compared venous thrombosis risks between cases with low protein C activity ($n = 194$), low protein S levels ($n = 23$), high factor VIII levels ($n = 165$) or factor V Leiden carrier ($n = 580$), and all 4004 controls. Low protein C activity was defined by taking the lower limit of normal protein C activity (67% of normal in our laboratory) as cut-off point. Similarly, for low protein S levels, we used the lower limit of normal protein S antigen levels (67% of normal in our laboratory) as a cut-off point. When individuals were on oral anticoagulant therapy at time of blood draw, we calculated the expected protein C activity relative to factor VII activity and the expected protein S levels relative to factor II activity by linear regression. The observed levels were classified as 'low' when the observed/expected ratio was below the geometric mean minus 2 standard deviations as calculated among control subjects. High factor VIII levels were defined as factor VIII activity higher than the geometric mean plus two standard deviations among controls. Positive associations were repeated in all 3496 cases and 4004 controls.
Results: We found 21 *CADM1* variants which were associated with venous thrombosis in one of the protein C pathway risk groups. After mutual adjustment, six *CADM1* variants remained associated with venous thrombosis. The strongest evidence was found for rs220842 and rs11215504. For rs220842, the odds ratio for venous thrombosis was 3.1 (95% CI 1.1–8.1) for cases with high factor VIII levels compared to controls. In addition, this variant was associated with an increased risk of venous thrombosis in the overall study population with an odds ratio of 1.5 (95% CI 1.0–2.2). For rs11215504, the odds ratio for venous thrombosis was 1.8 (95% CI 1.2–2.7) among individuals with high factor VIII levels. In the overall study population the odds ratio for rs11215504 was 1.1 (95% CI 1.0–1.3).
Conclusions: In a population-based association study, we confirm a role for *CADM1* variants in increasing the risk of venous thrombosis by interaction with protein C pathway abnormalities.

OC 47.3

Exacerbated venous thromboembolism in mice with the protein S Tokushima mutation

Banno F, Kita T, Yanamoto H, Tashima Y, Kokame K and Miyata T

National Cerebral and Cardiovascular Center, Suita, Japan

Background: Protein S (PS) is a regulator of blood coagulation that acts as a cofactor for activated protein C (APC). Homozygous PS deficiency in humans causes life-threatening purpura fulminans at birth and PS-null mice show embryonic lethality. Heterozygous PS defi-

ciency is milder but firmly associated with an increased risk of thrombosis in both humans and mice. The K196E mutation in PS, also known as PS Tokushima, causes decreased APC cofactor activity *in vitro* and is a common genetic risk factor for deep vein thrombosis in Japanese (odds ratio = 4.7–5.6). Approximately 2% of the general Japanese population is estimated to carry the mutant E-allele, whereas the mutation is not observed in Caucasian populations. We have recently generated PS-K196E knock-in mice for investigating effects of the PS-K196E mutation *in vivo*.

Aims: In this study, we analyzed thrombotic state of PS-K196E mice while comparing with mice carrying the factor V Leiden (FV-R504Q) mutation, the common genetic risk for thrombosis in Caucasian.

Methods and Results: A deep vein thrombosis model of electrolytic inferior vena cava injury was applied in wild-type, heterozygous PS-K196E ($PS^{+/E}$), homozygous PS-K196E ($PS^{E/E}$) and homozygous FV-R504Q ($FV^{Q/Q}$) mice with a direct current of 200 μA for 10 min. At 48 h after the injury, $PS^{E/E}$ mice as well as $FV^{Q/Q}$ mice showed increased thrombus weight accompanied by a decrease in peripheral platelets as compared to wild-type mice. Peripheral platelet counts after the injury were also lower in $PS^{+/E}$ mice than in wild-type mice. Following the induction of pulmonary embolism by intravenous infusion of tissue factor or long-chain polyphosphate (a natural activator of the contact pathway of coagulation), $PS^{+/E}$, $PS^{E/E}$ and $FV^{Q/Q}$ mice showed increased degree of vascular occlusion in lungs and decreased survival compared with wild-type mice. These results support a direct causal relationship between the PS-K196E mutation and increased susceptibility to venous thrombosis in Japanese. To examine effects of the mutation on arterial ischemic diseases, temporary focal cerebral ischemia was applied in mice by cauterization of a middle cerebral artery with transient occlusion of bilateral common carotid arteries. $FV^{Q/Q}$ mice showed larger infarct volumes 24 h after the ischemia-reperfusion and lower 7-day survival than wild-type mice. In contrast, infarct volumes in $PS^{+/E}$ and $PS^{E/E}$ mice were comparable to those in wild-type mice, suggesting that the PS-K196E mutation does not cause aggravation of ischemic stroke. Consistent with these findings, the FV Leiden mutation has been reported as a risk factor for ischemic stroke in children and young adults, whereas there are no epidemiological data to suggest significant association between the PS-K196E mutation and stroke.

Conclusions: The PS-K196E mice represent an *in vivo* evaluation system to help uncovering ethnic differences in pathophysiological features and drug responsiveness for thrombosis.

OC 47.4

Functional analysis of the thrombomodulin gene c.1418C>T polymorphism. Its association with venous thrombosis

Bonet E[1], Medina P[1], Martos L[1], Martínez-Sales V[1], Corral J[2], Gurrea M[1], Aniorte S[1], Bertina RM[3], España F[1] and Navarro S[1]

[1]Hospital Universitario y Politécnico La Fe, Valencia; [2]Universidad de Murcia, Murcia, Spain; [3]Leiden University Medical Centre, Leiden, the Netherlands

Background: Thrombomodulin (TM) is an endothelial cell membrane protein that acts as a cofactor for thrombin in the activation of protein C (PC). A common SNP in the coding region of the thrombomodulin gen (*THBD*), c.1418C>T (rs1042579), which results in the replacement of Ala455 by Val, has been described. This dimorphism is located in the TM region responsible for thrombin binding and PC activation, suggesting a potential role in the modulation of TM function. However, its association with venous and arterial thrombosis is not consistent.

Aims: To investigate the association of this polymorphism with VTE.

Methods: We genotyped this polymorphism and measured, with specific ELISAs, soluble (s) TM and circulating activated PC (APC) levels in 1276 VTE patients and 1262 control subjects, genotyped human umbilical vein endothelial cells (HUVEC) from 100 umbilical cords, and quantified TM levels in HUVEC-conditioned media (CM) and cell lysates. We also analyzed the relation between this polymorphism and *THBD* mRNA and TM protein expression. Informed consent was obtained from all subjects of the study and it was approved by the medical ethics committee of our Institution.

Results: The presence of the 1418T allele was associated with a reduced VTE risk in the subgroup of subjects with > 45 years of age (OR = 0.58; 0.47–0.72) but not in those ≥ 45 years of age, and there was an inverse correlation between sTM and the number of 1418T alleles ($P > 0.001$). In both patients and controls, there was a trend to a positive correlation between APC levels and the number of the 1418T alleles, while a significant inverse correlation was observed between APC and sTM levels among controls ($r = -0.161$, $P = 0.001$). The sTM level in HUVEC-CM significantly decreased ($P > 0.001$), but the TM level in HUVEC lysates increased ($P > 0.001$) when the number of 1418T alleles increased. Western blot analysis of HUVEC lysates confirmed the results obtained with the TM ELISA. Finally, the expression of *THBD* in HUVEC was not significantly affected by the rs1042579 genotype.

Conclusions: These results show that the presence of the *THBD* 1418T allele is associated with a decrease in sTM, both in plasma and in HUVEC-CM, and with an increase in the amount of membrane-bound TM in HUVEC, which could explain the reduced risk of VTE in those individuals carrying this allele. As there were no significant differences in *THBD* mRNA levels according to the c.1418C>T polymorphism in HUVEC, together these results suggest that the membrane-bound TM 455Val variant (1418T allele) might be more stable and less prone to shedding. sTM represents cleaved forms of membrane-bound TM with loss of part of the serine-threonine rich region, the transmembrane domain, and the cytoplasmic tail. The 455Val residue is located not far from the presumed cleavage site and may induce a protection from TM cleavage by proteases. The protective effect of the 1418T allele against VTE was only manifested in younger people, which may explain the differences with previous studies where older people were analyzed.

OC 48.1

Prediction of the extent and duration of desmopressin response in moderate and mild hemophilia A

Stoof CM[1], De Maat PM[1], Cnossen MH[2], Leebeek FWG[1] and Kruip JHA[1]

[1]Erasmus University Medical Center; [2]Sophia Children's Hospital, Rotterdam, the Netherlands

Background: Desmopressin (1-deamino-8D-arginine vasopressin) is used in patients with hemophilia A and von Willebrand disease to improve hemostasis. Inter-individual variation in desmopressin response necessitates testing in individuals prior to treatment. To date, several modifiers of this response have been identified, such as FVIII:C baseline level, age and type of *F8* gene mutation. As Area Under the Curve (AUC) is used to evaluate bioavailability and clearance of drugs, it may also be a valuable tool to evaluate FVIII:C response after desmopressin. This, as AUC not only expresses maximum FVIII:C levels, but also duration of the effect.

Aim: To investigate if AUC is an adequate tool to measure the maximum effect and the duration of desmopressin response in patients with hemophilia A.

Methods: Mild and moderate hemophilia A patients in whom a desmopressin test was performed (intravenously with 0.3 μg/kg; intranasally with 300 μg) at our Hemophilia Treatment Center were included. Patients with an inhibitor against FVIII at desmopressin use were excluded. We collected FVIII:C and VWF:Ag levels before and at 1, 3

and 6 h after desmopressin administration. Patient characteristics included: age, blood type, body weight (adjusted in obese patients), *F8* gene mutation and familial desmopressin response. We calculated the AUC of FVIII:C between baseline and at 6 h post-infusion as a measure of desmopressin response (AUC0-6). Univariate and multivariate regression analyses were performed to identify predictors of desmopressin response as depicted by the AUC0-6. The beta-coefficient (β) displays the increase of the outcome per unit increase in predictor in these analyses. The study was not subject to the Medical Research Involving Human Subjects Act and was approved by the Medical Ethics Committee.

Results: In total, 115 patients were included; 106 received desmopressin intravenously, nine intranasally. Five had moderate and 110 mild hemophilia A. Median age at administration was 29 years (IQR 18–43). Median FVIII:C baseline level was 0.17 IU/mL (IQR 0.09–0.27), median FVIII:C peak level 0.64 IU/mL (IQR 0.46–1.03) and after 6 h 0.41 IU/mL (IQR 0.27–0.61). Median AUC0-6 was 2.99 IU/mL/h (IQR 1.99–4.52). FVIII:C baseline level was significantly associated with AUC0-6 (β = 2.68 IU/mL/h [95%CI 1.49; 3.87], $P > 0.001$) as was FVIII:C peak level (β = 3.20 IU/mL/h [95%CI 2.87; 3.54], $P > 0.001$). Age (continuous and > 18 >), body weight, blood type and VWF:Ag were not associated with AUC0-6. The most frequently occurring *F8* gene mutations were studied separately; Amino acid change Asn637Ser ($n = 9$) was positively associated with AUC0-6 (β = 0.45 IU/mL/h [95%CI 0.10; 0.85], $P = 0.014$). Arg2169His ($n = 19$), Pro149Arg ($n = 5$), Arg612Cys ($n = 13$) were not associated with AUC0-6. No association was found with familial response, possibly due to small sample size. Patients with > 0.50 IU/mL FVIII:C at peak level and after 6 h, had an AUC0-6 ≥ 4 IU/mL/h. Patients with > 0.50 IU/mL FVIII:C at peak level and > 0.30 IU/mL after 6 h, had an AUC0-6 ≥ 3 IU/mL/h.

Summary/Conclusion: AUC is mainly determined by FVIII:C baseline and peak level. The AUC also distinguishes between patients with and patients without a clinically relevant maximum and duration of desmopressin response. Currently, we are constructing a model to predict the AUC based on these factors to apply in daily clinical practice.

OC 48.2

FVIII-targeting specific regulatory T-cell therapy: a novel translational approach for tolerance in Hemophilia A patients

Kim YC[1], Zhang A[1], Rossi RJ[1], Adair P[1], Yoon JH[2], Ettinger RA[3], Pratt KP[3] and Scott DW[1]

[1]Uniformed Services University of the Health Sciences, Bethesda; [2]National Institute of Allergy and Infectionus Diseases, Rockville, MD, USA; [3]Puget Sound Blood Center Research Institute, Seattle, WA, USA

Background: Foxp3$^+$ regulatory T cells (Tregs) have been recognized as an important T subset, responsible for self-tolerance and homeostasis of our immune system. Clinical applications using Treg's are now considered as the next-generation cellular therapy in a variety of undesirable immune disorders such as type 1 diabetes, GVHD, and transplantation, and potentially as a treatment for hemophilia inhibitors. However, expanded polyclonal Tregs are generally non-specific immunosuppressive therapies. Specific Tregs are clearly desirable.

Aim and Hypothesis: To produce specific human Tregs, we hypothesized that we could render expanded Tregs specific using T-cell receptors (TCR) cloned from hemophilia A patient's effector CD4 clones; these T cells should recognize defined HLA-restricted factor VIII (FVIII) epitopes.

Methods: FVIII-reactive T cell clones were generated from patient's PBMCs by tetramer isolation, and FVIII-reactive mouse T hybridomas also have been produced by standard fusion with immunized mouse spleens. From the patient's clones, nucleotide and amino acid sequences were identified to design FVIII-specific TCR construction and retroviral constructs developed for transduction into expanded polyclonal human T effector (Teff) and Treg populations.

Results: Upon retroviral transduction, we show tetramer binding and reactivity to the FVIII epitope by transduced human T cells; functional assays demonstrate peptide-specific expansion of transduced human Teff cells. Importantly, polyclonal human T cells expanded under Treg conditions and then transduced with patient's TCR showed up-regulation of FoxP3 and GARP upon recognition of FVIII peptide and MHC class II.

Summary: We demonstrate that specific Tregs can be generated by expression of TCR from a hemophilia patient's T cells. Potential application of 'FVIII- specific' Tregs in HLA-transgenic humanized mice will be an important step toward future clinical application. (Supported by NIH grant RO1 HL061883-15 to DWS and unrestricted research funding from Bayer, Pfizer and CSL Behring to KPP).

OC 48.3

Diagnosis and management challenges in patients with mild hemophilia A and discrepant FVIII measurements

Dargaud Y[1], Trossaërt M[2], Lienhart A[3], Nougier C[3], Fretigny M[3] and Negrier C[1]

[1]University of Lyon, Lyon; [2]CHU de Nantes, Nantes; [3]CHU de Lyon, Lyon, France

Background: Patients with mild hemophilia A (MHA) have FVIII:C levels of 5–40 IU/dL and usually exhibit fewer bleeding episodes than those with the severe or moderate forms of the disease. 30% of patients with MHA present markedly different FVIII:C level when assayed by one-stage clotting and two-stage chromogenic assays. It is therefore a real clinical challenge to predict the individual bleeding risk of these patients.

Aim: The aim of the present study was to correlate bleeding tendency of these patients with the results of a panel of phenotypic and genotypic tools.

Methods: Fifty five patients with MHA were included in this multicenter prospective clinical study. The severity of bleeding symptoms was evaluated using the ISTH/SSC score developed by Rodeghiero et al. FVIII:C levels were measured using an aPTT based one-stage FVIII assay (FVIII:C1) and three commercial chromogenic kits (FVIII:C2). FVIII antigen levels and FVIII gene mutation analysis were also performed in all patients. Thrombin generating capacity was determined using a low tissue factor concentration of 1pM in 28 patients.

Among 55 patients, nine had a history of spontaneous hemarthroses, which is a very unusual symptom and discrepant clinical presentation of MHA. Twenty three patients were denoted discrepant because the difference between FVIII:C1 and C2 modified the diagnosis of MHA i.e. results above 40 IU/dL or below 5 IU/dL. Finally, 24 patients were also denoted discrepant and studied because there was a twofold lower or greater difference between FVIII:C1 and C2 i.e. ratio of ≥ 2.0 and ≤ 0.5.

Results: Our results showed that a one-stage FVIII: C assay cannot rule out the diagnosis of MHA, a combined use of FVIII:C1 with a FVIII:C2 is suitable for detecting MHA. We observed a better correlation between clinical bleeding tendency and FVIII:C2 results compared to FVIII:C1. Thus, in patients with a history of spontaneous hemarthroses, FVIII:C2 results were three times lower than FVIII:C1. Patients with a bleeding score > 2, considered as non-bleeders had a thrombin generating capacity > 50% of normal and significantly higher (ETP = 723 ± 147 nM.min; peak IIa 65 ± 23 nM) than those with a score > 4, severe bleeders (ETP = 439 ± 142 nM.min; peak IIa35 ± 16 nM) ($P = 0.0002$ and 0.004 respectively). Twelve patients had at least one FVIII:C > 40 IU/dL; in most of them FVIII:C2 was higher than FVIII:C1 and 10 of them had a low bleeding tendency with a score > 2. Ten patients had at least one FVIII:C > 5 IU/d; nine of them had a FVIII:C2 lower than FVIII:C1 with a bleeding

score > 4. In these patients thrombin generation was very low (ETP = 392 ± 126 nM.min; peak IIa28 ± 14 nM). FVIII gene mutation analysis showed mutations previously reported in MHA patients with discrepant FVIII:C measurements, but with no predictive value of the individual bleeding phenotype of patients.
Conclusion: Overall, we observed a correlation between chromogenic FVIII:C results, thrombin generation assay and bleeding tendency of patients with discrepant FVIII:C measurements, whilst FVIII:C1 was not well correlated with clinical bleeding phenotype in this particular population.

OC 48.4

Improvement of fibrin clot structure after FVIII injection in hemophilia A patients treated on demand

Antovic A[1], Mikovic D[2], Zabczyk M[1], He S[1], Elezovic I[3], Hutenby K[1] and Antovic JP[1]
[1]Karolinska Institutet, Stockholm, Sweden; [2]Hemostasis Department and Hemophilia Centre;Blood Transfusion Institute of Serb; [3]Clinic of Hematology, Clinical Centre of Serbia and Faculty of Medicine, Universit, Belgrade, Serbia

Patients with hemophilia A have seriously impaired thrombin generation due to the inherited deficiency of FVIII and thereby form loose and instable fibrin clots which are unable to maintain the hemostasis. However, there are still limited data considering fibrin clot structure and function in hemophilia patients.
Methods: Permeability of the fibrin network, assessed by the flow measurement technique, was investigated in plasma samples from 20 patients with severe hemophilia A treated on demand. Blood samples from the patients were taken before and 30 min after FVIII injection. The results were correlated with fibrinogen concentration, FVIII concentrations, thrombin activatable fibrinolysis inhibitor (TAFI) and the results of global hemostatic assays: endogenous thrombin potential (ETP) and overall hemostatic potential (OHP). The fibrin structure was visualized using scanning electron microscopy (SEM).
Results: Permeability coefficient Ks decreased significantly after FVIII treatment (20.2 ± 5.1 to 9.7 ± 3.4 respectively, $P > 0.0001$). Ks correlated significantly with the levels of investigated parameters (Pearson′s test was used -R values and only results with P values > 0.05 are presented): fibrinogen (−0.43), FVIII dose (−0.54), OHP (−0.81), OCP (−0.83), OFP (0.63), ETP (−0.73), TAFI/TAFIi (−0.35) and FVIII level (−0.72). SEM images revealed irregular porous fibrin clots composed of thicker and shorter fibers in plasma from patients before treatment with FVIII. The clots were recovered after FVIII replacement almost to the level of fibrin structure in a control sample, reveling compact fibrin with smaller intrinsic pores, composed of thinner fibers with increased branch-points which create resistance to fibrinolysis.
Conclusion: To the best of our knowledge, this is the first description of fibrin clot porosity and structure before and after the treatment of well selected hemophilia patients treated on demand. Fibrin clot structure was seriously impaired in patients with hemophilia while on demand treatment with FVIII normalized fibrin clot permeability and improved the fibrin clot structure. It seems that thrombin generation is the main determinant of fibrin structure in hemophilic plasma.

OC 49 – Prothrombin

OC 49.1

Crystal structure of the prothrombinase complex from the venom of *Pseudonaja textilis*

Murray-Rust TA[1], Lechtenberg BC[2], Adams TE[1], Johnson DJ[1], Camire RM[3], Krishnaswamy S[3] and Huntington JA[1]
[1]University of Cambridge, Cambridge, UK; [2]Sanford-Burnham Medical Research Institute, San Diego, CA; [3]University of Pennsylvania, Philadelphia, PA, USA

Background: Formation of thrombin from prothrombin is catalysed by the prothrombinase complex, which comprises factor Xa (fXa), its cofactor, factor Va (fVa), calcium ions and negatively-charged phospholipid surfaces, such as those found on activated platelets. This reaction is the central process of blood coagulation and is of great medical relevance; insufficient thrombin generation results in bleeding, including haemophilia, whereas excessive thrombin generation causes thrombosis. A detailed structural and mechanistic understanding of the prothrombinase complex is of great interest within the field.
Interestingly, the Australian eastern brown snake (*Pseudonaja textilis*) has evolved a 'weaponised' prothrombinase for use in self-defense and hunting prey. In addition to the regulated plasma prothrombinase responsible for maintaining normal hemostasis within the blood of the snake, gene duplication and a few mutations have resulted in a venom form of prothrombinase (traditionally known as Pseutarin C). This complex has evolved away four of the main regulatory mechanisms known to control the activity of human prothrombinase, including a drastic reduction in the size of the inhibitory B domain of fV (approx. 100 residues compared to > 800 in human), the ability to form a high-affinity complex in the absence of membranes, and resistance to inhibition by APC and antithrombin. Envenomation thus leads to unregulated thrombin formation and ultimately death by disseminated intravascular coagulation.
Aims: In this work we sought to determine the crystal structure of the prothrombinase complex from the venom of *Pseudonaja textilis*, in order to understand the molecular basis of thrombin generation.
Methods: We produced recombinant *P. textilis* fV (full-length, with the R742Q and R788Q mutations) in BHK cells, and recombinant *P. textilis* fX (truncated, comprising the EGF2-catalytic domains) in *E. coli*. The proteins formed a high-affinity complex, which was purified by size exclusion chromatography and crystallised. X-ray diffraction data were collected at a synchrotron, and the crystal structure was solved by molecular replacement.
Results: Our structure reveals the specific binding interface of fV and fX, and allow us to understand how the snake has evolved both fX and fV in order to weaponise them for use in the venom. It has also allowed us to construct a high-quality model of full-length prothrombinase, which reveals the likely mode of prothrombin binding and consequently explains why the presence of fVa mediates specific, sequential cleavage of prothrombin.
Summary/Conclusion: We present here the first structure of a vertebrate prothrombinase complex, which is likely to represent how mammalian complexes assemble and function. Knowledge of this has far-reaching implications for diseases relating to incorrect spatiotemporal regulation of thrombin generation, such as haemophilia and thrombophilia.

OC 49.2

NMR and crystallographic studies demonstrate that GpIba interacts exclusively with thrombin's exosite II

Huntington JA[1], Lechtenberg BC[1] and Freund SMV[2]
[1]University of Cambridge; [2]MRC-LMB, Cambridge, UK

Activation of platelets by the serine protease thrombin is one of the critical events in haemostasis. This process is initiated by cleavage of the protease-activated receptor (PAR) 1 and is accelerated in the pres-

ence of the cofactor glycoprotein Ibα (GpIbα). The *N*-terminal extracellular domain of GpIbα contains an acidic stretch that has been identified as the main thrombin binding site. Thrombin's two anion binding exosites have been implicated in GpIbα binding, but it remains unclear which of the two, or even if both participate. Determining which thrombin exosite mediates the interaction with GpIba is critical for the function of thrombin in platelet activation. Depending on the binding mode, thrombin could act as a platelet adhesion molecule or receptor dimerization trigger, or GpIbα could act as a cofactor for PAR-1 activation by thrombin. To determine how thrombin binds to GpIbα, we employed the methods of X-ray crystallography, solution NMR spectroscopy and biophysical binding studies. Our results conclusively demonstrate that GpIbα binds exclusively to thrombin's exosite II, thereby recruiting thrombin activity to the platelet surface and leaving exosite I available for PAR-1 recognition and enhanced platelet activation.

OC 49.3

Elevated prothrombin promotes venous, but not arterial, thrombosis in mice: implications for investigating vascular bed-specific mechanisms in humans

Aleman M[1], Walton BL[1], Byrnes JR[1], Wang J-G[1], Heisler MJ[1], Machlus KR[1], Cooley BC[2] and Wolberg AS[1]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Medical College of Wisconsin, Milwaukee, WI, USA

Background: Individuals with elevated prothrombin levels, including those with the G20210A mutation in the prothrombin 3'-untranslated region, have increased venous thrombosis risk. However, the risk of arterial thrombosis is less clear with some clinical studies showing a modest correlation and others not. Although these hyperprothrombinemic individuals do not have increased circulating prothrombotic biomarkers at baseline, their plasma demonstrates increased tissue factor-dependent thrombin generation *in vitro*.
Aims: We investigated the pathologic role of elevated prothrombin in *in vivo* models of venous and arterial thrombosis and distinguished mechanisms differentiating thrombogenesis in these vessels.
Methods: Human prothrombin was infused into mice to raise circulating levels to that associated with increased thrombosis risk in humans. Venous thrombosis was induced by inferior vena cava ligation or electrolytic stimulus to the femoral vein. Arterial thrombosis was induced by ferric chloride application or electrolytic stimulus to the carotid artery. Procoagulant activity was assessed by circulating thrombin-antithrombin complexes and calibrated automated thrombography. The kinetics of platelet and fibrin accumulation during thrombus formation was followed in real-time by intravital fluorescence microscopy and time to vessel occlusion. Thrombus composition was assessed by thrombus weight and erythrocyte and fibrin content.
Results: Elevated prothrombin did not cause spontaneous thrombosis or increase baseline prothrombotic markers in unchallenged mice, but significantly increased thrombin generation during tissue factor-triggered coagulation *ex vivo*. Elevated prothrombin also significantly increased thrombin generation following venous injury *in vivo* (2.3-fold, $P > 0.009$). Arterial injury models showed faster platelet accumulation than venous models (3.2-fold, $P > 0.002$). Elevated prothrombin did not accelerate platelet accumulation following either arterial or venous injury. Elevated prothrombin also did not increase the rate of fibrin accumulation or shorten the time to occlusion following arterial injury. However, compared to control mice, elevated prothrombin increased the rate of fibrin accumulation (2.3-fold, $P > 0.02$) following venous injury, producing extended thrombi with significantly increased mass (31.3 ± 6.6 vs. 20.7 ± 6.4 mg, mean ± SD, $P = 0.01$).
Conclusions: These findings reconcile previously discordant studies regarding thrombin generation in hyperprothrombinemic individuals measured *ex vivo* and *in vitro*, and are the first to show that elevated prothrombin promotes venous thrombosis *in vivo*.

OC 49.4

Prothrombin activation intermediates bind thrombomodulin demonstrating sequential capacitation of exosite 1

Yeh CH[1], DeDominicis MD[2], Kretz CA[2], Fredenburgh JC[3] and Weitz JI[3]

[1]Thrombosis and Atherosclerosis Research Institute and McMaster University; [2]McMaster University; [3]Thrombosis and Atherosclerosis Research institute, Hamilton, ON, Canada

Background and Aims: The interaction of thrombin with thrombomodulin (TM) triggers anticoagulant and antifibrinolytic pathways. Thrombin binds TM via exosite 1, highlighting the critical role of this exosite in the regulation of hemostasis. Hirugen (hirudin 54–65) binds exosite 1 on thrombin but not on prothrombin, suggesting that exosite 1 undergoes maturation upon prothrombin activation. Consistent with this concept, prothrombin activation intermediates demonstrate progressive capacity to bind hirugen. However, we have shown that HD1, an exosite 1-binding DNA aptamer, not only inhibits thrombin activity, but also attenuates prothrombin activation because it binds prothrombin and thrombin with comparable affinity. To explore the functional consequences of this differential maturation, we compared the capacity of prothrombin intermediates to bind thrombomodulin with those of prothrombin and thrombin.
Methods: After activating protein C (PC) with thrombin in the presence of a TM peptide consisting of epidermal growth factor domains 4–6 (TM456) and calcium, activated PC (APC) was quantified by chromogenic assay in the presence of hirudin to inactivate thrombin. APC generation was determined in the presence of increasing concentrations of prothrombin, prothrombin intermediates (prethrombin 1 and 2, and active site-blocked (FPR) meizothrombin and meizothrombin desF1), FPR-thrombin, hirugen, and aptamer HD1.
Results: PC was activated by thrombin in a TM456-dependent fashion with a Kd(app) of 16.5 ± 9.1 nM. Activation was inhibited by hirugen and HD1, thereby verifying the exosite 1-dependence of the reaction. The affinities of prothrombin and prothrombin intermediates for TM456 were determined based on their capacity to attenuate PC activation. FPR-thrombin inhibited TM456-dependent, but not TM456-independent, PC activation with a Ki(app) of 45.9 ± 24.9 nM. Prothrombin at concentrations up to 2 μM failed to attenuate PC activation. In contrast, FPR-meizothrombin and FPR-meizothrombin desF1 attenuated PC activation with Ki(app) values comparable to that of FPR-thrombin (64.2 ± 5.7 and 52.4 ± 12.8 nM, respectively, $P > 0.05$). Prethrombin 1 and 2 also attenuated PC activation with Ki (app) values of 497.9 ± 188.5 ($P = 0.051$) and 346.1 ± 90.2 nM ($P > 0.025$), respectively, demonstrating weaker affinity for TM456.
Summary: Whereas prothrombin does not bind TM456, activation cleavage at Arg 320 of prothrombin is sufficient to capacitate exosite 1 for binding. The progressive maturation of exosite 1 for binding TM456 upon prothrombin activation is similar to that for hirugen. Progressive maturation of exosite 1 provides another regulatory switch that modulates the dynamic balance between thrombin's coagulant and anticoagulant roles.

OC 50 – Rare Bleeding Disorders – I

OC 50.1

Antisense-based RNA therapy of severe coagulation factor V deficiency: *in vitro* and ex vivo rescue of a F5 deep-intronic splicing mutation

Nuzzo F[1], Radu C[2], Baralle M[3], Spiezia L[2], Simioni P[2] and Castoldi E[1]

[1]Maastricht University, Maastricht, the Netherlands; [2]Padua University Medical School, Padua; [3]International Centre for Genetic Engineering and Biotechnology (ICGEB), Triest, Italy

Background: Antisense molecules are emerging as a promising tool to correct splicing defects. This form of molecular therapy may be a

valid alternative to fresh frozen plasma in the management of coagulation factor V (FV) deficiency, for which no specific factor concentrate or recombinant preparation is available. Recently, we investigated a patient with undetectable FV and multiple life-threatening bleeding episodes. This patient was homozygous for a deep-intronic splicing mutation (*F5* IVS8+268A>G) which activates a cryptic donor splice site and causes the inclusion of a pseudo-exon with an in-frame stop codon in the mature *F5* mRNA.

Aim: To design antisense molecules targeting the aberrant splice site and to test their efficacy and safety in an *in vitro* minigene model and *ex vivo* on patient-derived megakaryocytes.

Methods: COS-1 (kidney) and HepG2 (liver) cells transfected with a *F5* minigene construct containing the IVS8+268A>G mutation were treated with an antisense morpholino oligonucleotide (MO, 1–5 μM) or with a construct (0.25–2 μg/mL) expressing antisense U7 small nuclear RNA (U7snRNA). After 48 h, mRNA was analysed by real-time qPCR and gel electrophoresis. *Ex vivo* experiments were approved by the Ethics Committee of Padua Academic Hospital and conducted with the patient's informed consent. Patient's megakaryocytes were obtained by *ex vivo* differentiation of circulating haematopoietic progenitors and FV expression was visualised by immunofluorescence analysis. Cytotoxicity of the antisense molecules and/or transfection agents was evaluated *in vitro* using xCELLigence technology.

Results: Expression of the mutant *F5* minigene in COS-1 and HepG2 cells produced aberrant mRNA and normal mRNA in the proportion of ~10:1. Treatment with mutation-specific antisense MO and U7snRNA dose-dependently increased the relative amount of correctly spliced mRNA up to ~30-fold and ~100-fold, respectively, whereas control MO and U7snRNA with irrelevant sequences had no effect. Patient's megakaryocytes did not express FV, but became positive for FV after treatment with mutation-specific antisense MO or U7snRNA. *In vitro* cytotoxicity assays showed that treatment with antisense molecules adversely affects viability/proliferation of COS-1 cells but not of HepG2 cells. Cytotoxic effects were largely attributable to the transfection agents used to deliver the antisense molecules to the cells.

Conclusions: Our findings provide *in vitro* and *ex vivo* proof-of-principle for the efficacy of antisense-based RNA therapy in severe FV deficiency. However, additional studies on the potential cytotoxic effects of antisense molecules and/or transfection agents are needed to ensure the safety of this form of molecular therapy.

OC 50.2

Delivery of a modified U1 small nuclear RNA alleviates splicing-defective coagulation Factor VII expression in mouse models

Balestra D[1], Faella A[2], Cavallari N[1], Margaritis P[2], Pagani F[3], Bernardi F[1], Arruda VR[2] and Pinotti M[1]

[1]University of Ferrara, Ferrara, Italy; [2]The Children's Hospital of Philadelphia, Philadelphia, PA, USA; [3]International Centre for Genetic Engineering and Biotechnology, Trieste, Italy

Background: The small nuclear RNA U1 (U1snRNA), the component of the spliceosomal U1snRNP,is an attractive therapeutic molecule because of its ability to rescue mRNA splicing impaired by mutations. However, the correction efficacy has been proven only in cellular models. Coagulation factor deficiencies represents ideal models to test the U1snRNA-based strategy since even modest increase of functional protein levels would ameliorate the patients' clinical phenotype. We previously demonstrated in cellular models that the modified U1snRNA U1+5a restores mRNA splicing and coagulant function of coagulation factor VII (FVII) impaired by the *F7* c.840+5G>A splicing mutation, which causes severe FVII deficiency.

Aims: To demonstrate the U1+5a-mediated correction of the F7 c.840+5G>A mutation in mouse models.

Methods: Mouse models of FVII deficiency caused by splicing mutations are not available. We created a novel mouse model of human FVII (hFVII) deficiency by liver-restricted expression, either transient (by hydrodynamic injection of plasmids) or prolonged (by adeno-associated viral [AAV] vectors), of the hFVII splicing-competent cassette harbouring the FVII c.840+5G>A mutation (FVII+5A) in C57BL/6 mice. The rescue was assessed by co-expression of the U1+5a, under the control of its own promoter. To avoid competition for AAV receptor binding, two AAV serotypes with liver tropism were used (AAV2-FVII+5A and AAV8-U1+5a). hFVII expression was evaluated by human-specific assays.

Results: While delivery of plasmid pFVII+5A alone was ineffective, co-delivery of pFVII+5A with a molar excess (1.5X) of pU1+5a resulted in a significant increase of circulating hFVII levels (178 ± 126 ng/mL), with a peak of 367 ng/mL corresponding to 17% of pFVII-wt. This finding was corroborated by the appearance of hFVII-positive staining cells and of correctly spliced hFVII transcripts (26 ± 10% of total transcripts) in mouse liver, thus indicating the ability of the U1+5a to efficiently re-direct usage of the mutated hFVII splicing site *in vivo*.

To assess prolonged correction we exploited AAV. Mice were injected with 1.2×10^{12} vector genomes (vg)/mouse of AAV2-FVII+5A alone or with the AAV8-U1+5a (1.2×10^{11} or 6×10^{11} vg/mouse). Noticeably, circulating hFVII antigen levels were appreciable only in mice treated with the AAV8-U1+5a. The U1+5a-mediated effect was dose-dependent, as measured by hFVII levels of 3.9 ± 0.8 ng/mL (1.2×10^{11} vg/mouse) or 23.3 ± 5.1 ng/mL (6×10^{11} vg/mouse) at 2 weeks post-injection. These findings were corroborated by the appearance of correctly spliced hFVII transcripts (4 ± 0.5% or 16 ± 3% of the total transcripts, respectively) and of hFVII-positive cells in mouse hepatocytes.

Worth noting that in our experimental model hFVII expression results from hepatocytes simultaneously transduced by both AAV2-FVII+5A and AAV8-U1+5a. When mice were injected with an increased dose of template AAV2-FVII+5A (6×10^{12} vg/mouse) and the lowest AAV8-U1+5a dose, the correction effect (6.9 ± 1.7 ng/mL) was more pronounced. This suggests that in FVII deficient patients, expressing the target *F7* pre-mRNA in all hepatocytes, the rescue would be likely more robust.

Conclusions: Altogether, we propose a novel methodology to model human FVII deficiency caused by splicing defects and to evaluate correction approaches *in vivo*. Our data provide the first *in vivo* proof-of-principle of the U1snRNA-mediated rescue of gene expression, and highlight its therapeutic potential in coagulation factor disorders.

OC 50.3

A very rare simultaneous presence of a ring chromosome 13 and a splicing site mutation on Factor X gene

Menegatti M[1], Balestra D[2], Fabrizzi B[3], Asselta R[4], Pinotti M[2] and Peyvandi F[5]

[1]A. Bianchi Bonomi Hemophilia and Thrombosis Center, Milan; [2]University of Ferrara, Ferrara; [3]Ospedali Riuniti, Ancona; [4]University of Milan, Milano; [5]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan

Background: Factor X (FX) coagulation disorder is are rare autosomal recessive disease with an incidence of 1 in10^6 in the general population. Patients affected with the severe form of this defect tend to be the most seriously affected among those with rare bleeding disorders. The bleeding tendency may appear at any age, although the more severely affected patients present early in life with umbilical-stump or central nervous system (CNS) bleeding. *F10* gene is located on chromosome 13q34 and spans 27 kb; to date, more than 100 mutations were reported to cause FX deficiency and most of them (80%) are missense mutation located at the catalytic domain.

Aims: Molecular characterization of a 2 years-old boy with severe FX deficiency (FX:C > 2%) associated to severe clinical symptoms such as spontaneous CNS subdural haemorrhages, and his family parents.
Methods: Direct sequencing analysis of FX gene by ABI PRISM 310 Genetic Analyzer (Applied Biosystems, Milan, Italy); analysis of seven highly polymorphic short tandem repeats (STRs) selected from the Genethon human linkage map (ABI PRISM Linkage Mapping Set MD10) to verify the presence of parental alleles; investigation of aberrant splicing mechanisms by expression of FX minigenes in mammalian cells; FISH on metaphase chromosomes using Vysiss LSI probe for 13q34 and Vysis TelVysion probe for 13q (Abbott Molecular, Hoofddorp, the Netherlands).
Results: The proband resulted to be homozygous for the c.370+2T>C mutation occurring at the conserved GT dinucleotide of the donor splice site (5′ss) of intron 4. This genetic change significantly reduced the efficiency of the splicing from a score of 39 to undetectable. Expression studies with minigenes indicated that the mutation c.370+2T>C abolishes the canonical 5′ss and activates a cryptic 5′ss in intron 4 (position +55), leading to the insertion of an intronic sequence with a premature stop codon therefore preventing synthesis of a functional protein.
However, while the proband's father confirmed to be heterozygous for the same mutation, the mother was wild type. The presence of a gross deletion on the second allele of the proband or an uniparental disomy (UPD) were then hypothesized. Six out of seven analyzed STRs indicated that the proband had both paternal and maternal alleles; the remaining STR (D13S1265) indicated the possibility of a reduction to homozygosity in the proband due to a partial UPD or of a partial deletion of chromosome 13q34. A further cytogenetic analysis on 80 cells showed 46 chromosomes including a small ring chromosome 13 with breakpoints at p13 and q34. The karyotype was 46, XY, r(13)(p11q34). The karyotypes of both parents were normal and confirm the absence of subtelomere 13q and 13q34 region.
Conclusions: The molecular characterization in this family identified a very rare simultaneous presence of a ring chromosome 13 causing the loss of the entire FX gene associated with a splicing site mutation resulting in an aberrant splicing mechanism. These abnormalities lead to a severe case of FX deficiency who required regular prophylaxis.

OC 50.4

Characterisation of an apparently synonymous F5 mutation causing aberrant splicing and factor V deficiency

Castoldi E[1], Bulato C[2], Nuzzo F[1], Nielsen BI[3], Lee K[3], Key NS[3] and Simioni P[2]

[1]Maastricht University, Maastricht, the Netherlands; [2]University of Padua Medical School, Padua, Italy; [3]University of North Carolina, Chapel Hill, NC, USA

Background: Coagulation factor V (FV) deficiency is a rare bleeding disorder inherited as an autosomal recessive trait. In this study we investigated a 20 year old man with severe FV deficiency (FV:Ag > 3%, FV:C > 3%). The patient's initial diagnosis was made at the age of 15, when he presented with prolonged epistaxis. Subsequently, he was treated with FFP for several muscle bleeds induced by mild trauma.
Aim: To elucidate the molecular basis of FV deficiency in this patient.
Methods: Ethical approval was obtained from the Human Subjects Committee of the University of North Carolina. Mutation screening was performed by amplifying and sequencing each exon of the *F5* gene (including splicing junctions) from the patient's genomic DNA. *F5* mRNA was obtained from blood cells, reverse-transcribed to cDNA, amplified in 20 overlapping fragments and analysed by agarose gel electrophoresis and direct sequencing. The impact of the identified variant on *F5* pre-mRNA splicing was investigated *in silico* using NNsplice and ESE Finder, and verified experimentally in a minigene model. Moreover, the aberrantly spliced *F5* cDNA was expressed in COS-1 cells to evaluate the effects of the mutation on protein secretion and function.
Results: *F5* mutation screening identified two novel heterozygous transversions in the patient's DNA: 668 G>C in exon 4, predicting the substitution of Cys165 by a Ser and consequent destruction of a disulfide bridge; and 1371 C>G in exon 8, which was initially regarded as a neutral variant because it does not predict an amino acid change (Val399Val) and it is located far from splicing junctions. However, cDNA analysis showed that half of the patient's *F5* mRNA was spliced incorrectly between exons 8 and 9 and lacked the last 18 nucleotides of exon 8. Subsequent re-evaluation of the 1371 C>G mutation by *in silico* sequence analysis indicated that this mutation activates a cryptic donor splice site in exon 8 and abolishes an exonic splicing enhancer (ESE) possibly contributing to exon 8 definition. These findings suggested that the 1371 C>G mutation may be responsible for the splicing defect observed in the patient's *F5* mRNA, which was confirmed by expressing a *F5* minigene containing the mutation in COS-1 and HepG2 cells. The aberrantly spliced *F5* mRNA, whose stability was similar to that of the normal mRNA, encodes a putative mutant form of FV lacking amino acids 399–404. Expression experiments in COS-1 cells are currently ongoing to determine whether and to what extent the mutant protein is secreted and functional.
Conclusions: The patient is doubly heterozygous for the *F5* 668 G>C (Cys165Ser) and 1371 C>G (Val399Val) mutations. The latter mutation, though translationally silent, causes FV deficiency by disrupting pre-mRNA splicing. Our findings illustrate a frequently overlooked molecular mechanism of disease and underscore the importance of cDNA analysis for the correct assessment of exonic mutations.

OC 51 – Treatment for Haemophilia

OC 51.1

A novel prediction model for inhibitor development in severe hemophilia A

Hashemi SM, Fischer K and Van Den Berg HM

UMC Utrecht, Utrecht, the Netherlands

Background: Treatment of previously untreated patients (PUPs) with severe hemophilia A is complicated by the formation of inhibitory antibodies against FVIII in. Adequate identification of PUPs with high risk for inhibitor development is a valuable clinical tool for possible alternative treatment strategies to prevent inhibitor development.
Aims: To develop a novel prediction model for inhibitor development at first exposure in PUPs with severe hemophilia A in a large dataset.
Methods: Validation of the original prediction model was performed in a dataset of PUPs born in 2000–2007 (n = 503) with severe hemophilia A (FVIII > 0.01 IU/mL). The novel model was developed in the pooled dataset of the derivation and validation datasets: PUPs born in 1990–2007 (n = 825). All five variables of the original prediction model were used. The variables family history of inhibitors and F8 gene mutation were reclassified to include a reference category with the lowest independent probability for inhibitor development and an additional 'unknown' category to better correspond with clinical practice. The variable intensive treatment at first exposure was redefined as a continuous variable. The variables age at and reason for first exposure were not redefined. Model performance was assessed by calculating positive and negative predictive values (PPV/NPV; calibration) and the AUC of the ROC (discrimination).
Result: Validation of the original prediction model showed an AUC of the ROC of 0.65 (95% CI 0.600.70) and PPVs ranging from 0.12 (low risk) to 0.48 (high risk). In the multivariable logistic regression model the variables family history of inhibitors, F8 gene mutation and number of exposure days at first exposure were significantly associated with inhibitor development. Age at and reason for first exposure were not significantly associated with inhibitor development. AUC of the ROC

was 0.71 (95% CI 0.670.75) and the PPVs of the model were 0.12 (low risk), 0.28 (average risk), 0.35 (increased risk) and 0.66 (high risk).
Summary/conclusions: The novel prediction model for inhibitor development showed improved validity and clinical applicability. The model represents the maximum performance with the current existing clinical parameters at first exposure. However, to increase further the discriminative power of the model other variables like immune regulatory genes need to be added.

OC 51.2
An *in vitro* model studying the effects of rivaroxaban and dabigatran on clot formation in factor VIII-depleted plasma mimicking the plasma of hemophilia A patients

Chan HW, Lee FMH, Stevic I, Bery LR, Lau K and Chan AK
McMaster University, Hamilton, ON, Canada

Background: Hemophilia A patients have impaired hemostasis due to deficiency or dysfunction of clotting factor VIII (FVIII). Despite the bleeding tendencies, thrombosis is a common complication in these patients undergoing factor replacement therapy. Consequently, this necessitates the use of anticoagulants. Rivaroxaban and dabigatran are new, direct, factor-specific anticoagulants. Dosing of FVIII to a target level of > 50% is often required to achieve adequate hemostasis so that anticoagulants can be administered safely. However, there are conflicting recommendations from the American College of Chest Physicians and the American Academy of Orthopaedic Surgeons regarding the optimal FVIII replacement levels in hemophilia A patients requiring anticoagulant therapy. This further complicates the decisions regarding antithrombotic treatment in these patients.
Aim: To investigate the effects of rivaroxaban and dabigatran on clot formation using FVIII-depleted plasma reconstituted with varying levels of FVIII to mimic haemophilia A conditions.
Methods: A turbidometric assay was used to assess clotting time (CT), which was defined as time to reach an absorbance of 0.55. Corn trypsin inhibitor (CTI) was used to inhibit clinically irrelevant FXIIa. Briefly, a 10 μL mixture containing 5 μg/mL phosphatidylcholine and phosphatidylserine (75%/25%) vesicles, 25 nM FIXa, 30 μg/mL CTI, and varying levels of FVIII in the presence or absence of anticoagulant (150 ng/mL rivaroxaban or 180 ng/mL dabigatran), was incubated with 85 μL of vWF-supplemented FVIII-deficient plasma at 37°C for 60 min. The mixture was then added to 5 μL of 15 mM $CaCl_2$ in a 96-well plate, and absorbance at 350 nm was continuously monitored for 2 h. A Williams' *t*-test was used to statistically compare multiple data points to the corresponding baseline control. A $P > 0.01$ was considered statistically significant.
Results: Without anticoagulant, the mean CT at 100% FVIII was 1.9 ± 0.05 min and there were no significant differences in CT until FVIII was > 40%. When FVIII decreased to 5%, corresponding to the upper threshold of moderate hemophilia, the CT increased fourfold to approximately 8.58 ± 0.56 min. At 1% FVIII, which represents the critical level at which hemophilic patients may exhibit spontaneous bleeding, CT further prolonged to 28.1 ± 0.84 min, a 15-fold prolongation as compared to controls with 100% FVIII. Both rivaroxaban and dabigatran increased the CT throughout all the different FVIII levels. In order to achieve a CT equivalent to the values with 1% FVIII in the control, ~10% FVIII was required for samples containing rivaroxaban and ~25% FVIII for dabigatran.
Conclusion: In patients with severe hemophilia A (> 1% FVIII levels) requiring anticoagulant therapy, it is a common practice to supplement these patients with FVIII until the plasma concentration reaches at least 50% that of normal. Our *in vitro* data suggest that, relative to the control with 1% FVIII, we achieved a similar prolongation of CT when FVIII levels were ~10% and ~25% for rivaroxaban and dabigatran, respectively. This suggests that less FVIII replacement may be required to achieve adequate hemostasis in patients receiving new factor-specific anticoagulants, thereby avoiding over-utilization of costly and potentially prothrombotic FVIII in hemophilia A patients requiring anticoagulants therapy.

OC 51.3
Binding and inhibition of cell surface tissue factor pathway inhibitor by an inhibitory fusion peptide

Dockal M, Pachlinger R, Baldin-Stoyanova A, Knofl F, Ullrich N, Ehrlich HJ and Scheiflinger F
Baxter Innovations GmbH, Vienna, Austria

Background: Tissue factor pathway inhibitor (TFPI) is a key regulator of factor X (FX) activation in the extrinsic pathway of blood coagulation. It inhibits FXa generation by formation of a quaternary complex consisting of factor VIIa (FVIIa), tissue factor (TF), FXa and TFPI. The main portion (~80%) of TFPI in humans is reportedly associated with endothelial cells.
Aim: We used human umbilical vein endothelial cells (HUVECs) as a model to demonstrate improved cell surface TFPI inhibition by a fusion peptide consisting of two peptides targeting two different binding epitopes on TFPI.
Methods: Binding studies of an inhibitory fusion peptide to TFPI on living cells were performed using fluorescence activated cell sorting (FACS) and fluorescence microscopy. HUVECs were incubated directly on the plates with different concentrations of a biotinylated TFPI inhibitory fusion peptide, and subsequently stained with streptavidin FITC. Competition experiments were performed using simultaneous incubation of biotinylated fusion peptide with a molar excess of non-biotinylated fusion peptide. To demonstrate binding of the fusion peptide to TFPI alpha and TFPI beta, cells were treated, before peptide incubation, with phosphatidylinositol phospholipase C (PI-PLC) to remove glycosylphosphatidylinositol (GPI) anchored TFPI beta from the cell surface. Inhibition of cell surface TFPI was analyzed in an FX activation assay performed on living cells. Incubation with an FVIIa-peptide mix and subsequent addition of FX and a FXa-specific fluorogenic substrate monitored the extrinsic tenase activity *in situ* in a fluorescence reader.
Results: Our findings clearly demonstrate that the fusion peptide binds TFPI in a concentration dependent manner; the specificity of its binding to cell surface TFPI was confirmed by competition experiments. We also showed that the fusion peptide binds TFPI alpha as well as TFPI beta on the surface of living HUVECs. This is consistent with its binding epitopes located on Kunitz domain (KD) 1, KD2 and their linker, which result in inhibition of cell surface TFPI in the cell based FX activation assay. FX activation assays demonstrated maximal inhibition of cell surface TFPI at fusion peptide concentrations as low as 10 nM. In contrast, the two peptides comprising the fusion peptide, alone or in combination, did not completely inhibit TFPI, even at very high concentrations.
Summary/conclusions: We provide evidence that a fusion peptide efficiently binds and inhibits endothelial cell surface TFPI as well as plasma TFPI, strongly suggesting that it may inhibit all vascular TFPI forms. Importantly, the molecular fusion of two peptide entities translates to a far more potent inhibition of cell surface TFPI than its two single peptide constituents; thus, the introduction of bivalency resulted in a synergistic effect. Highly potent inhibition of all intravascular TFPI forms is likely to ameliorate hemostasis in hemophilia.

OC 51.4

Plasma-derived factor IX concentrates, but not rFIX, support direct platelet activation and microparticle formation and, as a result of this, increase platelet mediated endogenous thrombin potential

Bertling A, Griess K, Brodde MF, Müller A and Kehrel BE
University Hospital Muenster, Muenster, Germany

Bachground: In pharmacokinetic studies the *in vivo* mean incremental recovery of BeneFIX was shown to be about 30% lower compared to plasma derived products although the mean half-life was similar. This indicates towards a different platelet activation and/or binding pattern of recombinant FIX in comparison to pdFIX. Surface-associated PDI is an important regulator of coagulation factor ligation to thrombin-stimulated platelets and of subsequent feedback activation of platelet thrombin generation.
Aims: The binding behaviour of rFIX Benefix and different plasma-derived factor IX (pdFIX) concentrates to platelets were studied and the ability to support thrombin formation in the presence of platelets was compared.
Methods: The influence of rFIX and pdFIX on platelet activation, microparticle formation and endogenous thrombin potential of gelfiltered human platelets resuspended in FIX depleted plasma was studied.
Results: rFIX and the different pdFIX concentrates did not differ in the promotion of endogenous thrombin potential in FIX deficient plasma that was depleted of cells, cell fragments and microparticles by ultracentrifugation. In contrast, the endogenous thrombin potential induced by a minute amount of thrombin was markedly increased by pdFIX in comparison to the rFIX Benefix. The observed increase in thrombin formation by pdFIX in comparison to the rFIX Benefix did not occur when external tissue factor was added. Several of the pdFIX products bound, in contrast to BeneFIX, already to non-activated platelets. In contrast, to induce rFIX binding to platelets, these needed to get activated by high concentrations of thrombin or collagen plus thrombin as described in the literature for FIX inside human plasma. PdFIX supported platelet microparticle formation induced by low concentrations of agonists, while rFIX did not.
Conclusion: We assume that support of platelet activation, microparticle formation and platelet mediated endogenous thrombin potential by pdFIX leads to the pharmacokinetic differences observed for rFIX and pdFIX.

OC 52.1

Intensive care outcomes of patients with thrombotic thrombocytopenic purpura: a single centre study

Alcada J[1], Hockings C[1], Taylor A[1], McGuckin S[1], Westwood JP[2], Walker D[1], Scully M[1] and MacCallum N[1]
[1]University College London Hospitals; [2]Haemostasis Research Unit, University College London, London, UK

Background: Thrombotic thrombocytopenic purpura (TTP) is a rare haematological disorder, associated with significant morbidity and mortality. Specifically, severe neurological or cardiac complications may require a high level of supportive care in the intensive care unit (ICU) setting.
Aims: To describe the TTP population admitted to ICU in a tertiary referral hospital.
Materials and Methods: Single-centre retrospective cohort study of consecutive patients admitted with TTP to ICU between September 2006 and October 2012. Patients were followed-up for a minimum of 3 months after hospital discharge.
Patient demographics, clinical, physiological and laboratory parameters were collected from admission and follow-up data. Acute Physiology And Chronic Health Evaluation II (APACHE II; ICU admission severity score) and Sequential Organ Failure Assessment (SOFA; daily organ dysfunction score) were determined, with normal scores being zero in healthy individuals.
ADAMTS13 activity using Frets and IgG auto-antibody to ADAMTS 13 (ELISA), were measured at presentation and throughout patients course and follow-up.
Results: There were 151 admissions with confirmed TTP, of which 58 acute episodes (57 patients) were admitted to ICU, representing 38% of TTP hospital admissions. 69% ($n = 39$) were female. Median age was 45 (IQR 33–59) years. 51% ($n = 29$) were Caucasian.
APACHE II was 16 (IQR 11.3–20.0), SOFA*tmax* (the cumulative organ insult during ICU) was 9.0 (IQR 5.0–14.8). Mean ICU and hospital length of stay (LOS) was 4.9 $\pm$ 9.8 and 16.7 $\pm$ 14.6 days respectively.
Mortality was 23% ($n = 13$). All deaths occurred in ICU, within 10 days of admission and 31% ($n = 4$) within 24 h. The most common reason for admission to ICU was neurological dysfunction (66%, $n = 38$), with decreased GCS accounting for 45%($n = 27$). ECG changes, ischemic cardiac pain, and cardiac monitoring represented 17% ($n = 10$) of admissions.
Mechanical ventilation was required for 41.7% ($n = 25$) (initiated in the referring centre in 12 cases), cardiovascular support for 23.3% ($n = 14$) and renal replacement therapy for 3.3% ($n = 2$). ADAMTS13 activity at presentation was > 5% in 86.7% ($n = 52$). 98% ($n = 57$) were treated by plasma exchange, 90% ($n = 54$) received steroids and 80% ($n = 48$) rituximab.
Death was the primary outcome. Patients who died had greater median APACHE II score (22.5 [IQR 16.3–31.5] vs. 13.0 [IQR 11.0–18.8]), SOFA*tmax* (19.0 [IQR 13.5–20.5] vs. 7.0 [IQR 5.0–10.5]), IgG anti-ADAMTS 13 antibody titre (70.0 [IQR 38.5–86.5] vs. 38.5 [IQR 12.3–73.0]) and troponin T (0.16 [IQR 0.08–0.43] vs. 0.05 [IQR 0.01–0.17]).
Decreased GCS ($P > 0.01$), mechanical ventilation ($P > 0.001$), cardiovascular support ($P > 0.001$) and troponin T > 0.05 μg/L ($P = 0.011$) were strongly associated with death.
Conclusion: From this large patient cohort, mortality is higher in patients admitted to ICU, a reflection of their greater physiological derangement and associated organ dysfunction. Neurological and cardiac involvements were the most common precipitants to ICU admission. Increasing severity of organ dysfunction, and hence corresponding organ support, as well as biochemical markers of disease severity were associated with death in ICU. Severity scores may be of use in triaging ICU admissions, with APACHE II predicted mortality (22.3%) closely matching actual mortality. We advocate close collaboration between haematologists and intensivists to develop the expertise required to manage this challenging groups of patients.

OC 52.2

ADAMTS13 and Von Willebrand factor antigen levels in patients with severe leptospirosis

Pangarsa EA[1], Gasem MH[2], Farhanah N[2], Suharti C[1] and Isbandrio B[3]
[1]Division of Hematology-Medical Oncology; [2]Division of Infectious Disease, Tropical Medicine and Immunology; [3]Faculty of Medicine, Diponegoro University, Semarang, Indonesia

Background: Leptospirosis is an acute febrile illness caused by infection with pathogenic *Leptospira* sp. The clinical spectrum of the disease varies from sub-clinical infection or flu-like episodes to severe disease characterized by jaundice, acute kidney injury and serious hemorrhages. Hematological manifestation is the hallmark of leptospirosis with thrombocytopenia and bleeding of multi-organs are common in the severe cases. Previous studies have shown the elevated soluble E-selectin and von Willebrand Factor (vWF) antigen in severe leptospirosis, reflecting endothelial cell dysfunction. The pathogenesis of thrombocytopenia in leptopirosis is not well understood. We do not

know whether ADAMTS13 has important role in the pathogenesis of thrombocytopenia in patients with leptospirosis.
Aims: To know the ADAMTS13 and vWF antigen levels in severe leptospirosis patients with and without bleeding manifestations.
Methods: A clinical cohort study was conducted in Dr Kariadi hospital, from 2011 to 2012. Sixty severe leptospirosis patients with bleeding, 10 severe leptospirosis patients without apparent bleeding manifestations, and 10 mild anicteric leptospirosis patients were included in the study. The levels of ADAMTS13 and vWF antigens were measured by ELISA.
Results: Fifty six (70%) patients were male, mean age: 48 years (range: 16–81). The levels of ADAMTS13:Ag were significantly different ($P = 0.024$) between the groups of severe leptospirosis with bleeding median: 352 ng/mL (29–885), without apparent bleeding 318 ng/mL (120–572) and mild leptospirosis 562 ng/mL (283–851). No statistical difference between the ADAMTS13:Ag levels in severe patients with bleeding compared to that of severe patients without apparent bleeding ($P = 0.163$). The levels of vWF: Ag were significantly different among the three groups, with median values of 1.1 (0.14–3.4) vs. 0.93 (0.46–1.84) vs. 0.97 (0.56–1.38) ng/mL. The low platelet count was correlated positively with the low levels of ADAMTS13:Ag (r = 0.389, $P = 0.000$), but there was a negative correlation between the platelet count and the level of VWF: Ag. (r = −0.349, $P = 0.002$).
Conclusion: In severe leptospirosis patients with bleeding, the levels of ADAMTS13:Ag decreased while the level of von Willebrand Factor: Ag elevated. The levels of ADAMTS13:Ag and vWF:Ag were associated with the thrombocytopenia.

OC 52.3
Very early onset of autoimmune thrombotic thrombocytopenic purpura in five children with polynesian origin in four combined with immunodeficiency

Mansouri Taleghani M[1], Bradbeer P[2], Cole N[2], Chan G[3], Lämmle B[1] and Kremer Hovinga JA[1]
[1]Bern University Hospital and University of Bern, Bern, Switzerland; [2]Starship Children's Hospital; [3]Auckland City Hospital, Auckland, New Zealand

Background: Autoimmune thrombotic thrombocytopenic purpura (aTTP) is a rare disease characterized by thrombocytopenia, microangiopathic hemolytic anemia with schistocytes on the peripheral blood smear and a variable degree of end organ ischemia. The seriousness of this disease is underlined by the high mortality if left untreated (80–90%) and relapsing courses in 44% of survivors which demands an optimal treatment regimen. The incidence is about 1.7 cases/million/year. Underlying is a severe ADAMTS13 deficiency (> 10% of the normal activity) due to inhibitory autoantibodies preventing normal processing of strong procoagulative unusually large Von Willebrand factor multimers. The first onset of aTTP typically occur in women between 20 and 40 years of age and are rarely seen in children.
Observation: Strikingly, over the last 7 years we observed frequently relapsing aTTP with severe acquired ADAMTS13 deficiency and inhibitory autoantibodies in five children 1–11 years of age of Polynesian origin. At least four of the five cases have additional signs and symptoms indicative of a common variable immune deficiency (CVID).
Results: Case 1, 2 and 3 have hypogammaglobulinaemia requiring regular intravenous immunoglobulin infusions (IvIg) for at least 5 years now. While in case 1 hypogammaglobulinaemia and other symptoms indicative of immunological dysregulation (eosinophilic colitis, asthma, eczema…) had been documented prior to the first aTTP episode, in cases 2 and 3 (siblings) this was noted after Rituximab treatment for relapsing aTTP episodes. A poor response to single vaccinations (Diphtheria and Tetanus, Pneumococcus) was documented in case 1 and 2. Case 4 has a negative pneumococcal serology. Case 1 and 3 suffer from recurrent invasive infections including pneumococcal pneumonia, meningitis and otitis media. Flowcytometry was done in two children revealing low CD4 (Case 1) and decreased switched- and memory B-cell levels (case 3), respectively.
Conclusions: Although cytopenias such as idiopathic thrombocytopenia or Evans' syndrome, which are both differential diagnoses of aTTP, and various other autoimmune diseases have been reported in CVID, the association with aTTP is novel (or underreported). The common Polynesian ethnicity and the shared clinical phenotype with the unusual early onset of aTTP hints at a new genetic underlying mechanism. Further detailed diagnostics to confirm CVID or similar according to standard criteria (www.esid.com), family studies and the search for common underlying genetic aberrations are underway.

OC 52.4
Genetic predisposing factors in five portuguese patients with atypical hemolytic uremic syndromeidentification of a new mutation in the CFH gene

Silva Pinto C, Fidalgo T, Martinho P, Salvado R, Oliveira AC, Gonçalves E, Sevivas T, Martins N and Ribeiro ML
CHUC-EPE, Coimbra, Portugal

Introduction: Atypical Hemolytic uremic syndrome (aHUS) is a rare disease characterized by thrombotic microangiopathic anemia (TMA) predominant renal impairment and absence of Shiga toxin infection as a trigger. Complement alternative pathway dysregulation plays an important role in the pathogenesis of aHUS; approximately 60% of aHUS patients have loss-of-function mutations in the genes encoding complement regulatory proteins (*CFH, CFI, MCP and THBD*) and gain-of-function mutations in complement activators, like factor B (*CFB*) and complement component 3 (*C3*). However, in nearly 40% of the patients no mutations have been identified, in these genes raising the possibility of other genetic causes. Polymorphisms in *CFH* gene have been associated with aHUS, age-related macular degeneration (AMD) and membrane-proliferative glomerulonephritis (MPGN). ADAMTS13 (disintegrin and metalloprotease with thrombospondin motifs) mutations have been associated to thrombotic thrombocytopenic purpura (TTP), characterized by TMA with neurologic symptoms, fever and kidney failure. TTP and aHUS overlap some of the phenotypic features and sometimes their clinical distinction is not clear.
Aim: In order to characterize the clinical diagnosis and molecular background in five patients with aHUS, we performed the screening of *ADAMTS13, CFH, CFI and MCP* genes.
Patients and Methods: Five unrelated Portuguese patients with aHUS were investigated: three children (age: 2, 7 and 10 years) and two adults (age: 35 and 39 years). The children and one adult male had more than two episodes. One adult patient died at presentation. Diagnosis of aHUS was considered in patients with microangiopathic hemolytic anemia, thrombocytopenia, acute renal failure, not associated with Shiga toxin, who presented ADAMTS13 antigen, activity and antibody within the normal range. *ADAMTS13*, *CFH*, *CFI* and *MCP* mutations were screened by PCR/direct sequencing of the promoter regions, exons and exon-intron boundaries. Hemolytic assay was performed using liposome immunoassay (LIA) and C3 and C4 serum levels were determined.
Results: (i) *Clinical and laboratory data:* In 4/5 patients the first episode of aHUS occurred at childhood (≤ 11 years). Plasma complement levels and plasma ADAMTS13 activity (45–107%; RV: 40–130) were normal in all patients. (ii) G*ene analysis: ADAMTS13*- 3 patients presented polymorphisms: Q448E; Q448E/A900V and R7W. Complement regulatory genes – three patients (two children and one adult) have mutations in the heterozygous state: *CFH*- p.N1050Y and p.R1215L; *MCP*c.287-2A>G. CFH p.R1215L, in the short consensus repeat-20, has not been previously reported and is considered 'proba-

bly damaging' by *in silico* analysis. All patients present 3–5 combined polymorphisms in *CFH* (V62I, A307A, H402Y, A473A, Q672Q, E936D) and *MCP* (IVS8+23 G>T). Two of the patients only presented polymorphisms in *ADAMTS13, CFH* and *MCP* genes.
Conclusion: All the five patients' with aHUS have polymorphisms in the complement regulatory genes and three of them also have mutations in *CFH* or *MCP* genes. Three of the patients have polymorphisms in *ADAMTS13*. The adult patient with *MCP* mutation also has two *ADAMTS13* polymorphisms in the heterozygous state. The study of the other complement genes is underway. Genetic screening of patients with aHUS is important to elucidate the diagnosis and to lead their management and specific treatment, eventually with complement inhibitors.

OC 53 – Contact activation

OC 53.1
Polyphosphate stimulates FXIIa-mediated fibrinolysis

Lionikiene AS and Mutch NJ
University of Aberdeen, Aberdeen, UK

Background: Factor XII (FXII) is classified as a coagulation factor, but is structurally homologous to the tissue-type plasminogen activator and urokinase. The activated form, FXIIa, is reported to function in fibrinolysis, but its role is not well characterised. FXII is activated upon binding to an anionic surface generating αFXIIa, a two-chain enzyme that retains the surface binding site within the heavy chain. Platelet polyphosphate (polyP) is known to bind FXII and accelerate autoactivation and activation by kallikrein.
Aim: This study investigates whether polyP regulates the function of FXIIa in fibrinolysis.
Methods: Fibrin clots were formed with fibrinogen (3.8 μM), glu- or lys-plasminogen (240 nM), αFXIIa (100 nM) ± polyP with an average chain length of 65 phosphates ($polyP_{65}$; 1 μM). In some experiments zymogen FXII (100 nM) was preincubated for 30 min with $polyP_{65}$ (2 μM) before addition to the fibrinogen-plasminogen mixture. Clotting was initiated with thrombin (0.25 U/mL) and $CaCl_2$ (10 mM) and fibrinolysis monitored at 405 nm. 50% clot lysis times were calculated and expressed as mean ± SEM. Plasminogen (200 nM) activation by αFXIIa (100 nM) ± polyP (1 μM) or FXII (100 nM) preincubated ± polyP (2 μM) was monitored using a chromogenic substrate (S2251).
Results: $PolyP_{65}$ significantly enhanced αFXIIa-mediated clot lysis (137 ± 3 min vs. > 360 min; $P > 0.0001$). Clots prepared with lys-plasminogen were more susceptible to αFXIIa-mediated lysis than clots formed with glu-plasminogen (154 ± 2.6 min vs. > 360 min; $P > 0.0001$); consistent with superior binding of the truncated form, lys-plasminogen, to fibrin. $PolyP_{65}$ enhanced αFXIIa-mediated lysis of clots formed with glu-plasminogen (137 ± 3 min) and lys-plasminogen (60 ± 4.1 min) to a similar degree (~2.6-fold). Therefore the ability of polyP to stimulate αFXIIa-mediated fibrinolysis does not arise from increased transition of the closed (glu) to open (lys) form of plasminogen. Chromogenic studies revealed that $polyP_{65}$ accelerates rates of activation of both glu-plasminogen and lys-plasminogen. $PolyP_{65}$ alone was unable to stimulate plasminogen activation and does not directly modify plasmin activity, indicating that $polyP_{65}$ is acting as a cofactor in αFXIIa-mediated cleavage of plasminogen to plasmin. We have previously shown that platelet polyP stimulates autoactivation of FXII. We therefore monitored the ability of $polyP_{65}$ to activate zymogen FXII and subsequently function as a cofactor in fibrinolysis. Addition of FXII, that had been pre-incubated with $polyP_{65}$, to clots containing fibrinogen and glu-plasminogen yielded clot lysis times of 203 ± 13 min. In the absence of $polyP_{65}$ FXII was unable to induce lysis within the 480 min time frame analysed. Consistent with the effects observed on clot lysis, accelerated rates of plasminogen activation were apparent in chromogenic assays when FXII was preincubated with $polyP_{65}$.
Conclusions: PolyP provides an appropriate surface for FXII activation and remains associated with the heavy chain of the enzyme. PolyP promotes the plasminogen activator function of FXIIa, thereby accelerating plasmin generation and downstream fibrinolysis. FXII circulates at high concentrations in plasma and, in the presence of platelet polyP, may be a potent regulator of fibrinolysis.

OC 53.2
A nanobody-based method for tracking factor XII activation in plasma

De Maat S, Van Dooremalen S, De Groot PG and Maas C
University Medical Center Utrecht, Utrecht, the Netherlands

Introduction: Factor XII (FXII) initiates blood coagulation, but can also independently trigger the inflammatory kallikrein-kinin system when plasma contacts anionic materials. While all contact activators induce inflammation, only few induce coagulation. Interestingly, active FXII (FXIIa) can occur in two forms: full-size α-FXIIa (80 kDa) triggers both coagulation and inflammation simultaneously, whereas truncated β-FXIIa (28 kDa) only displays proinflammatory activity. This suggests that the formation of trigger-specific FXIIa isoforms underlies each of the two contact activation responses. At present no method is available to detect free FXIIa in patient plasma.
Aim: To develop a bioassay for tracking FXII activation by various triggers in plasma.
Methods: FXIIa specific nanobodies (17 kDa monovalent camelid antibody fragments) were selected using a phage display system and implemented in an ELISA-based bioassay.
Results: Two nanobodies were selected for their ability to recognize FXIIa, but not FXII zymogen. Nanobody A10 recognizes the catalytic domain of purified α-FXIIa, but not that of purified β-FXIIa, whereas nanobody B7 recognizes both. This suggests minute differences in the catalytic domain between these two isoforms of FXIIa.
Capturing of FXIIa from human plasma is strongly enhanced by the small-molecular protease inhibitor PPACK. This molecule occupies the FXIIa active site and prevents the association of macromolecular plasma protease inhibitors, which prevents nanobody recognition.
Upon *in vitro* activation of the plasma contact system, our nanobody-based assays distinguish activation products of FXII that vary with the type of activator present: whereas procoagulant activators solely trigger the formation of a species that is captured by B7, proinflammatory activators first generate a species that is recognized by B7, which is later converted into a second species that is recognized by A10.
Conclusions: Our studies shows that the development of nanobodies offers new opportunities to investigate the activated enzymes in health and disease. Findings from our new bioassay indicate that a progressive proteolysis of FXIIa converts it from a coagulation factor into an inflammatory enzyme. The sensitivity achieved in this new assay is far greater than that of purified chromogenic substrate assays, enabling us to further examine the role of FXII in biocompatibility issues, cardiovascular disease or inflammatory conditions such as angioedema.

OC 53.3
Aberrant contact system activity causes hereditary angioedema type III

Björkqvist J[1], Sala-Cunill A[2], Cichon S[3] and Renné T[1]
[1]*Karolinska Institutet, Stockholm, Sweden;* [2]*Institut de Recerca Vall d'Hebron, Barcelona, Spain;* [3]*University of Bonn, Bonn, Germany*

Background and Aim: Hereditary angioedema (HAE) is an inherited rare disorder that is clinically characterized by life-threatening swelling attacks. In contrast to the classical HAE types I and II that are caused by deficiency in functional C1-esterase inhibitor, HAE type III patients have normal C1-esterase inhibitor. A single point mutation at position

Thr328 in coagulation factor XII (FXII) has been associated with HAE type III, however, mechanism and therapy of the disease have remained enigmatic.
Methods and Results: Here, we analyze mechanism of HAE type III in patient plasma and in edema models in genetically altered humanized mice. Chromogenic assays and substrate conversions indicated largely increased enzymatic activity of mutated vs. normal FXII. Recombinant and patient-derived FXII variants showed that the Thr328 substitution in FXII causes excessive activation of the plasma contact system resulting in overshooting production of the inflammatory mediator bradykinin. Addition of C1-esterase inhibitor dose-dependently blocked bradykinin production in HAE types I and II, but was inactive in HAE type III. Biological and small molecule FXII inhibitors interfered with aberrant contact system-triggered bradykinin formation in HAE type III plasma. To analyze the mechanism of HAE type III *in vivo*, we reconstituted FXII null mice with recombinant human FXII mutants and established a transgenic mouse that tetracycline-regulatable expresses Thr328-mutated human FXII in the liver. Intravital confocal scanning microscopy and tracer extravasation-based methods showed excessive bradykinin-mediated vascular leakage in HAE type III mice challenged by infused FXII-contact activators and in IgE/allergen-stimulated cutaneous anaphylaxis models, respectively.
Conclusion: This study elucidates the disease mechanism of HAE type III *in vivo* and *in vitro*, and suggests that FXII inhibition might be a rational therapeutic strategy for prevention and treatment of edema.

OC 53.4
Identification of leukocyte factor XII: a critical regulator of WBC function

Stavrou E[1], Fang C[1], LaRusch GA[1], Fullana MJ[1], Meyerson H[2], Qu CK[1], Wnek G[1] and Schmaier AH[1]
[1]Case Western Reserve University; [2]University Hospitals Case Medical Center, Cleveland, OH, USA

Background: Leukocytes from Factor XII (FXII) deficient patients migrate less into skin windows. Zymogen FXII binds to uPAR and stimulates cell signaling through β1 integrins, leading to endothelial cell proliferation and angiogenesis. *In vivo* FXII KO mice have reduced wound angiogenesis (Blood 115:4979, 2010).
Aims: Since FXII modulates wound angiogenesis, we examined FXII in inflammation and wound repair *in vivo*.
Methods: Skin wound (5 mm punch biopsies) and thioglycolate (TG)-induced chemical peritonitis were performed on *F12*−/−, uPAR-deleted (*Plaur*−/−), and Bradykinin B2 Receptor-deleted (*Bdkrb2*−/−)mice. Wounds were harvested from days 1 to 7 (D1-7) and frozen sections were stained with anti-CD11b, Gr-1, and F4-80. Analysis determined the relative number of neutrophils and macrophages in the wounds. In TG-induced peritonitis, the number of peritoneal exudate cells (PECs) was measured by cell counting and flow cytometry. Bone marrow (BM) transplantation experiments determined if the defect in murine *F12*−/− leukocytes was host- or bone marrow-derived. Determination of a leukocyte pool of FXII was performed by isolating bone marrow cells' mRNA followed by PCR on its cDNA. Leukocyte FXII antigen was determined by immunofluorescence. The contribution of plasma/liver- vs. leukocyte/bone marrow-derived FXII was determined by intravenous FXII siRNA injection creating plasma FXII deficiency in WT mice. The *in vivo* functions of leukocyte FXII were examined in wound healing experiments.
Results: On Day 1 after punch biopsy wounds, *F12*−/− mice exhibit decreased recruitment ($P = 0.0136$) of CD11b-labeled inflammatory cells to injury sites. *F12*−/− mice have reduced wound Gr-1(+) neutrophils and F4-80(+) macrophages. Similar findings were observed with *Plaur*−/− but not with *Bdkrb2*−/− mice. In the TG-induced peritoneal inflammation assay, *F12*−/− mice exhibited significantly decreased number of PECs on D1 and D7. *Plaur*−/− and *Bdkrb2*−/− mice had no defects in this assay. In *F12*−/− mice, there was a disproportionate decrease in neutrophil recruitment in peritoneal fluid. *F12*−/− macrophages have reduced adherence to plastic. On adoptive BM transplantation experiments, WT BM transplanted to *F12*−/− mice corrected the TG-induced PEC migration defect for D1 and D7 from instillation. Alternatively, *F12*−/− BM transplanted into WT, recapitulated the leukocyte defect observed in *F12*−/− mice. WT mice treated with FXII siRNA reduced plasma FXII activity, > 10% at 24 h ($T_{1/2} = 6.7$ h). Plasma FXII deficient mice did not have a PEC recruitment defect. Additionally, *in vivo* infusion of purified FXII did not correct the PEC recruitment defect in *F12*−/− mice. BM cell-derived mRNA from WT mice, reverse-transcribed to cDNA, demonstrates XII cDNA that shares sequence homology to hepatic XII from exons 2 through 14. Immunofluorescence staining of BM-derived leukocytes demonstrates XII in cells with nuclear morphology resembling monocytes and neutrophils. *In vivo*, murine FXII deficiency is associated with an improved rate of punch biopsy wound healing.
Conclusions: These data show that *in vivo*, there is a unique pool of leukocyte FXII (BM-derived) distinct from plasma (hepatic) FXII. Leukocyte FXII is responsible for leukocyte function in wounds and inflammation sites. *F12*−/−mice have attenuated wound injury and, paradoxically, improved wound healing rates. Modulation of leukocyte FXII promotes wound healing.

OC 53.5
Targeting the polyphosphate-coagulation factor XII pathway prevents cardiac ischemia-reperfusion injury without influencing bleeding risk

Nickel KF[1], Frantz S[2], Esmon CT[3], Gailani D[4] and Renné T[1]
[1]Karolinska Institutet, Stockholm, Sweden; [2]University Hospital Würzburg, Würzburg, Germany; [3]Howard Hughes Medical Institute, Oklahoma City, OK; [4]Vanderbilt University, Nashville, TN, USA

Background and Aims: Ischemia and reperfusion-elicited cardiac injury contributes to mortality in myocardial infarction. We have identified a critical role for the plasma protease coagulation factor XII (FXII) and its platelet-derived inorganic activator polyphosphate in cardiac ischemia-reperfusion injury.
Methods and Results: FXII deficiency and neutralization of polyphosphate with phosphatase largely reduced fibrin deposition and infarct size in ischemic myocardium. *Vice versa*, reconstituting FXII null mice with human FXII restored fibrin formation and myocardial injury in ischemic heart tissues. Factor XII deficient mice, animals lacking the FXII substrate factor XI, and mice with combined deficiency in factors XII and XI, are protected from myocardial infarction to similar degrees, indicating that FXII contributes to cardiac ischemia-reperfusion injury via the intrinsic pathway of coagulation. Deficiency in FXII and degradation of polyphosphate attenuated procoagulant platelet activity, impaired clot stability, and blocked thrombus formation under flow, resulting in significant protection from myocardial infarction. Despite its critical role in thrombus formation and tissue ischemia, genetic and pharmacologic targeting of the polyphosphate-FXII pathway did not increase bleeding risk.
Conclusion: The data reveal a fundamental role for polyphosphate-initiated, FXII-dependent coagulation in cardiac ischemia and implicate this pathway as a target for safe interference with ischemia-reperfusion injury.

OC 53.6

A pivotal role of regulatory pathways of autophagy during the formation of neutrophil extracellular traps (NETs) in human neutrophils

Itakura A and McCarty OJT

Oregon Health and Science University, Portland, OR, USA

Background: Activated neutrophils can form neutrophil extracellular traps (NETs) to sequester microbes in the extracellular environment through the mechanism called NETosis. The steps of NETosis are characterized by massive vacuolization, chromatin decondensation, membrane disruption and extracellular release of chromatin fibers armed with antimicrobial granular cargos. These dynamic cellular events require both activities of oxidative burst and autophagy; in fact, the lack of either axis leads to neutrophil apoptosis. However, the mechanistic detail of the regulation of NETosis is still poorly understood.

Aims: We aimed to determine the molecular mechanisms that coordinate neutrophil NETs formation in response to inflammatory stimuli. In particular, we investigated roles of the inhibitory pathways of autophagy, mTOR and calpain during NETosis.

Methods: Purified human neutrophils were stimulated with phorbol 12-myristate 13-acetate (PMA; an activator of protein kinase C), or f-Met-Leu-Phe (fMLP; a bacterial-derived peptide). In selected experiments, neutrophils were pretreated with pharmacological inhibitors. NETs formation was monitored in the presence of the cell-permeable DNA-binding dye, Hoechst 33342 and/or the cell-impermeable DNA dye, Sytox Green, using fluorescence microscopy.

Results: We found that the kinetics of PMA-driven NETosis was accelerated in the presence of inhibitors for the mTOR pathway (rapamycin) or calpain (ALLN), and that the combination of these two inhibitors resulted in an additive increase of NET formation as compared to vehicle-treated cells. Stimulation of neutrophils with fMLP alone failed to produce NETs; however the presence of the calpain inhibitor ALLN, but not the mTOR inhibitor rapamycin, resulted in vacuolization and efficient induction of NETosis in response to fMLP. Our data show that inhibitors for cytoskeletal machinery, such as myosin II (blebbistatin), microtubule (nocodazole) and actin polymerization (cytochalasin D), blocked PMA-induced NETs formation, as well as the effect of ALLN on NETosis downstream of fMLP.

Conclusions: Our findings suggest that mTOR and calpain pathways, which serve as inhibitory pathways of autophagy, can negatively regulate the initial stage of PMA-induced NETosis. This calpain activity may prevent neutrophils from undergoing NETosis downstream of the fMLP-receptor signaling pathways, thus playing a pivotal role in driving neutrophils toward either apoptosis or NETosis. Moreover, we show that NETs formation requires the activity of cytoskeletal machinery, highlighting multiple layers of regulatory mechanisms underlying NETosis.

OC 54 – Endothelial cells

OC 54.1

Fuelling the knowledge of blood coagulation signaling with time resolved quantitative phosphoproteomics of thrombin-stimulated endothelial cells

Van Den Biggelaar M[1], Hernandez J-R[2], Meijer AB[1], Mertens K[1] and Zanivan S[2]

[1]*Sanquin Research, Amsterdam, the Netherlands;* [2]*The Beatson Institute for Cancer Research, Glasgow, UK*

Thrombin is the central enzyme involved in blood coagulation. It serves an additional important function beyond coagulation by cleaving protease-activated receptors (PARs) on the cell surface of endothelial cells, thereby initiating signal transduction cascades. Through these signal transduction cascades, thrombin regulates the barrier function of the endothelium and the release of storage organelles, called Weibel-Palade bodies that contain various hemostatic and vasoactive substances. The identification of downstream effectors of PARs is critical for understanding the interactions between signaling cascades and for developing new pharmacological approaches for controlling thrombin- and PAR-mediated responses. Due to the complexity of signal transduction networks, the molecular mechanisms underlying endothelial signaling in response to thrombin have remained incompletely understood. Here we have combined Stable Istotope Labeling with Amino acids in Cell culture (SILAC), affinity-based phospho-peptide enrichment and high resolution mass spectrometry to perform a quantitative and time-resolved analysis of the thrombin induced signaling events in endothelial cells. Blood outgrowth endothelial cells (BOECs) were SILAC labeled and stimulated with 1 U/mL thrombin for 2, 5, 10 or 30 min in a three-way reverse labeling experiment. Digested peptides were separated using Strong Cation Exchange chromatography, enriched for phospho-peptides by titanium dioxide precipitation, and analyzed at the LTQ-Orbitrap Elite mass spectrometer. We identified and accurately quantified 7791 class I phosphorylation sites localized on a total of 2593 gene products. Of those, 2224 phosphorylation sites were found significantly regulated over the 30-min time course. Amongst others, we found the established PAR1 (thrombin) receptor, Rho-associated kinase 2, protein kinase C and phospholipase C, which provide a positive control for our quantitative approach. Further bio-informatic analysis highlighted enrichment of KEGG pathways, such as leukocyte transendothelial migration, focal adhesion and regulation of actin cytoskeleton, as well as various gene ontology categories, including GTPase regulator activity, regulation of Ras and Rho protein signal transduction and adherens junction. In addition to the identification of these well-established events, a wealth of previously unidentified phosphorylation sites and processes were found to be regulated. Our study clearly shows the enormous potential of using a global phosphoproteomic approach to unravel endothelial cell signaling, and we anticipate that the present study will be a powerful resource for cell biologists working in the fields of endothelial barrier function, Weibel-Palade body release and PAR-mediated signaling. Moreover, our study demonstrates that the key enzyme of the coagulation cascade thrombin initiates a powerful signal transduction cascade that results in the phosphorylation of a large array of downstream effectors and therefore emphasizes the intimate relation between coagulation and vascular biology.

OC 54.2

Aldosterone decreases thrombin generation via enhancement of thrombomodulin-mediated protein C activation

Regnault V[1], Lagrange J[1], Bourhim M[1], Fassot C[2], Nguyen Dinh Cat A[3], Wahl D[1], Jaisser F[3] and Lacolley P[1]

[1]*Inserm U1116, Vandoeuvre-les-Nancy;* [2]*Inserm U1083, Angers;* [3]*Inserm U842, Paris, France*

Background: Aldosterone (aldo) and its receptor, the mineralocorticoid receptor (MR) are implicated in several physiopathological processes such as heart failure. Aldo has been proposed to be prothrombotic through impairment of fibrinolysis in animal models. On the other hand, aldo, via MR activation, upregulates the endothelial protein C receptor (EPCR) in bone marrow endothelial cells and prolong clotting times in presence of activated protein C (APC). These findings suggest an imbalance of the hemostatic system, modulated by the extent of MR activation on endothelial cells. However, the role of MR, a ligand-activated transcriptional factor, in endothelial anticoagulant function remains to be elucidated.

Aims: Our aim was to investigate whether MR activation decreases *in vitro* thrombin generation at the surface of endothelial cells and modifies the thrombotic risk *in vivo*.

Methods: *In vitro*, we used human aortic endothelial cells (HAECs) to explore the mechanisms of MR activation on the dynamic anticoagulant APC pathway. HAECs were treated for 24 h with 10^{-8} M aldo in the presence or not of 10^{-6} M MR or glucocorticoid receptor antagonists. *In vivo* we used our mouse model with conditional overexpression of the MR in endothelial cells (MR-EC) (Nguyen Dinh Cat et al., FASEB J. 2010; 24:2454–63). Thrombin generation in mouse plasma or at the surface of adherent HAEC was measured using calibrated automated thrombography (CAT). Thrombus formation was evaluated in MR-EC mice after $FeCl_3$ injury.
Results: At the surface of cultured HAECs, thrombin generation was attenuated (area under the curve values (ETP): 785 ± 16 vs. 661 ± 16 nM.min, $P > 0.05$) and EPCR synthesis and secretion were increased by 20 and 30% upon stimulation with aldo. Blocking the MR, but not the glucocorticoid receptor, reversed these effects. Inhibition of protein C activation by an anti-thrombomodulin antibody resulted in an enhancement of thrombin generation, which was not impaired by aldo. Similar results were obtained with protein C-deficient plasma. When washed HAECs were incubated with purified protein C and increasing concentrations of thrombin, aldo enhanced APC generation on these cells in a thrombin dose-dependent manner. Vessel occlusion times after exposure of the carotid artery surface to ferric chloride was delayed in MR-EC compared with control mice (7.4 ± 0.5 vs. 4.4 ± 0.3 min, $n = 6$ in each group). In the absence of the APC system, thrombin generation parameters did not differ between MR-EC and CT mice. There was a greater ability of added APC to diminish thrombin generation in plasma of MR-EC mice compared to plasma of controls (ETP: 57 ± 10 vs. 145 ± 30 nM.min).
Summary/Conclusions: These findings reveal that MR activation in the vascular endothelium of healthy vessels can protect against thrombosis and demonstrate that MR-mediated EPCR overexpression drives this anti-thrombotic property through enhancement of thrombomodulin-mediated protein C activation. This anti-thrombotic property of MR activation may have clinical implications in drospirenone-containing oral contraceptives since drospirenone is a potent MR antagonist.

OC 54.3
Endothelium but not platelet derived thiol isomerase ERp57 is required for thrombosis *in vivo*

Jasuja R, Sharda AV, Kim SH, Furie B and Furie BC
Beth Israel Deaconess Medical Center, Boston, MA, USA

Background: The thiol-disulfide oxidoreductase ERp57 is a member of the endoplasmic reticulum resident protein disulfide isomerase (PDI) family. ERp57 is also found on the activated platelet surface. Like PDI, ERp57 mediates platelet activation and thrombus formation.
Aims: Here we determine the contributions of endothelial- and platelet-derived ERp57 to thrombus formation and fibrin generation in the mouse laser injury model.
Methods: To study contributions from different cellular sources ERp57 was depleted in mouse platelets using targeted gene deletion by crossing $ERp57^{flox/flox}$ mice with PF4 $Cre^{+/0}$ mice. Knockdown of ERp57 in all adult mouse tissues was achieved by blocking translation of ERp57 protein using vivo-morpholinos. Finally thrombus formation was examined in the presence of a function blocking antibody to ERp57.
Results: *In vitro* studies using cultured endothelial cells show that ERp57 is secreted rapidly into the culture medium on thrombin stimulation. ERp57 was also detected on the surface of endothelial cells by flow cytometry. Morpholino mediated knockdown of ERp57 did not affect the translation of other thiol isomerases: PDI, ERp5 and ERp72. Knockdown of ERp57 resulted in diminished platelet aggregation *in vitro*. Aggregation of platelets by 50 μM AYPGKF, a PAR4 agonist was also inhibited in platelet specific conditional knockouts for ERp57. This defect in aggregation was similar to inhibition observed in the presence of a function-blocking antibody to ERp57. There was also a defect in hemostasis observed by increased tail bleeding times in mice with platelet conditional knockout or morpholino knockdown of ERp57. Using intravital microscopy, we observed that ERp57 is detectable on activated endothelium of the vessel wall after laser injury and in the developing thrombus. The median integrated fluorescence intensity for ERp57 in wild-type mice was compared to wild-type mice injected with eptifibatide, an inhibitor of platelet activation, and thus an inhibitor of the contribution of ERp57 derived from platelets. ERp57 expression was similar in both treated and untreated animals up to 20 sec after injury. After 20 sec, the expression of ERp57 in eptifibatide-treated mice decreased significantly compared to that in untreated mice, indicating that initial ERp57 was derived from the endothelium and later additional ERp57 was derived from platelets following their accumulation in the thrombus. Infusion of a function-blocking antibody to ERp57 prior to vessel wall injury led to dose-dependent inhibition of platelet thrombus formation and fibrin generation in the mouse laser injury model of thrombosis. Deletion of ERp57 by gene targeting of PF4 in platelets as well as vivo-morpholino mediated translational block demonstrated a reduction in platelet thrombus formation as well. However, the rate and amount of fibrin generation were diminished only in mice with global ERp57 knockdown either by antibody mediated functional inhibition or morpholino mediated translational block.
Summary/Conclusion: These results provide evidence for a role of platelet and endothelium derived thiol isomerase, ERp57, in thrombus formation. Early in the time course of laser-induced thrombus formation the primary source of ERp57 is the endothelium. As we have observed previously in our laser-induced injury model the activated endothelium at the injury site can support maximal fibrin formation.

OC 54.4
Parmodulins act at PAR1 to stimulate cytoprotective genetic program in endothelial cells

Aisiku OR[1], Peters CG[1], Dilks JR[1], Fitch-Tewfik JL[1], Dockendorff C[2] and Flaumenhaft R[1]
[1]Beth Israel Deaconess Medical Center, Boston, MA; [2]Marquette University, Milwaukee, WI, USA

Background: Activation of PAR1 in endothelial cells by thrombin elicits its loss of barrier function and apoptosis. In contrast, activation of PAR1 by APC stimulates cytoprotective signaling in endothelium. We have identified and characterized a novel class of small molecules, termed parmodulins, which modulate PAR1 function by acting at the intracellular face of the receptor. In platelets, parmodulin-1 (aka JF5, PNAS, 108:2951) and parmodulin-2 (aka ML161, ACS Med Chem Lett, 3:232) selectively block signaling downstream of PAR1 and interfere with thrombosis, but not hemostasis in murine models.
Aims: Our goal was to determine whether parmodulins act on PAR1 to modify the function of endothelial cells.
Results: Initial studies demonstrated that parmodulins blocked thrombin-induced loss of barrier function as assessed by immunofluorescence microscopy of phalloidin-stained human umbilical vein endothelial cell (HUVEC) monolayers. Unexpectedly, parmodulins also protected against apoptosis induced by TNF-α or staurosporine as assessed by staining with YO-PRO-1 dye. To confirm that parmodulins acted at PAR1 to achieve their cytoprotective activity, we tested their ability to prevent TNF-α-induced apoptosis in HUVECs transfected with either PAR1 siRNA or a vector control. Parmodulins and APC both protected mock-transfected HUVECs from TNF-α-induced apoptosis. In contrast, neither parmodulins nor APC protected against apoptosis in PAR1 knockout HUVECs. A 4 h exposure to parmodulins was required to achieve maximum protection against TNF-α-induced apoptosis, raising the possibility that parmodulins stimulate a cytoprotective genetic program in endothelial cells. Transcript profiling of > 30,000 genes was performed in HUVECs exposed to vehicle alone, parmodulin-2, TNF-α, or parmodulin 2 then TNF-α. TNF-α elicited the upregulation of 748 genes. Parmodulin-2 inhibited upregulation of 107 of these genes by > 1.5-fold and elicited upregulation of 26 genes by > 1.5-fold. RT-PCR confirmed parmodulin-2-mediated inhibition of MMP10, END1, TL2, and RSPO3 transcripts as well as parmodulin-2-mediated upregulation ofSTC-1 transcripts. Several of

the genes downregulated by parmodulin-2 are under the control of NF-kB. Both parmodulins and APC blocked TNF-α-induced expression of a GFP reporter construct under the control of a NF-kB sensitive promoter, confirming the transcript profiling results indicating that parmodulins act in part by inhibiting signaling to NF-kB. Stanniocalcin-1, which was upregulated in response to parmodulin-2, has cytoprotective effects in endothelial cells. We therefore evaluated stanniocalcin-1 protein expression in response to parmodulins. Exposure to parmodulins 1 and 2 resulted in a 3.7 + 1.1-fold and 4.4 + 0.4-fold increase in stanniocalcin-1, respectively. Stimulation with APC, low dose thrombin and SFLLRN stimulated stanniocalcin-1 levels 5.0 + 0.8-fold, 3.0 + 0.3-fold, and 2.8 + 0.8-fold, respectively. Since the cytoprotective effects of parmodulins resemble those of APC and APC blocks inflammation and sepsis *in vivo*, we evaluated parmodulin-2 in a mouse model of inflammation. In these studies, parmodulin-2 completely blocked the sixfold increase in leukocyte rolling observed over the 70 mins following surgical exposure of cremaster venules.

Conclusions: Parmodulins are the first small molecules identified to activate a cytoprotective genetic program in endothelial cells through PAR1. They interfere with NF-kB-mediated transcription and stimulate expression of stanniocalcin-1. These biased PAR1 endothelial cell agonists represent a new strategy in the treatment of inflammatory disorders and sepsis.

OC 54.5

Endothelial Protease Nexin-1 potentiates the cytoprotective effects of activated Protein C by preventing endothelial Protein C receptor shedding

Bouton M-Ch[1], Boulaftali Y[2], François D[1], Venisse L[1], Jandrot-Perrus M[1] and Arocas V[1]

[1]Inserm U698, Paris cedex18, France; [2]The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Background: Human protein C is a plasma serine protease that plays a key role in haemostasis, and activated protein C (aPC) is known to elicit protective responses in vascular endothelial cells. This cytoprotective activity requires the interaction of the protease with its cell membrane receptor, endothelial protein C receptor (EPCR), followed by the activation of the protease-activated receptor-1 (PAR-1). However, the mechanisms regulating the beneficial cellular effects of aPC are not well-known.

Aims: The scientific question we address is to determine whether a serine protease inhibitor called protease nexin-1 (PN-1) or serpinE2, expressed by vascular cells, can be considered as a new player in the cytoprotective aPC pathway.

Methods: We studied the cytoprotective activities of aPC *in vitro*, by analyzing its effect both in the model of staurosporine-induced apoptosis and in thrombin-induced permeability in a dual-chamber system, using EAhy926 endothelial cells whose PN-1 expression was silenced by siRNA transfection or blocked with a specific neutralizing anti-PN-1 antibody. Dermal vascular hyperpermeability was also explored *in vivo* by using a modified Miles assay. In this assay we compared the leakage of Evan's Blue in response to local intradermal injection of VEGF in both wild-type and PN-1-deficient mice.

Results: We observed that vascular barrier protective and anti-apoptotic activities of aPC were reduced both in endothelial cells underexpressing PN-1 and in endothelial cells whose PN-1 function was blocked by a neutralizing antibody. Our *in vitro* data were further confirmed *in vivo*, since local intradermal injection of aPC could abolish VEGF-mediated hypermeability in the skin of wild-type mice whereas it had no protective effect in the skin of PN-1-deficient mice. These data can be explained by a previously unknown protective role of endothelial PN-1 on EPCR shedding. We indeed provided evidence that PN-1 inhibits furin activity, a serine protease known to activate a disintegrin and metalloproteinase 17 (ADAM17) involved in the shedding of EPCR. We evidenced *in vitro* by using recombinant proteins that PN-1 forms a SDS-stable complex with furin which leads to the inhibition of furin activity, and thereby reduces the furin-dependent maturation of proADAM17. Moreover double immunofluorescence revealed that furin colocalized with PN-1 both at the intracellular level and at the surface of the cells, indicating a direct interaction between PN-1 and furin in endothelial cells.

Conclusions: Our results demonstrate an original role of endothelial PN-1 as a furin convertase inhibitor, providing new insights for understanding the regulation of EPCR-dependent aPC endothelial protective effects. Both PN-1 and furin are expressed in numerous cells, and since furin represents a processing enzyme of various cell surface receptors and growth factors, its inhibition by PN-1 open new fields of investigation in many different disciplines.

OC 54.6

Platelet endothelial aggregation receptor-1 is a critical determinant of endothelial cell function

Vandenbriele C[1], Kauskot A[2], Luttun A[2], Janssens S[2], Hoylaerts MF[2] and Verhamme P[2]

[1]KU Leuven; [2]Center for Molecular and Vascular Biology, Leuven, Belgium

Background: Platelet endothelial aggregation receptor-1 (PEAR1), a type I transmembrane receptor, is expressed on platelets and endothelial cells (ECs) but its contribution to EC function is unknown. We aimed at unraveling its physiological and pathophysiological role in ECs.

Methods and Results: PEAR1 expression was analyzed by qPCR in cultured human endothelial progenitors (blood outgrowth endothelial cells or BOECs), in ECs from human umbilical cord and in ECs freshly isolated from multiple vascular beds. PEAR1 mRNA expression was heterogeneous, with the lowest expression in BOECs and the highest in macrovascular and microvascular ECs from heart and liver tissue. ECs from umbilical cord showed intermediate expression levels. Stainings of fast growing hemangiomas (human pyogenic granuloma) revealed low expression of PEAR1 in the young, rapidly proliferating ECs of the granuloma compared to normal subcutaneous ECs.

The role of PEAR1 in EC proliferation was evaluated in the hybrid cell line EA.hy926. Knockdown of PEAR1 by lentiviral transduction with a short-hairpin anti-PEAR1 construct (shPEAR1) doubled the EA.hy926 EC proliferation rate, as compared to control lentiviral-transduced cells. This was associated with significantly increased baseline Akt-P levels (PI3K-activity) in shPEAR1 cells and significantly decreased levels of the Akt-P phosphatase PTEN. Expression of the nuclear proliferation suppressor p21/CIP1 in shPEAR1 ECs was reduced by 60 ± 2% (mean ± SEM, qPCR and Western blot), whereas the band intensity on Western blots for the cyclin-dependent kinase CDC2 significantly increased, consistent with increased mitosis. During *in vitro* matrigel tube formation assays, using human umbilical artery endothelial cells (HUAECs), PEAR1 expression rose fivefold. This was associated with a threefold increase of PTEN. In constrast, during tube formation of PEAR1-knockdown HUAECs, PTEN-levels dropped 1.5-fold. PEAR1-knockdown significantly ($P > 0.005$) increased total tube length, the number of tube branching points and the number of tubes compared to control HUAECs. These findings are in accordance with the increased baseline phosphorylation of Akt in shPEAR1 ECs.

Anti-PEAR1 antibodies behaved as a pseudo-ligand in EA.hy926 ECs and HUAECs and triggered PI3-kinase activation, resulting in PEAR1 phosphorylation and a short-term elevation of Akt-P levels. This elevation enhanced the phosphorylation of eNOS (activating site P1177 on Western blot), an enzyme responsible for rapid production of NO in ECs. Correspondingly, anti-PEAR1 antibodies mildly stimulated tube formation of control HUAECs.

Conclusions: Our study provides the first evidence that PEAR1 is expressed in ECs from multiple vascular beds and that PEAR1 sup-

presses proliferation, modulates eNOS-activation and controls tube formation processes via the PI3K/Akt/PTEN- pathway in ECs. The upregulation of PEAR1 during EC maturation is compatible with a role for PEAR1 in endothelial cell differentiation.

OC 55 – Immune Thrombocytopenia Purpura

OC 55.1

Modified HPA-1a monoclonal antibody to prevent fetal-alloimmune thrombocytopenia

Bakchoul T[1], Santoso S[2], Sachs UJ[2], Bein G[2], Greinacher A[1] and Newman P[3]

[1]Ernst-Moritz-Arndt University Greifswald, Greifswald; [2]Institute for Clinical Immunology and Transfusion Medicine, Justus-Liebig Univ, Giessen, Germany; [3]Blood Research Institute, BloodCenter of Wisconsin, Milwaukee, WI, USA

Background: Fetal/neonatal alloimmune thrombocytopenia (FNAIT) is often caused by maternal alloantibodies against the human platelet antigen (HPA)-1a. Subsequent platelet destruction is mediated via the Fc-part of the alloantibodies. The monoclonal antibody SZ21 binds to the HPA-1a-epitope and inhibits binding of maternal alloantibodies. However, it also promotes complement activation and phagocytosis. Deglycosylation of antibodies abrogates the Fc-related effector functions but may still allow transplacental transport.
Aims: To investigate the use of *N*-glycan modified HPA-1a antibody in preventing platelet destruction in FNAIT.
Methods: To modify the *N*-glycan of SZ21, deglycosylation was performed under native conditions using Endo F, and the modification was evaluated by Coomassie Blue and lectin blotting. To investigate transplacental transport, pregnant BALBc mice were injected with SZ21, *N*-glycan modified (NGM)-SZ21 or isotype-matched control IgG antibody at gestation day 17. The impact of *N*-glycan removal on the binding affinity of SZ21 for the HPA-1a-epitope on GPIIb-IIIa was analyzed using Surface Plasmon Resonance (SPR). The ability of NGM-SZ21 to prevent anti-HPA-1a-mediated platelet clearance *in vivo* was investigated using the NOD/SCID mouse model of alloimmune thrombocytopenia.
Results: Endo F treatment only removed the *N*-glycan attached to Asn 297 of the antibody heavy chain without altering the protein structures. When injected into pregnant mice, both native SZ21 and NGM-SZ21 were transported equally into fetal circulation (8.9% vs. 8.7%, $p > 0.05$). The binding properties of NGM-SZ21 to HPA-1a were not affected after *N*-glycan modification (fitted equilibrium dissociation constant 1.17×10^9 vs. 4.36×10^9 M, $p > 0.05$). NGM-SZ21 prevented platelet-destruction induced by maternal anti-HPA-1a antibodies *in vivo* in the NOD/SCID mouse model (Elimination of HPA-1a-platelets: 62% vs. 18%, $P = 0.013$).
Summary/Conclusion: Deglycosylation of SZ21 abrogates Fc-moiety related effector functions, while neither its transplacental transport nor its capacity to block binding of maternal HPA-1a antibodies to platelets was impaired. Humanized, deglycosylated anti-HPA-1a monoclonal antibodies may represent a novel treatment strategy to prevent anti-HPA-1a mediated platelet destruction in FNAIT.

OC 55.2

Anti-GPIb antibody induces platelet desialylation: a novel mechanism of Fc-independent immune thrombocytopenia, and a potential new diagnosis and therapy against refractory ITP

Van Der Wal E[1], Li J[2], Zhu G[3], Vadasz B[2], Ma L[2], Yougbare I[4], Lang S[2], Freedman J[2] and Ni H[5]

[1]Canadian Blood Services; [2]Li Ka Shing Knowledge Institute of St. Michael's Hospital, University of Toronto; [3]Li Ka Shing Knowledge Institute of St. Michael's Hospital; [4]Canadian Blood Services, St. Michael's Hospital; [5]St. Michaels Hospital, University of Toronto, Canadian Blood Services, Toronto, ON, Canada

Background: Autoimmune thrombocytopenia (ITP) is characterized by patients' antibodies targeting their own platelet antigens, primarily glycoprotein (GP)IIbIIIa-integrin (70–80%) and GPIb-complex (20–40%). Current paradigm suggests that clearance of opsonized platelets through the reticuloendothelial system via Fcγ-receptors results in thrombocytopenia and bleeding disorders. However, evidence from our group and others have demonstrated that anti-GPIbα, but not anti-GPIIbIIIa, can induce thrombocytopenia via an Fc-independent pathway, which is resistant to intravenous IgG (IVIG) therapy in murine ITP-models (Blood 2006). These observations are consistent with subsequent IVIG studies in human ITP patients. Interestingly, human anti-GPIb-mediated ITP patients seem also resistant to steroid therapy in our recent retrospective study (American Journal of Hematology 2012). This suggests that anti-GPIbα antibodies may induce platelet clearance through a different mechanism which is currently poorly understood.
Methods: We developed unique mouse anti-mouse monoclonal antibodies (mAbs) in GPIIIa or GPIbα deficient mice, which also cross-react with human GPIIbIIIa and GPIbα. Flow cytometry was used to evaluate whether these mAbs were able to induce platelet activation, apoptosis and desialylation. Fc-independent phagocytosis of anti-GPIbα opsonized platelets was examined using FcγR blockers. The role of desialylation on GPIbα in platelet clearance was assessed using neuraminidase (NA) and it's inhibitor *N*-acetyl-2,3-dehydro-2-deoxy neuraminic acid (DANA). We also repeated these experiments with human platelets and plasma from human ITP-patients.
We also investigated the effects of anti-GPIbα antibodies on platelet activation, apoptosis and clearance *in vivo*. Briefly, BALB/c mice were injected with anti-GPIbα or anti-GPIIIa mAbs and 24 h later, platelet desialylation, activation and apoptosis were measured by flow cytometry. The effect of desialylation on platelet clearance was assessed with DANA. The significance of Ashwell-Morell Receptors (AMR) in anti-GPIbα-mediated platelet clearance in the liver was examined using asialofetuin, a blocker of AMR.
Results and Discussion: We found that anti-GPIbα, but not anti-GPIIbIIIa mAbs, induced significant platelet desialylation, P-selectin expression, phosphatidylserine (PS)-exposure, and increased inner membrane mitochondrial depolarization (ΔY_m). Moreover, we found that desialylation of GPIbα is functionally coupled with platelet activation, as prior treatment with activation inhibitors abrogated desialylation and treatment with DANA diminished PS-exposure, and P-selectin expression. Most importantly, incubations of human platelets with ITP-patient plasma showed similar effects. *In vivo*, we found significant increases in PS-exposure and ΔY_m induced by anti-GPIbα, but not by anti-GPIIIa mAbs. Interestingly, prior injection with DANA rescued platelets numbers in anti-GPIbα, but not in anti-GPIIIa injected mice. A significant role for AMR and MAC-1 receptors in the clearance of deglycosylated platelets was observed; blocking of AMR by asialofetuin, decreased platelet clearance in anti-GPIbα, but not anti-GPIIbIIIa antibody injected mice and Fcγ-independent phagocytosis occurred with anti-GPIbα opsonized platelets but not anti-GPIIbIIIa. Thus, we demonstrate for the first time that anti-GPIbα antibodies induce GPIbα desialyation, platelet activation and apoptosis. Therefore, we identified novel

Fc-independent platelet clearance pathways, more specifically, via AMR and MAC-1 receptors in the liver. These findings may lead to novel therapeutic regimens including the potential use of sialidase inhibitors as a solution for anti-GPIb-mediated ITP patients previously refractory to both steroid and IVIG therapies.

Dendritic cells differently phagocytose activated or apoptotic blood platelets

Maitre B, Mawhin MA, Eckly A, Heim V, De La Salle H and Gachet C

UMR_S949, Inserm, Université de Strasbourg, EFS-Alsace, Strasbourg, France

Background: In several auto-immune diseases, platelets are destroyed by auto-antibodies, resulting in hemorrhagic syndromes. Among the cells involved in the immune response, dendritic cells (DCs) are crucial antigen presenting cells, as they may initiate autoimmunity through the stimulation of naïve T lymphocytes (TL). The ability of DCs to phagocytose platelets and further to present platelet antigens to T cells has still to be studied in depth.
Objectives: The aim of our project was to define whether resting, activated or apoptotic platelets could be internalized by DCs, which would be critical for the promotion of platelet antigen presentation to TL.
Methodology: Human immature DCs were derived from blood monocytes and co-cultured with resting, 1U/mL thrombin-activated or 1 μM ABT737-treated apoptotic platelets for 18 h at 37 °C. The cells were then fixed and analysed by confocal microscopy to establish a phagocytosis index. Immunolabeling and electron microscopy were performed to analyse the localization of the internalized platelets.
Results: After 18 h of co-incubation, the percentage of DCs that had phagocytosed resting platelets was $3 \pm 1\%$. This percentage reached $12 \pm 1\%$ and $18 \pm 2\%$ when activated or apoptotic platelets were incubated with DCs respectively, the difference between activated and apoptotic platelets being statistically significant ($n = 5$, $P > 0.01$). This process depends on the exposure of phosphatidylserine at the platelet surface, as it was inhibited ($7 \pm 1\%$ vs. 13 ± 2 for activated platelets, $8 \pm 2\%$ vs. 21% for apoptotic platelets), in the presence of recombinant annexin V ($n = 3$, $P > 0.05$). Interestingly, electron microscopy observation revealed that, after 18 h, activated platelets were found in Major Histocompatibility Class II (MHC-II)-positive compartments, while apoptotic platelets were found in MHC II-negative phagosomes, suggesting different routes of phagocytosis.
Conclusion: Our study provides evidence that DCs differentially internalize activated or apoptotic platelets which may result in different mechanisms of antigen handling, processing and presentation.

OC 55.4

Autoantibody binding to glycoprotein Iba induces Fc?RIIa-mediated platelet activation in a patient with immune thrombocytopenia

Gitz E[1], Van Der Wal E[2], Koekman CA[1], Huisman A[1], Van Den Heuvel DJ[3], Gerritsen HC[3], Deckmyn H[4], Akkerman JWN[1], Schutgens REG[1] and Urbanus RT[1]

[1]*University Medical Center Utrecht, Utrecht, the Netherlands;* [2]*Monash University, Melbourne, Vic., Australia;* [3]*University Utrecht, Utrecht, the Netherlands;* [4]*KU Leuven, Kortrijk, Belgium*

Background: The primary targets of autoantibodies in immune thrombocytopenia (ITP) are the platelet receptors αIIbβ3 (70–80%) and glycoprotein (GP) Ibα (20–40%). Anti-αIIbβ3 antibodies are thought to induce thrombocytopenia through increased platelet clearance by Fcγ receptor-bearing macrophages, which is prevented with intravenous immune globulins. The molecular mechanism of thrombocytopenia observed in patients with autoantibodies against GPIbα, who are often refractory to this treatment, is less clear. Anti-GPIbα antibodies are known to induce platelet activation, which may be a cause for accelerated platelet destruction in ITP patients with autoantibodies against this receptor.
Methods: We investigated the effects of anti-GPIbα autoantibodies on platelet activation with fluorescent activated cell sorting. GPIbα translocation, clustering and colocalization with FcγRIIa after autoantibody binding were determined by Förster Resonance Energy Transfer (FRET) using time-gated Fluorescence Lifetime Imaging Microscopy (FLIM).
Results: Platelets from an ITP patient with anti-GPIbα antibodies showed elevated surface expression of P-selectin (12-fold), fibrinogen (twofold) and phosphatidylserine (fivefold). Phagocytosis of patient platelets by matured monocytic THP-1 cells was 21-fold increased compared with controls. Incubation of normal platelets with patient plasma caused platelet activation, which was prevented by removal of the GPIbα ectodomain or IgG depletion. FRET/FLIM analysis revealed that patient antibodies induced translocation of GPIbα to lipid rafts, where it colocalized with the low affinity Fc-receptor FcγRIIa. A blocking antibody against FcγRIIa, or inhibition of GPIbα translocation to lipid rafts with ganglioside GM3 prevented antibody-induced platelet activation.
Conclusions: The results demonstrate that binding of autoantibodies induces GPIbα translocation to lipid rafts where it clusters. This facilitates autoantibody ligation to FcγRIIa, resulting in platelet activation and destruction by macrophages. Blockage of autoantibody-FcγRIIa interaction in lipid rafts may be a therapeutic target for the treatment of ITP.

OC 55.5

Therapeutic efficacy of rapamycin in patients with chronic immune thrombocytopenia

Dai L

Key Lab of Thrombosis and Hemostasis, Jiangsu Institute of Hematology, the First, Suzhou, China

Introduction: Although immune thrombocytopenia (ITP) is an autoantibody-mediated disease characterized by destruction and impaired platelet production, dysfunctional cellular immunity has also great importance in ITP pathogenesis. Rapamycin, as an immunosuppressant that inhibits T-cell proliferation but selectively spares regulatory T (Treg) cells, has broad prospects in the field of transplantation immunology and autoimmune diseases. In this study, we investigated the effects of rapamycin on the chronic ITP (cITP) patients and to further explore its possible mechanisms.
Design and Methods: Peripheral blood samples were collected from cITP patients. The rate of $CD4^+$ $CD25^+$ Treg cells was analyzed using flow cytometry (FCM), and the Foxp3 mRNA expression was assessed by quantitative reverse-transcription polymerase chain reaction (RT-PCR). In addition, the levels of relevant cytokines were measured by enzyme-linked immune sorbent assay (ELISA) before and after the rapamycin treatment. Furthermore, the suppressive ability of Treg cells isolated from patients and healthy controls was evaluated via coculturing Treg cells and their autologous $CD4^+$ T or $CD8^+$ T cells in the culture medium.
Results: Among thirty-five treated patients who did not respond to previous steroid and immunosuppressant agents, thirteen patients achieved complete response and eight patients achieved partial response. Following treatment with rapamycin, the levels of Treg cells increased ($P > 0.05$); the Foxp3 mRNA expression greatly enhanced and the concentrations of IL-10 and TGF-β(beta) also increased in the responsive group ($P > 0.05$); the suppressive ability of Treg cells isolated from cITP patients was significantly lower than that of the con-

trol group ($P > 0.05$), meanwhile, the Treg cells displayed enhanced function for $CD8^+$ T cells after treatment ($P > 0.05$).
Conclusions: For cITP patients who displayed impaired activity and frequencies of Treg cells, rapamycin could suppress proliferation of both $CD4^+$ T and $CD8^+$ T cells, promote expansion of functional Treg cells and increase their suppressive capacity. Our results suggest that rapamycin might be a potentially therapeutic tool for treating cITP patients.

OC 55.6

A novel monoclonal antibody against GPIbalpha (Gi10) inhibits human platelet clearance induced by autoantibodies against GPIb/IX from ITP patients in a NOD/SCID mice model

Santoso S[1], Sachs UJ[1], Bakchoul T[2], Giptner A[1] and Santoso S[1]
[1]*Clinical Immunology and Transfusion Medicine, Giessen;* [2]*Institute for Immunology and Transfusion Medicine, Greifswald, Germany*

Background: Idiopathic thrombocytopenic purpura (ITP) is an autoimmune disease caused by autoantibodies (aabs) against platelet glycoproteins (GPs) IIb/IIIa and Ib/IX. Recent evidence indicates that aabs against GPIb/IX mediate platelet destruction by a different mechanism in comparison to aabs against GPIIb/IIIa (Fc-independent vs. Fc-dependent pathway) (Webster et al., 2006). Accordingly, patients with ITP mediated by anti-GPIb/IX aabs seem to be less responsive to IVIG treatment (Li et al., 2012). Thus, alternative therapy option should be considered for these refractory patients.
Aims: In this study, we aimed to analyse the capability of a novel mouse monoclonal antibody (mab) specific for GPIb (mab Gi10) to interfere with the binding of aabs against GPIb/IX *in vitro*. In addition, the capability of this mab to inhibit platelet clearance *in vivo* was investigated in a previously established NOD/SCID mouse model (Newman et al., 2007).
Methods: Only sera from well-characterized ITP patients containing GPIb/IX aabs ($n = 10$) were included. All sera were tested by the glycoprotein specific immunoassay, MAIPA, using a panel of mabs against different GPIb/IX subunits (Ibalpha, Ibbeta and IX). The inhibitory capacity of mab Gi10 toward anti-GPIb/IX aabs was investigated by flow cytometry. Analysis of human platelet clearance by anti-GPIb/IX aabs and mab Gi10 was performed in the NOD/SCID mouse model.
Results: Mab Gi10 was characterized in our laboratory and showed specific reaction against GPIbalpha remnant on platelets. Mab Gi10 did not affect platelet function *in vitro* (Kiefel et al., 1991). Analysis of aabs against GPIb/IX in the MAIPA assay using mab Gi10 as capture antibody showed significant reduction of aabs reactivity when compared to other capture mabs against GPIbalpha (clone AP1, SZ2), GPIX (clone FMC25) and GPIbbeta (clone Gi22), indicating binding competition between mab Gi10 and GPIb/IX aabs. These results could be confirmed by flow cytometric analysis; pre-incubation of platelets with mab Gi10 blocked the binding of GPIb/IX aabs. When purified IgG fractions of GPIb/IX aabs or mab Gi10 were injected into the NOD/SCID mouse, clearance of human platelets from mice blood circulation were observed. However, a significant reduction of platelet clearance was detected when mice were pre-treated with deglycosylated mab Gi10 (NGM-Gi10) prior to injection of aabs against GPIb/IX.
Summary and Conclusions: These data demonstrate the capability of mab Gi10 to hinder the binding of GPIb/IX aabs and thereby to inhibit platelet clearance *in vivo*. The use of modified mab Gi10 (such as NGM-Gi10) may represent an alternative therapy option for selected ITP patients.

OC 56 – Inhibitor development in haemophilia A

Induction of antigen-specific tolerance upon infusion of Fc-fusion proteins via the Materno-fetal interface

Gupta N[1], Meslier Y[1], André S[1], Culina S[2], Delignat S[1], Mallone R[2], Kaveri SV[1] and Lacroix-Desmazes S[1]
[1]*Inserm UMRS 872, Université Pierre et Marie Curie;* [2]*Inserm, U986, Saint Vincent de Paul Hospital, Paris, France*

Background: Under physiological conditions, the organism is tolerant to self-constituents. The thymus provides the basis for so called '*central tolerance*' mechanisms, which both delete autoreactive T effectors (Teff) cells and rescue natural T regulatory (Treg) cells. Regulatory T cells (Tregs) that developed via central tolerance mechanisms in the thymus play a major role in the maintenance of peripheral tolerance. Several pathological situations result from a break of tolerance towards endogenous molecules, as seen in autoimmune diseases, or from the inability to mount tolerance towards exogenously administered innocuous molecules, as observed in alloimmune responses to protein therapeutics like in Hemophilia A. Self tolerance is probably established as early as during fetal life, at the time of lymphocyte development. Maternal IgG are transported across the placenta to fetal circulation via transcytosis through the neonatal Fc receptor (FcRn). This process shapes the immune repertoire of the newborns and imparts on the nature of the immune responses in adult life.
Aim: We exploited this physiological process of *materno-fetal* interface to shape the immune repertoire during the ontogeny of the immune system, by introducing the Ag of interest during fetal life, in order to induce tolerance to an immunogenic protein therapeutic: coagulation factor VIII (FVIII).
Methods: To this end, mouse Ig-Fc-fusion chimeric molecules were developed using immunodominant domains of FVIII (A2-Fc and C2-Fc) and using the first domain of hemagglutinin (HA1-Fc). The chimeric proteins were produced by stably transfected HKB11 cells, purified by affinity chromatography and characterized by ELISA and western blots. *In vivo* imaging and ELISA validated the placental transfer of the chimeric proteins into the fetal circulation during gestation, after intravenous infusion in pregnant mice. The functional avidity, thymic presentation, time window and therapeutic dose were determined in HA-specific T-cell receptor (TcR) transgenic (Tg) mice, where T cells specific for the $HA_{111\text{-}119}$ peptide can be identified using the 6.5 anti-clonotypic antibody.
Results: Intravenous injection of 100-μg chimeric proteins in pregnant mice during gestational day 16–18 was sufficient to significantly induce HA1-specific Tregs and to delete HA1-specific autoreactive T cells in the progeny at 2 weeks of age. These validated parameters were then applied to a mouse model of hemophilia A (FVIII−/−) utilizing A2-Fc, C2-Fc and a monoclonal mouse IgG1 as control. The progeny of treated mothers was then challenged with therapeutic doses of the FVIII neo-antigen at 6 weeks of age. The progeny of A2-Fc and C2-Fc treated mothers showed a drastic reduction in the levels of total anti-FVIII IgG with abrogation of the proliferation of FVIII-specific T cells.
Conclusion: Our study provides the first proof of concept towards exploiting the materno-fetal interface to shape the immune repertoire and to induce tolerance in allo-immune pathological conditions.

OC 56.2

Role of mannose-ending glycans in the endocytosis and presentation of FVIII to T cell by human and mouse antigen-presenting cells

Delignat S[1], Gilardin L[1], Plantier J-L[2], Chtourou S[2], Martinez-Pomares L[3], Lone YC[4], Robinson J[5], Lacroix-Desmazes S[1] and Kaveri SV[1]

[1]Inserm, Paris; [2]LFB, Les Ulis, France; [3]Queens Medical Center University, Nottingham, UK; [4]UMRS1014, Villejuif, France; [5]Newcastle University, Newcastle, UK

Background: Development of FVIII inhibitors is the major complication in hemophilia A patients. The anti-FVIII immune response involves uptake and processing of therapeutic FVIII by antigen presenting cells (APCs), which leads to FVIII peptide presentation to naïve CD4+ T cells. Previously, using two models of APCs, human monocyte-derived dendritic cells (Mo-DCs) and murine bone marrow-derived dendritic cells (BM-DCs), we had shown that both APCs internalize FVIII. While FVIII endocytosis by Mo-DCs was mediated in part through the macrophage mannose receptor (CD206), FVIII endocytosis by BM-DCs did not involve mannose-sensitive pathways.

Aim: The aim of this study was to compare the importance of FVIII mannose-ending sugars for endocytosis and presentation of FVIII to T cells by mouse splenocytes and human Mo-DCs.

Methods: We produced human B domain-deleted FVIII lacking oligomannose carbohydrates at Asn239 and Asn2118 (DM-FVIII), and wild-type B domain-deleted FVIII (WT-FVIII, Δ2FVIII, LFB, Les Ulis, France) by transducing CHO-S cells with lentiviral vectors. We also generated a FVIII-specific mouse T-cell hybridoma restricted to the HLA DRB1*0101, following immunization with B domain-deleted FVIII (BDD-FVIII) of HLA-A2.1-/HLA-DRB1-transgenic H-2 class I/class II KO mice (SureL1). Lymph node cells from immunized mice were stimulated 3 days *ex vivo* with BDD-FVIII and fused with BWZ36 (TCR−/−) cells by polyethylene glycol fusion. Screening of hybridomas was performed using BDD-FVIII and splenocytes from SureL1 mice. Hybridoma activation was assessed by measuring secreted Il-2. To compare FVIII presentation by mouse and human APCs, T-cell stimulation assays were performed using either splenocytes from SureL1 mice or human Mo-DCs generated from a healthy donor with the DRB1*0101/0301HLA class II locus.

Results: We generated 13 FVIII-specific hybridomas. One FVIII-specific hybridoma was sub-cloned and used for all *in vitro* antigen presentation assays. This sub-clone was activated in a dose-dependent manner by WT-FVIII when presented by HLA DRB1 0101/0301 human Mo-DCs or splenocytes from SureL1 mice. Mouse splenocytes activated equally the T-cell hybridoma whether WT-FVIII or DM-FVIII was used in the assay (117 ± 13 vs. 97 ± 23 pg/mL of Il-2, respectively). In contrast, T-cell activation by Mo-DCs was drastically reduced when DM-FVIII was used instead of WT-FVIII (4 ± 2 and 21 ± 7 pg/mL of Il-2, respectively).

Conclusion: This study highlights the differences in FVIII endocytosis pathways by mice and human APCs. This work also confirms the relevance of mannose-sensitive pathways in FVIII uptake and presentation to CD4+ T cells by Mo-DCs.

OC 56.3

Inhibitor eradication therapy in non-severe hemophilia A

Van Velzen AS[1], Eckhardt CL[1], Peters M[1], Hart P[2], Rangarajan S[3], Hay CRM[4], Mancuso ME[5], Smiers F[6], Liesner R[7], Petrini P[8], Jiménez Yuste V[9], Van Der Bom JG[6], Fijnvandraat KJ[1], Yee T[10] and For the INSIGHT consortium[11]

[1]Emma Children's Hospital, Academic Medical Center, Amsterdam, the Netherlands; [2]Royal London Hospital, London, UK; [3]Haemophilia Reference Centre, St. Thomas' Hospital, Londen, UK; [4]Royal Infirmary Hospital, Manchester, UK; [5]IRCCS Maggiore Hospital Foundation and University of Milan, Milan, Italy; [6]Leiden University Medical Center, leiden, the Netherlands; [7]Great Ormond Street Hospital, London, UK; [8]Karolinska Hospital, Stockholm, Sweden; [9]University Hospital la Paz, Madrid, Spain; [10]Royal Free Hospital, London, UK; [11]the Netherlands

Background: In patients with non-severe hemophilia A (HA) presence of an inhibitor may exacerbate the bleeding phenotype dramatically. There are very limited data on the optimal therapeutic approach to eradicate inhibitors in non-severe HA patients.

Methods: All non-severe HA patients (FVIII:C 2–40%), who developed a clinically relevant inhibitor between 1980 and 2011 in the participating centers of the INSIGHT study, were included. Data on clinical and inhibitor characteristics and eradication therapy were collected. High titer (HT) inhibitor was defined as a Bethesda assay of > 5 BU/mL and low titer (LT) as ≤ 5 BU/mL. 'Re-challenge' was defined as exposure to FVIII concentrates after the inhibitor became undetectable (with or without inhibitor eradication treatment) and 'sustained success' was defined as a negative inhibitor assay after re-challenge. Proportions were analyzed using chi-square or Fischer's exact tests, as appropriate.

Results: In total, 108 non-severe HA patients from 30 centers in Europe and Australia were included. Inhibitors occurred at a median age of 37 years (inter quartile range (IQR) 1560) after a median cumulative exposure days (ED) to FVIII concentrates of 29 days (IQR 1470). There were 56 HT inhibitors, 45 LT inhibitors and in seven patients the peak titer was unknown. The median historical peak titer was 7.0 BU/mL (IQR 230).

Data on eradication treatment were available in 101 patients. Eradication treatment was administered in 27 patients: 16 patients were treated with Immune Tolerance Induction (ITI) exclusively, four were treated with immunosuppressives exclusively and seven were treated with both ITI and immunosuppressives. Eradication treatment resulted in undetectable inhibitor levels in 21/27 patients (78%). Sustained success was obtained in 15/17 patients (88%) that were re-challenged. A majority of 74 inhibitor patients did not receive any inhibitor eradication treatment. The inhibitor became undetectable in 52/74 patients (70%) and was still present in the other 22 patients at end of follow-up. In 21/35 patients (60%) with undetectable inhibitors that were not treated with eradication treatment and re-challenged with factor VIII, sustained success was attained. Use of eradication treatment was associated with sustained success in comparison to no eradication treatment: relative risk (RR) 1.47, 95% confidence interval (CI) 1.072.03.

Next, we calculated the effect of eradication treatment separately for the HT and LT group. In the HT group, sustained success was attained in all eight patients that were re-challenged after eradication treatment, compared to 6/14 patients without eradication that were re-challenged (RR 2.33, CI 1.274.27). In the LT group 7/9 patients that were re-challenged attained sustained success after eradication, compared to 15/21 patients that were re-challenged without eradication treatment (RR 1.09, CI 0.701.69).

Conclusion: In this unique cohort of 108 non-severe HA patients with inhibiting antibodies inhibitor eradication treatment was associated with sustained success after re-challenge with factor VIII in HT inhibitor patients, but not in LT inhibitor patients.

OC 56.4

Mechanisms of immune tolerance induction by rFVIIIFc in hemophilia A mice

Krishnamoorthy S, Liu Z, Drager D, Patarroyo-White S, Liu T, Van Der Flier A, Chhabra ES, Salas J, Zhu L, Kistanova E, Peters RT, Light D, Pierce GF and Jiang H

Biogen Idec Hemophilia, Waltham, MA, USA

Background and Aims: Alloantibodies to factor VIII (FVIII) are a significant impediment in treating hemophilia A (HemA). Previously, we reported that repeated administration of therapeutic doses of rFVIIIFc in HemA mice resulted in significantly lower subsequent antibody responses to FVIII, compared with B-domain-deleted and full length FVIII. Reduced antibody responses to rFVIIIFc are consistent with the presence of higher percentage of Tregs and tolerogenic cytokines in the spleens of these mice. In this study we further elucidate the mechanisms by which rFVIIIFc induces these tolerogenic effects, including identifying the genes regulated by rFVIIIFc and related to either immune or tolerance responses and the effects of interaction of rFVIIIFc with Fc receptors (FcγR and FcRn).

Methods: HemA mice were injected with rFVIIIFc at therapeutic (50 IU/kg) or supraphysiological doses (250 IU/kg) or vehicle once weekly for 4 weeks followed by two injections every 2 weeks. cDNAs from splenocytes were used for immune tolerance gene profiling. In addition, two rFVIIIFc mutants were constructed containing either FcγR non-binding mutation (N297A) or FcRn non-binding mutation (IHH). Splenic T-cells were isolated from HemA mice treated with these variants and used for T-cell proliferation and IFNγ secretion assays.

Results: Microarray analysis revealed that genes related to tolerance (Foxp3, CTLA4, and IL-10) and anergy (Egr2, Dgka, and Cblb) were upregulated and pro-inflammatory genes such as CCL3 and STAT3 were down-regulated in splenocytes of mice receiving 50 IU/kg rFVIIIFc in comparison to vehicle and 250 IU/kg treatments. The results were validated using real time PCR. CD4+ T-cells from the 250 IU/kg group elicited higher proliferation and IFNϒ secretion compared to those from the 50 IU/kg and vehicle-treated groups, whereas the IFNγ secretion from 250 IU/kg of rFVIIIFc N297A group was significantly reduced. IFNγ production from the 50 IU/kg groups of rFVIIIFc or rFVIIIFc N297A was comparable to vehicle. Nevertheless, T-cells from mice receiving 50 IU/kg rFVIIIFc maintained robust proliferation and IFNϒ secretion in response to anti-CD3/CD28 antibody suggesting the absence of non-specific immunosuppression.

Summary/Conclusions: Therapeutic doses of rFVIIIFc induced expression of tolerance-specific genes in comparison to supraphysiological doses of rFVIIIFc. Gene candidates identified here that are regulated by rFVIIIFc provide insight into the mechanism of tolerance induction to FVIII. This is supported by findings that T-cells from the 250 IU/kg displayed robust proliferation and IFNγ production, in contrast to the 50 IU/kg and vehicle treated groups, in response to rFVIII. Failure to interact with FcgR family of receptors (comprising of both activating FcϒR and inhibitory FcϒR2B receptors) by rFVIIIFc N297A dampened the T-cell response in mice immunized with supraphysiological doses of rFVIIIFc. Moreover, rFVIIIFc treated mice maintained robust T-cell responses to anti-CD3/CD28 antibody suggesting the lack of non-specific immunosuppression. The evaluation of rFVIIIFc IHH variant will further elucidate the role of FcRn in immune tolerance. In summary, these findings provide insight on the possible mechanisms of rFVIIIFc in inducing immune tolerance to rFVIII in hemA mice.

OC 56.5

Novel strategies to target long-lived plasma cells for treating Hemophilia A inhibitors

Liu CL, Lyle M, Shin S and Miao CH

Seattle Children's Research Institute, Seattle, WA, USA

Background: Formation of inhibitory antibodies is a critical and challenging problem for therapeutic treatment in hemophilia A patients. It is hypothesized that long-lived plasma cells (LLPCs) play an important role in the persistent production of anti-FVIII antibodies in hemophilia A (HemA) inhibitor patients. The migration of plasma cells to the BM, where they become the LLPCs, is largely controlled by an interaction between the C-X-C type chemokine ligand 12 (CXCL12) produced by bone marrow (BM) stromal cells and its receptor CXC receptor4 (CXCR4; CD184) on plasma cells. Our previous data showed that administration of anti-murine CD20 (IgG2a) can deplete B cells significantly and reduce anti-FVIII inhibitor titers in FVIII plasmid-treated HemA mice with pre-existing inhibitors, however, complete tolerance to FVIII was not achieved probably due to the persistence of LLPCs.

Aims: We sought novel therapeutic strategies that target CXCL12/CXCR4 pathway to reduce/eliminate LLPCs and achieve the goal for long-term tolerance to FVIII in the HemA inhibitor mice.

Methods: AMD3100, the CXCR4 antagonist, plus G-CSF inhibit the interaction of CXCL12 and CXCR4, thus facilitating the mobilization of CD34+ cells and blocking the homing and retention of LLPCs. We also combined these reagents with the specific IL-2/IL-2mAb (JES6-1) complexes to target both B and T cell-dependent anti-FVIII immune responses. Two groups of FVIII-primed inhibitor mice were treated with different combined immunomodulation regimens: (i) IL-2 complexes+AMD3100+G-CSF+anti-CD20, (ii) AMD3100+G-CSF+anti-CD20. Control mouse groups were treated with each of the single regimens and FVIII only, or untreated as the naïve control. All the treatments were administered one cycle per 2 weeks for 4 weeks and the therapeutic effects (FVIII activities) as well as immune responses (anti-FVIII inhibitors) were evaluated at different time points after treatment.

Results: Significant expansion of Treg cells reaching a 5~7-fold increase on the peak days (day 3–7 after treatment) was observed in the IL-2/IL-2mAb complexes treated groups, whereas ~98% of B cell populations were depleted in the anti-CD20 treated groups. In addition, administration of AMD3100 plus G-CSF significantly reduced circulating and bone marrow CXCR4+ plasma cells. Except for the control groups, the two mouse groups treated with combined immunosuppressive regimens showed a significant reduction of inhibitory titers following the treatment. Long-term responses are being followed and second challenge with FVIII plasmid will be used to evaluate the induction of long term tolerance to FVIII.

Summary/Conclusions: These combination regimens are highly promising in modulating/eliminating pre-existing anti-FVIII antibodies and inducing long-term tolerance in FVIII primed subjects.

OC 56.6

Co-administration of factor VIII and dexamethasone prevents anti-factor VIII antibody development in a mouse model of hemophilia A

Moorehead PC[1], Van Velzen A[2], Sponagle K[3], Steinitz KN[4], Reipert BM[4] and Lillicrap D[3]

[1]Janeway Child Health and Rehabilitation Centre, St. John's, NL, Canada; [2]Emma Children's Hospital, Amsterdam, the Netherlands; [3]Queen's University, Kingston, ON, Canada; [4]Baxter Biosciences, Vienna, Austria

Background: Antibodies that inhibit the coagulant function of factor VIII (FVIII) are a major complication of treatment for patients with hemophilia A. Inhibitor development depends on components of adaptive immunity, such as B cells and $CD4^+$ T cells, and on components of innate immunity, which activate antigen-presenting cells. The immunologic 'decision' for immunity or tolerance may occur early during exposure to FVIII. Corticosteroids, which are used extensively in humans, have suppressive effects on adaptive and innate immunity, but the effect of immunosuppression at the time of initial FVIII exposure on the risk of inhibitor development has not been investigated.

Aims: To determine if dexamethasone administered during initial exposure to FVIII will prevent the occurrence of anti-FVIII antibodies in a mouse model of hemophilia A, and to assess if dexamethasone-induced immunologic tolerance will withstand a subsequent exposure to FVIII.
Methods: Hemophilia A mice with knockout of exon 17 of the *F8* gene and with a chimeric human/murine major histocompatibility complex type II transgene carrying the binding sites of the human HLA-DRB1*1501 allele were used. Recombinant human FVIII (Advate, approximately 0.1 mcg/IU) was given by tail vein injection at 6 IU per dose, dexamethasone was given by intraperitoneal injection at 75 mcg per dose, and lipopolysaccharide (LPS) was given IV at 2 mcg per dose. The experiment consisted of two phases: in Phase 1, mice were given either FVIII and Dexamethasone (Dex group) or FVIII alone (Control group) for 5 days; in Phase 2, which began 7 weeks after the start of Phase 1, Control mice without evidence of anti-FVIII antibodies were given FVIII for 3 days, and Dex mice were given either FVIII (FVIII group) or FVIII and LPS (FVIII-LPS group) for 3 days. Plasma samples were collected 6 weeks after the start of Phase 1 by retro-orbital venous plexus, and 3 weeks after the start of Phase 2 by cardiac puncture. Plasma was examined for evidence of anti-FVIII antibodies and FVIII inhibitory activity with ELISA for anti-FVIII IgG and Bethesda assay, respectively. Proportions of mice with positive titres were analyzed using Fisher's exact test.
Results: After Phase 1, 0/17 Dex mice had detectable anti-FVIII IgG, as compared to 5/17 Control mice ($P = 0.04$). A subset of these mice had completed Phase 2: 3/6 Control mice had detectable anti-FVIII IgG, compared to 2/5 FVIII-LPS mice and 0/4 FVIII mice ($P = 0.31$). Bethesda assays were performed after Phase 2: 1/6 Control mice had detectable FVIII inhibitory activity, compared to 2/5 FVIII-LPS mice and 0/4 FVIII mice ($P = 0.57$).
Conclusions: Dexamethasone administration at the time of initial exposure to FVIII prevented the development of anti-FVIII IgG in all treated mice. It may be the case that this tolerance withstands a subsequent exposure to FVIII, and may even blunt the immunostimulatory effect of LPS. The mechanisms leading to this effect warrant further study, as there is an obvious possible translational application for these findings.

OC 57 – Modifications in Factors VIII, IX and XI

OC 57.1

Selective mutagenesis of the heparin and antithrombin exosites on human factor IX(a) enhances thrombin generation in human plasma

Westmark PR and Sheehan JP
University of Wisconsin-Madison, Madison, WI, USA

Background: Hemophilia B is an X-linked genetic disorder characterized by defective factor IX activity. Recombinant factor IX (rFIX) is employed as protein replacement for the treatment and prophylaxis of bleeding episodes. Antithrombin is the primary plasma inhibitor of factor IXa, and inhibition is enhanced by endothelial heparan sulfate. We hypothesize that selective disruption of protease interactions with heparin and antithrombin may enhance rFIX efficacy by prolonging the protease half-life *in vivo*.
Aims: The aim of these studies was to assess the effect of mutations in the factor IX(a) heparin and antithrombin-binding exosites on activity in human plasma.
Methods: Human rFIX cDNA constructs with alanine substitutions (chymotrypsinogen numbering) in the heparin binding exosite (K126A, K132A, K126A/K132A), antithrombin-binding exosite (R150A), or both (K126A/K132A/R150A) were expressed in HEK293 cell lines. Recombinant zymogens were purified from conditioned media, and a portion activated to protease with human factor XIa. Both zymogen and protease forms were characterized in APTT-based clotting assays, and in tissue factor (TF) and factor IXa-initiated thrombin generation (TG) assays in pooled human factor IX-deficient plasma. Comparisons were made with human plasma-derived factor IX(a)(pFIX) and recombinant factor IX(a) wild type (WT).
Results: APTT based clotting activities for zymogens expressed as a% $\pm$ SEM relative to rFIX WT were: pFIX 105.2 $\pm$ 2.8, WT 100.8 $\pm$ 7.1, K126A 63.3 $\pm$ 2.3, R150A 62.4 $\pm$ 4.0, K132A 30.9 $\pm$ 1.1, K126A/K132A 20.6 $\pm$ 9.2, and K126A/K132A/R150A 7.3 $\pm$ 3.8. Likewise, APTT clotting activities for the proteases were: WT 100 $\pm$ 6.1, pFIXa 98.4 $\pm$ 11.4, K132A 91.4 $\pm$ 1.6, R150A 77.1 $\pm$ 5.8, K126A 39.5 $\pm$ 2.4, K126A/K132A/R150A 10.9 $\pm$ 0.6, and K126A/K132A 9.3 $\pm$ 0.6. In contrast to their clotting activities, both FIX R150A and K126A demonstrated markedly enhanced TF-initiated TG relative to WT protein ($\geq$ 2-fold). Likewise, the magnitude of TG by FIX K132A was similar to FIX WT. FIX K126A/K132A had reduced thrombin generation proportionate to clotting activity (~20%), and addition of R150A (triple mutant), increased TG to about half that of FIX WT. In the FIXa-initiated assay, FIXa K132A and R150A demonstrated TG roughly proportional to their clotting activities, FIXa K126A had moderately enhanced TG (60–70%) relative to clotting activity, and FIXa K126A/K132A had reduced TG proportionate to clotting activity, with a modest increase with addition of R150A (triple mutant).
Conclusion: Selected disruption of the heparin and antithrombin exosites on human factor IX by alanine substitution reduces traditional clotting activity to a variable extent. Despite moderate reductions in clotting activity, the mutations K126A and R150A enhanced TF-initiated TG in human plasma relative to WT protein. Combined mutations in the heparin-binding site (K126A/K132A) significantly reduced both clotting activity and plasma TG, likely due to disruption of the protease-cofactor interaction. Mutation of the antithrombin-binding site (R150A) tended to increase plasma TG relative to clotting activity, either alone or in the context of combined mutations in the heparin-binding exosite (double vs. triple mutant). These results suggest that optimization of these exosite mutations will enhance TG by rFIX in human plasma.

OC 57.2

Optimizing factor IX-Triple clotting activity *in vitro* and *in vivo*

Kao CY[1], Yang S-J[1], Tao MH[2], Hsu YC[1] and Lin SW[1]
[1]*College of Medicine, National Taiwan University Hospital;*
[2]*Academia Sinica, Taipei, Taiwan*

Background: Using gain-of-function factor IX (FIX) for replacement therapy for hemophilia B (HB) has been an attractive strategy. We previously reported a high activity FIX, FIX-Triple (FIX-V86A/E277A/R338A) as a good substitute for FIX-WT (wild-type) in protein replacement therapy and gene therapy as well as cell therapy.
Aims: To test whether FIX Padua mutation improves the clotting activities of FIX-Triple, a novel recombinant FIX named FIX-TripleL (FIX-V86A/E277A/R338L) was generated in this study by modifying FIX-Triple at residue 338 from alanine to leucine as identified in FIX-Padua (FIX-R338L).
Methods: Both *in vitro* and *in vivo* models were used to demonstrate the clotting function of FIX-TripleL.
Results: Purified FIX-TripleL exhibited a 22-fold higher specific activity and a 14-fold increased binding affinity to activated FVIII compared to FIX-WT. FIX-TripleL improved the therapeutic potential of FIX-Triple increased by 100% as demonstrated by calibrated automated thrombogram and thromboelastography. With normal clearance rate in HB mice, the clotting activities of FIX-TripleL were consistently 2–3-fold higher than those of FIX-Triple or FIX-R338L. Tail-vein administration of adeno-associated virus (AAV) expressing FIX in HB mice showed that FIX-TripleL had a 14-fold higher specific activity than FIX-WT, which was significantly better than FIX-Triple

(ninefold) or FIX-R338L (sixfold). Moreover, there were no signs of adverse thrombotic events in long-term AAV-FIX-treated C57Bl/6 mice. Abnormality in AAV-FIX-treated livers was observed exclusively in some of the mice injected with high but not medium or low dose AAV-FIX, indicating the advantages of using hyperfunctional FIX variants to reduce viral doses and meanwhile maintain therapeutic clotting activities.

Conclusions: These studies suggest that incorporation of FIX Padua mutation into FIX-Triple significantly improves the clotting function of FIX-Triple so as to optimize protein replacement therapy and gene therapy.

OC 57.3

Increasing the binding affinity between FVIIIa subunits results in higher stability and greater thrombin generation in plasma

Monaghan M, Wakabayashi H, Wintermute J and Fay PJ

University of Rochester, Rochester, NY, USA

Factor (F)VIIIa is a heterotrimer of A1, A2 and A3C1C2 subunits. FVIIIa activity is labile due to the tendency of A2 subunit to dissociate from the A1/A3C1C2 dimer. This dissociation of A2 subunit inactivates FVIIIa activity, thereby down-regulating FXase. Thus retention and dissociation of A2 subunit reflect FVIIIa stability and FXase activity. Earlier results from our laboratory showed that replacing the acidic residues D519, E665, and E1984, that localize in hydrophobic patches at the interfaces between the A2 and either the A1 or A3C1C2 subunits, with either Ala or Val reduced rates of FVIIIa decay and yielded increased thrombin generation (Wakabayashi et al., 2008, 2009). We now show that the observed increase in FVIIIa stability and thrombin generation with these FVIIIa variants result from an increased binding affinity between A2 subunit and A1/A3C1C2 dimer in FVIIIa, as well as a higher stability of FVIIIa in plasma. For these studies, the isolated A2 domains with Ala or Val substitution for D519 and/or E665 were expressed in a baculovirus system. Ala and Val substitution for E1984 (A3 domain) was achieved by mutating this residue in FVIII, expressing the intact protein in BHK cells, activating the FVIII to FVIIIa, purifying the A3C1C2 subunit, and combining it with A1 subunit to form the A1/A3C1C2 dimer. To assess inter-subunit affinity, FVIIIa was reconstituted from variable concentrations of either the isolated A2 subunit or A1/A3C1C2 dimer, using either the WT or variant subunit. Resultant FVIIIa activity was determined in a FXa generation assay. The FXa generation curve were fitted to a single-site binding equation, and the dissociation constant (Kd) for A2 was determined for WT and each variant. The Kd value for the interaction of WT A2 combined with WT A1/A3C1C2 (44 $\pm$ 3 nM) was 3–7-fold higher than Kd values observed for the A2 variants at D519 (16 $\pm$ 1 nM, Ala; 11 $\pm$ 1 nM, Val) and E665 (13 $\pm$ 1 nM, Ala; 6 $\pm$ 1 nM, Val) and for the A3C1C2 variant at E1984 (16 $\pm$ 3 nM, Ala; 6 $\pm$ 1 nM, Val). Overall, Val containing variants showed higher affinity interactions than the Ala variants. Furthermore, the double mutant (D519V/E665V) showed an approximately 40-fold lower Kd (0.9 $\pm$ 0.7 nM) than WT. In another series of experiments, the reconstituted WT and A2 variant FVIIIa forms at various dilutions were incubated in hemophilic plasma for 1 min, and the remaining activity was determined by clotting assays. All variants showed greater activity levels than WT FVIIIa with 9- and 22- fold increases for the D519A and D519V, respectively and 15- and 21-fold increases for the E665A and E665V, respectively. Again, the double mutant D519V/E665V showed the greatest increase (42-fold) relative to WT. Therefore, these hydrophobic mutations at the A2-A1 and A2-A3C1C2 subunit interfaces result in a high binding affinity for the A2 subunit. This high binding affinity is responsible for the high plasma stability and correlates well with the previously observed reduced rates in FVIIIa decay and increased thrombin generation parameters.

OC 57.4

Transcriptional and post-transcriptional targeting of FVIII expression to overcome immunological responses to gene therapy for Hemophilia A

Merlin S, Cannizzo ES, Feola M and Follenzi A

University of Piemonte Orientale "A.Avogadro", Novara, Italy

Background: Hemophilia A (HA) is an X-linked bleeding disorder due to mutations in clotting factor VIII (FVIII) gene. To date HA patients are treated with recombinant or plasma-derived FVIII with a high probability of developing inhibitors (20–40%). Several efforts have been focused on the improvement of lentiviral vectors (LV) to obtain selective targeted expression by transcriptional and post-transcriptional regulation. However, immune responses to FVIII remain the major obstacle. The liver is known to induce tolerance rather than immunity towards antigens presented locally to T cells by specialized resident cells, such as liver sinusoidal endothelial cells (LSEC) and Kupffer cells (KC).

Aims: To investigate the possible role of LSEC and KC in gene therapy for HA using LV expressing human FVIII under the control of cell-specific promoters $\pm$ specific microRNA target sequence (miRTs).

Methods: We implemented two different strategies of targeting LV to LSEC or KC in hemophilia A mice, preparing LVs containing GFP or FVIII under the control of the ubiquitous PGK promoter, or the CD11b (surface integrin, monocyte/macrophage-specific) or VEC (vascular endothelial cadherin, endothelial-specific) promoters in combination with miRTs: miR142 (silenced in hematopoietic cells), miR126 (silenced in endothelial cells), miRT122 (silenced in hepatocytes). These sequences were inserted in the LV alone or in pairs.

Results: Co-staining with F4/80 or CD31 and GFP antibodies on liver sections taken at different time points after LV-GFP injection in mice confirmed a widespread pattern of GFP expression for up to 3 m, the longest time tested. Immunofluorescence showed GFP expression restricted to specific cell types within the liver by addition of one or two miRTs. After injection of LV.VEC.GFP and LV.CD11b.GFP, transgene expression was restricted to LSEC and KC respectively, although some off-target expression was detected. The addition of the miRT122-142 combination to LV.VEC.GFP restricted GFP-expression to LSEC and miRT126 to LV.CD11b.GFP further increased specific expression in KC, with no off-target expression and sustained GFP expression at all-time points analyzed up to 6 months. We then injected HA mice with LV.PGK.FVIII $\pm$ miRT142 and LV.VEC.FVIII $\pm$ miRT122-142. In the first group anti-FVIII antibodies were detected starting at 2 weeks after vector delivery, however the presence of miRT142 alone halved the titer of neutralizing antibodies in LV-injected mice. In HA mice injected with LV.VEC.FVIII $\pm$ miRT122-miRT142 long term phenotypic correction was shown by functional assay in both groups of the latter injected mice for up to 6 months with reduced clotting time and an average of 5% FVIII activity in injected mice and virtually no inhibitors were detected. Finally, we recently injected LV.CD11b.hFVIII $\pm$ miRT126 in HA mice to verify if overexpression of FVIII by KC is associated with tolerance induction as reported after FVIII-expression by LV-transduced LSEC.

Conclusion: In our study, endothelial or monocyte/macrophage specific-promoters in combination of selected miRT sequences in LV were able to overcome FVIII off-target expression limiting immune responses and providing phenotypic correction in treated HA mice.

OC 57.5

Factor VIII C1-domain spikes 2092–2093 and 2158–2159 comprise regions that modulate cofactor function and cellular uptake

Bloem E[1], Van Den Biggelaar M[1], Wroblewska A[1], Voorberg J[1], Faber JH[2], Kjalke M[2], Stennicke HR[2], Mertens K[1] and Meijer AB[1]
[1]*Sanquin Blood Supply, Amsterdam, the Netherlands;* [2]*Novo Nordisk A/S, Måløv, Denmark*

The C1-domain of factor VIII (FVIII) has recently been implicated in phospholipid binding of activated FVIII. It has further been found to contribute to Low density lipoprotein Receptor-related Protein (LRP)-dependent FVIII endocytosis, and uptake of FVIII by antigen-presenting dendritic cells. We have previously established that anti-C1 domain antibody KM33 blocks all these biological processes. In the present study, we employed hydrogen-deuterium exchange (HDX) mass spectrometry to identify the molecular hot-spot on FVIII to which this antibody binds. The results showed that the FVIII regions 2091–2103 and 2157–2162 are protected by KM33 from HDX. These peptides comprise the two C1-domain spikes 2092–2093 and 2158–2159, which have previously been suggested to contribute to phospholipid binding. We have recently demonstrated that the spike 2092–2093 contributes to assembly with lipid membranes with low PS content. This raises the question as to whether spike 2158–2159 would serve a similar role. To investigate this, we took advantage of the fact that replacement of R2159 for an asparagine would introduce an N-linked glycosylation motif in the KM33 binding region. Upon expression of this variant in human 293 cells, the purified mutant indeed proved to be glycosylated in this position. Binding studies revealed that the glycosylated R2159N variant did not display any interaction with antibody KM33. We further found that the R2159N variant exhibits reduced binding to LRP. In accordance with this finding, FVIII R2159N also displayed reduced uptake by LRP expressing cells, including human monocyte-derived dendritic cells. While cellular uptake was reduced, FVIII cofactor function of FVIII R2159N was maintained on phospholipid membranes containing 15% phosphatidylserine (PS). On membranes with low, i.e. 5% PS content, however, FVIII function was reduced, in accordance with the apparently reduced affinity of the R2159N variant for membranes of cells that are capable of FVIII uptake. These findings imply that the two C1 domain spikes 2092–2093 and 2158–2159 both modulate the assembly of FVIII with PS-containing membranes. These data further demonstrate that the two spikes in the FVIII C1-domain regulate FVIII function by a subtle, PS-dependent mechanism. The reduced uptake of FVIII R2159N by dendritic cells suggests that this mutant may display reduced immunogenicity. Collectively, these data suggest that the two spikes of the FVIII C1-domain are structure elements that contribute to both membrane-driven FVIII function and immunogenicity. While previous studies have proposed that it is predominantly the FVIII C2-domain that drives membrane assembly, the present data contribute evidence for an increasingly important role of the C1-domain role in FVIII biology.

OC 57.6

The role of lysine residues in the interaction of blood coagulation factor VIII with its clearance receptor low-density lipoprotein receptor-related protein

Van Den Biggelaar M[1], Faber JH[2], Zuurveld M[1], Van Der Zwaan C[1], Madsen J[2], Olsen OH[2], Stennicke HR[2], Mertens K[1] and Meijer AB[1]
[1]*Sanquin Research, Amsterdam, the Netherlands;* [2]*Novo Nordisk, Malov, Denmark*

Members of the LDL receptor family contribute to the rapid clearance of blood coagulation factor VIII from the circulation. It has been implicated that positively charged lysine residues, but not arginine residues, drive the interaction between the LDL receptor family members and their ligands. However, it has remained unclear which residues on factor VIII contribute to the interaction and how the specificity of the interaction is regulated. Using two independent approaches, we now study the interaction of factor VIII with the largest member of the LDL receptor family, low-density lipoprotein receptor-related protein (LRP1) in detail, with particular emphasis on lysine residues. Hydrogen deuterium exchange-mass spectrometry (HDX-MS) experiments identified eight regions in the FVIII light chain that display significant protection from exchange with solvent in the presence of LRP1 cluster II. These regions include residues 1671–1689, 1737–1746, 1804–1835, 2057–2069, 2078–2099, 2213–2235, 2266–2271, and 2293–2296 and are likely to constitute the core of the interface between factor VIII and LRP1. Intriguingly, these regions are scattered throughout the *a3*, A3, C1 and C2 domains of the factor VIII light chain. To further systematically address the contribution of individual lysine residues within the *a3*, A3, C1 and C2 domains of the factor VIII light chain, we constructed a library of FVIII variants carrying lysine to arginine (KR), alanine (KA) or glutamic acid (KE) replacements using site-directed mutagenesis. The interaction of the variants with LRP cluster II was evaluated using Surface Plasmon Resonance (SPR) analysis. Factor VIII light chain variants were expressed in 293 Freestyle cells, captured on the SPR chip (17 fmol/mm^2) using an anti-C2 antibody and LRP cluster II (0.2–200 nM) was passed over in solution. These experiments revealed that multiple (11) lysine residues within the factor VIII light chain including 1673/1674, 1693, 1813/1818, 1827, 1967, 1972, 2065, 2092 and 2136 contribute to the interaction with LRP1 cluster II. However, none of these residues accounts completely for LRP1 cluster II binding. Replacements of contributing lysine residues by positively charged arginine, uncharged alanine or negatively charged glutamic acid residues indicated that reversing the positive charge had the strongest effect on the interaction. In addition, an additive effect of combining multiple lysine replacements was observed. The majority of the lysine residues that were identified in the mutagenesis study are located within those regions that were also identified using the HDX-MS study and are therefore considered 'hot spots'. Taken together, our combined experimental approach using HDX-MS and site-directed mutagenesis suggests that the interaction of factor VIII with LRP1 occurs over an extended surface containing multiple lysine residues in the factor VIII light chain. Crystal structure analysis and docking studies proved to be compatible with a model in which the acidic binding pockets of the ligand binding regions of the receptor spatially align with the putative 'hot spot' lysine residues in such a way that the receptor engages the bottom of the C1 domain and curls around the factor VIII molecule.

OC 58 – New Developments in Thrombus Formation

OC 58.1

Polo-like kinase 3 regulates *in vivo* thrombosis through the regulation of thromboxane A2 generation, granular secretion, and integrin aIIbβ3 outside-in signaling

Naik MU[1], Bachman B[1], Kostyak JC[1], Dai W[2] and Naik UP[1]
[1]*University of Delaware, Newark, DE;* [2]*New York University, New York, NY, USA*

Background: Polo-like kinase (Plk) family members are serine/threonine kinases involved in cell cycle regulation. Their expression and function in platelets are not known. We identified for the first time the presence of Plk3 in human and mouse platelets.
Aim: To evaluate the functional role of Plk3 in platelet activation and thrombosis.
Methods: We used *Plk3−/−* mice in C57Bl/6 background. *In vivo* thrombosis was assessed by tail bleeding assay, 10% $FeCl_3$-induced

carotid artery injury, and pulmonary thromboembolism induced by collagen/epinephrine. Wild-type (WT) mice were used as controls.
Results: We found that Plk3 is localized to the filopodia of activated platelets. Furthermore, Plk3 co-immunoprecipitated with integrin $a_{IIb}b_3$ in an aggregation-dependent manner, suggesting that it may play a role in integrin outside-in signaling. Since Plk3 is a mitotic kinase, we evaluated the effect of loss of Plk3 on platelet counts in *Plk3−/−* mice. We found that ablation of Plk3 significantly elevated the platelet number, indicating a thrombocytotic phenotype. We next evaluated the degree of megakaryocyte (MK) ploidy and found no difference between WT and *Plk3−/−* mice. When analyzed for the total MK number, we found that lack of Plk3 resulted in a significantly increased number of MKs in the bone marrow, which may account for the increased platelet number. We next examined the effect of lack of Plk3 on platelet functions induced by physiological agonists. We found that platelet aggregation induced by low dose of collagen, thrombin, or PAR4 peptide was significantly augmented ($P > 0.02$) in Plk3 null platelets compared to WT. This was further supported by the significantly increased ($P > 0.05$) fibrinogen receptor exposure on platelets. To determine the molecular mechanism of the observed hyperaggregation, we analyzed signaling events such as ERK1/2 and Akt, upstream regulators of integrin $a_{IIb}b_3$ activation. Interestingly, we found that agonist-induced activation of ERK2 and Akt was significantly enhanced in the absence of Plk3, suggesting that lack of Plk3 may cause a prothrombotic phenotype. When we tested the *in vivo* effect of Plk3 ablation, to our surprise, we found that *Plk3−/−* mice showed an anti-thrombotic phenotype as assessed by a significantly ($P > 0.001$) delayed average tail bleeding time, extended carotid vessel occlusion time ($P > 0.001$), as well as a marked protection ($P > 0.0004$) from pulmonary thromboembolism compared to WT mice. Thrombin-induced generation of TxA2 ($P > 0.03$) as well as a- and d- granules secretion was significantly attenuated ($P > 0.007$) in *Plk3−/−* mice compared to WT. Furthermore, phosphorylation of cPLA2, a key enzyme involved in TxA2 generation, was significantly attenuated ($P > 0.05$) in Plk3 null platelets. When analyzed for fibrin clot retraction, a function of outside-in signaling, we found that Plk3 null platelets failed to retract the fibrin clot, supporting the observed anti-thrombotic phenotype *in vivo*. The severity of the anti-thrombotic phenotype in *Plk3−/−* mice may have been dampened due to the opposing role of Plk3.
Summary: The results presented here suggest that Plk3, a mitotic kinase, plays a significant role in the regulation of platelet function such as TxA2 generation, granular secretion, and clot retraction, thus affecting the process of thrombosis.

OC 58.2
Disruption of ICAM-4 mediated direct erythrocyte-platelet interaction leads to reduced thrombus formation

Du V[1], De Groot PG[1], Van Wijk R[1], Marchese P[2], Ruggeri ZM[2] and De Laat B[3]
[1]*University Medical Center Utrecht, Utrecht, the Netherlands;* [2]*The Scripps Research Institute, La Jolla, CA, USA;* [3]*Maastricht University Medical Center, Maastricht, the Netherlands*

Background: Direct platelet-erythrocyte interaction has been published but no information is available on the mechanism of the interaction and its physiological function. Intercellular adhesion molecule 4 (ICAM-4) is an erythroid-specific membrane component that belongs to the family of immunoglobulin superfamily of proteins and it has been shown to be a ligand for platelet activated $\alpha_{IIb}\beta_3$.
Aims: Our aim is to investigate the involvement of ICAM-4 and $\alpha_{IIb}\beta_3$ in the direct erythrocyte-platelets interaction under near physiological conditions *in-vitro*. Secondly we aim to explore the physiological function of the ICAM-4 mediated erythrocyte-platelet interaction *in-vivo*.
Methods: An *in-vitro* perfusion system connected to a light microscope and a digital camera was used to study erythrocyte binding to platelets adhered to surfaces coated with different adhesive proteins at different flow-rates. Flow cytometry analysis was performed to further study the binding of an ICAM-4 mimetic peptide (resembling an extracellular domain of ICAM-4) to $\alpha_{IIb}\beta_3$ on platelets. A $FeCl_3$-based experimental thrombosis model in mice was applied to study the effect of an anti-ICAM-4 antibody and an ICAM-4 blocking peptide on thrombus formation. Platelet deposition and fibrin formation was recorded under a fluorescence microscope with calcein labelled donor platelets and FITC labelled anti-fibrin antibody.
Results: Erythrocytes bind to platelets both in buffer and in whole blood under low shear flow. Erythrocytes attached to platelets with a sort of 'focal adhesion point', resulting in a tear-drop shape. This adhesion was inversely correlated with flow shear rate and predominately occurred at shear rates lower than 300/s. The addition of platelet agonists during the flow experiments increased erythrocyte binding to platelets 3–6-folds indicating that platelet activation is involved in capturing erythrocytes from the circulation. An Arg-Gly-Asp (RGD) containing peptide (d-RGDW), known to inhibit $\alpha_{IIb}\beta_3$ mediated platelet aggregation inhibited erythrocyte-platelet adhesion up to 72%, depending on the agonist used ($P > 0.05$, $n = 4$). Erythrocyte-platelet adhesion under flow was inhibited with both an anti-ICAM-4 antibody (40%, $P > 0.01$, $n = 8$) and an anti- integrin β_3 (CD61) antibody (46%, $P > 0.001$, $n = 8$). In addition, the ICAM-4 mimetic peptide demonstrated a significant inhibitory effect on erythrocyte-platelet adhesion. Flow cytometry experiments showed that this ICAM-4 peptide also reduced fibrinogen binding to platelets (43%, at 125 μM ADP, $P > 0.05$, $n = 5$), suggesting that the ICAM-4 mimetic peptide competes with fibrinogen for binding to activated $\alpha_{IIb}\beta_3$. The *in-vivo* thrombosis model in mice demonstrated that the anti-ICAM-4 antibody profoundly inhibited platelets deposition and fibrin formation at the site of injury. Comparing to control mice, which shows a vessel occlusion time of approximately 10 min, the anti-ICAM-4 antibody treated mice shows no vessel occlusion in the first 20 min. The ICAM-4 mimetic peptide demonstrated similar inhibitory effect *in-vivo*.
Conclusions: We observed a direct erythrocyte-platelet interaction under conditions of low shear. This interaction is partly mediated via erythrocyte-receptor ICAM-4 and $\alpha_{IIb}\beta_3$ on platelets. In addition, we found that disruption of the ICAM-4 mediated erythrocyte-platelet interaction *in vivo* by an anti-ICAM-4 antibody or a ICAM-4 mimetic peptide led to reduced platelet deposition and fibrin formation at the injury sites in mouse vessels.

OC 58.3
PDK1 regulates platelet activation and arterial thrombosis

Chen X[1], Zhang Y[1], Luo X[2], Wang Y[1], Zhang L[1], Wang K[1], Yang Z[3], Wu Y[4] and Liu J[1]
[1]*Shanghai Jiao Tong University School of Medicine;* [2]*Huashan Hospital, Fudan University, Shanghai;* [3]*Nanjing University, Nanjing;* [4]*First Affiliated Hospital, Soochow University, Suzhou, China*

The effects of PDK1, a master kinase in PI3K/Akt pathway, on platelet activation are unknown. Accordingly, platelet-specific PDK1 deficient mice were characterized to elucidate the platelet-related function (s) of PDK1. We found that PDK1 deficiency caused a mild thrombocytopenia. Also, the aggregation of $PDK1^{-/-}$ platelets was diminished in response to low levels of α-thrombin, U46619 and ADP, respectively. Further results demonstrated that PDK1 regulates thrombin-induced platelet activation by affecting αIIbβ3-mediated outside-in signaling. This result provided an explanation for the diminished spreading of $PDK1^{-/-}$ platelets on immobilized fibrinogen (Fg) and the decreased rate of clot retraction in platelet rich plasma containing $PDK1^{-/-}$ platelets. PDK1 deficiency diminished agonist-induced Akt Ser473 phosphorylation, and thoroughly abolished Akt Thr308 and Gsk3β Ser9 phosphorylation in response to agonist treatment, and

platelet spreading, respectively. A Gsk3β inhibitor fully restored the aggregation of PDK1$^{-/-}$ platelets in response to low levels of thrombin, the normal spreading of PDK1$^{-/-}$ platelets on Fg, and normal clot retraction in PRP containing PDK1$^{-/-}$ platelets. Those results indicated that Gsk3β is a major downstream effector of PDK1 in αIIbβ3-mediated outside-in signaling and thrombin-induced platelet activation. Finally, the *in vivo* data demonstrated that PDK1 is an important regulator in arterial thrombosis formation.

OC 58.4

Thrombus formation *in vivo* can occur independently of Syk kinase function

Van Eeuwijk JMM[1], Stegner D[2], Thielmann I[1], Königsberger S[3], Kiefer F[3] and Nieswandt B[1]

[1]*University of Würzburg, Rudolf Virchow Center;* [2]*University Hospital, Würzburg;* [3]*Max Planck Institute for Molecular Biomedicine, Münster, Germany*

Background: Spleen tyrosine kinase (Syk) and ζ-chain associated protein kinase of 70 kDa (Zap-70) are both spleen tyrosine kinase family members, which phosphorylate key adapter proteins and phospholipase C γ isoforms. Both kinases display partly overlapping expression patterns, but the intrinsic kinase activity of Zap-70 is lower. In contrast to Syk, which is highly expressed by haematopoietic cells, Zap-70 expression is largely confined to T cells and natural killer cells. In platelets, Zap-70 is not expressed, but Syk is present in the immunoreceptor tyrosine-based activation motif (ITAM) and hemITAM signalling pathways mediating signal transduction by glycoprotein (GP) VI and the C-type lectin-like receptor 2 (CLEC-2). Furthermore, Syk is involved in platelet integrin outside-in signalling. To assess if the two kinases exhibit interchangeable functions *in vivo*, we generated mice, which express Zap-70 under the control of intrinsic Syk promoter elements (*SykZap70/Zap70* mice).
Aims: In this study, we aimed to determine the consequence of the kinase replacement for platelet activation, integrin outside-in signalling and thrombus formation *ex vivo* and *in vivo*.
Methods: Platelet activation *in vitro* was analysed by flow cytometry and aggregometry. Platelet outside-in signalling was assessed using a platelet spreading assay with and without second wave inhibitors. Thrombus formation *ex vivo* was determined by a flow adhesion assay. To investigate the impact of the kinase exchange on haemostasis, tail bleeding times were measured. In addition, *SykZap70/Zap70* mice were subjected to two different models of arterial thrombosis.
Results: *SykZap70/Zap70* platelets spread normally on a fibrinogen-coated surface, indicating that Zap-70 fully compensated for the loss of Syk in the integrin outside-in signalling pathway. Consistent with our data on the abrogated GPVI and CLEC-2 signalling *in vitro* in *SykZap70/Zap70* platelets, thrombus formation under flow on a collagen-coated surface was abolished. The tail bleeding times in the *SykZap70/Zap70* mice were significantly increased, which is in agreement with the recently reported severe haemostatic defect in GPVI/CLEC-2 double-deficient mice. However, in stark contrast to GPVI-, CLEC-2- or double-deficient mice, occlusive arterial thrombus formation *in vivo* was unaltered in *SykZap70/Zap70* mice.
Summary/Conclusion: Syk signalling is essential for maintaining haemostasis. Remarkably, however, Syk appears to be dispensable for arterial thrombus formation *in vivo*. Further studies are required to elucidate whether Zap-70 compensates for the loss of Syk or whether the two platelet receptors GPVI and CLEC-2 have signalling-independent roles in arterial thrombus formation.

Hemostasis and thrombosis in JAK2V617F-KI mice

Lamrani L[1], Lacout C[2], Ollivier V[1], Ho Tin Noe B[1], Vainchenker W[3], Villeval JL[3] and Jandrot-Perrus M[1]

[1]*Inserm U698, Paris Cedex 18;* [2]*Inserm1009e;* [3]*Inserm 1009, Villejuif, France*

Background: Hemostasis disorders represent a leading cause of mortality and morbidity in patients suffering from myeloproliferative neoplasms (MPN) with a high incidence of thrombosis and a lower incidence of hemorrhagic disorders.
The pathophysiology of these anomalies is not known but some risk factors have been identified including the V617F mutation of JAK2 found in 95% and 60% of PV and TE patients, respectively. The specific effect of JAK2^{V617F} on hemostasis deregulation is difficult to characterize in patients because of their heterogeneity in JAK2^{V617F} allele burden and prophylactic treatments. Recently, animal models of MPN were developed as JAK2^{V617F} transgenic and knock-in mice.
Aims: Our objective was to determine, the effect of the JAK2^{V617F} mutation on the *in vitro* and *in vivo* hemostatic responses using JAK2^{V617F}mice.
Methods: We used two KI models, the Vav-Cre and Scl-CreERt/JAK2^{V617F} KI that constitutively and upon tamoxifen induction express the mutation in hematopoietic cells, respectively. Both models mimic a PV-like disease with its evolution into secondary myelofibrosis. The effect of the mutation on platelets was analyzed *in vitro* by flow cytometry, and by measuring adhesion and aggregation in flow conditions on collagen-coated area. Hemostatic responses were assessed *in vivo* by measuring the tail bleeding time and FeCl3-induced thrombosis on mesenteric vessels.
Results: Platelets from Vav-Cre/JAK2^{V617F} mice did not exhibit elevated CD62P level and had normal surface expressions of the major glycoproteins to the exception of GPVI that was significantly decreased ($P > 0.01$). Platelets adhesion and aggregation, in arterial flow conditions (1200/s) on immobilized collagen was profoundly impaired with a platelet surface decreased by up to 80% ($P > 0.01$). *In vivo*, Vav-Cre/JAK2^{V617F} mice exhibited an enlargement of mesenteric vessels and have a prolonged tail bleeding time ($P > 0.01$). After FeCl3-induced injury, platelet aggregates formed rapidly but were highly unstable.
Interestingly, using Scl-CreERt/JAK2^{V617F} mice, platelet GPVI deficiency, morphological vessel abnormalities, the increased tail bleeding time, and the *in vivo* accelerated rate of thrombosis with low thrombus stability, only appeared 2 months after induction of the mutation by the tamoxifen suggesting no direct link with it.
Secondary polycythemia induced by EPO-treatment of WT mice occurred without hemostasis disturbance; Thrombocytemia induced by retroviral expression of TPO in WT mice reproduced the GPVI deficiency, the prolonged bleeding time and the absence of *in vivo* occluding thrombi.
Conclusions: Our results in JAK2^{V617F} mice are consistent with the complex hemostasis disorders observed in MPN patients i.e. thrombosis, embolism and hemorrhages. They seemed not directly associated with the mutation but rather with the development of MPN. Further work is needed to evaluate the cause and consequence of the GPVI and collagen adhesion deficit.

OC 58.6

The JAK2V617F mutation causes an increase in platelet reactivity in a knock-in mouse model of essential thrombocythaemia

Hobbs C[1], Bennett C[1], Manning H[1], Mazharian A[2], Brain L[2], Severin S[2], Li J[1], Green AR[1], Watson SP[2] and Ghevaert C[1]

[1]*University of Cambridge, Cambridge;* [2]*University of Birmingham, Birmingham, UK*

Background: The major clinical challenge in treating patients with myeloproliferative diseases (MPDs) such as polycythaemia vera (PV)

and essential thrombocythaemia (ET) is the prevention of thrombotic events. The JAK2V617F mutation is found in > 90% and ~50% of patients with PV and ET respectively. Initial studies to identify whether platelet reactivity was modified in MPD patients were inconclusive as they were performed before identification of the V617F mutation, and hampered by the co-existance of normal and clonal haematopoiesis. We have generated a knock-in Cre-inducible JAK2V617F mutant mouse in which the human JAK2V617F (huJAK2V617F) has been knocked into one of the endogenous mouse alleles of the JAK2 gene. After induction, comparable transcript levels of the huJAK2V617F and the normal mouse allele have been shown, phenocopying the heterozygous nature of ET patients. This is in contrast to previous studies in transgenic animal models in which the mutation was highly overexpressed.

Methods and Results: Using this model, we have shown increased platelet aggregation to collagen-related peptide (CRP), and mid-range concentrations of collagen in platelet rich plasma (PRP). Fibrinogen binding is increased in whole blood from JAK2V617F mice in response to CRP and thrombin, but decreased in response to ADP compared to WT, with P-selectin expression also increased in response to CRP in JAK2V617F mice. Thrombus formation on a collagen-coated surface increases in whole blood laminar flow assay. Platelet spreading under static conditions on a fibrinogen-coated surface also increased. *In vivo* studies showed a marked decrease in tail bleeding time in mutant animals.

Conclusion: This mouse model offers a unique opportunity to dissect the differences in platelet biology in the context of the JAK2V617F mutation. Our data strongly suggests that JAK2V617F platelets are hyper-reactive, and therefore we postulate that solely reducing the platelet count in ET patients to normal levels is not sufficient to reduce the hyperthrombotic effect of the disease.

OC 59 – Non Inherited Risk Factors for Venous Thrombosis

OC 59.1

A randomized study on 1 vs. 4 weeks prophylaxis for venous thromboembolism after laparoscopic surgery for colorectal cancer

Vedovati MC[1], Becattini C[1], Rondelli F[2], Boncompagni M[3], Camporese G[4], Balzarotti R[5], Mariani E[6], Flamini O[7], Pucciarelli S[8] and Agnelli G[1]

[1]Internal and Cardiovascular Medicine and Stroke Unit, University of Perugia; [2]Department of Oncologic Surgery, University of Perugia; [3]Department of General Surgery, S. Maria della Misericordia Hospital, Perugia; [4]Unit of Angiology, University Hospital of Padua, Padua; [5]Department of General Surgery, Niguarda Hospital, Milan; [6]Department of General Surgery, S. Giovanni Battista Hospital; [7]Unit of Angiology, S. Giovanni Battista Hospital, Foligno; [8]Department of Surgical, Oncological and Gastroenterological Sciences, Padua, Italy

Background: Extending antithrombotic prophylaxis beyond 1 week reduces the incidence of venous thromboembolism (VTE) in patients undergoing open abdominal surgery for cancer. Whether extended prophylaxis is required after laparoscopic surgery for cancer is unknown.

Aims: The aim of the study was to evaluate the efficacy and safety of 4 weeks compared to 1 week antithrombotic prophylaxis in patients who underwent laparoscopic surgery for colon-rectal cancer.

Methods: Complete compression ultrasonography (cCUS) of the lower limbs was performed in consecutive patients after 8 ± 2 days of antithrombotic prophylaxis. Patients with no evidence of VTE were randomized to two prophylaxis regimens: short (heparin discontinuation) or extended (heparin for three additional weeks). cCUS was repeated at day 28 ± 2 after surgery by a study physician blinded to treatment allocation. The study primary outcome was the incidence of VTE at day 28 ± 2 from surgery.

Results: Overall, 301 patients were evaluated for inclusion in the study and 225 were randomized. VTE occurred at day 28 ± 2 in 11 out of 113 patients randomized to short (9.7%) and in none of the 112 patients randomized to extended heparin prophylaxis (RRR 53%, 95% CI 46–59%, $P = 0.001$). The incidence of VTE at 3 months was 0.9% and 9.7% in patients randomized to extended or to short heparin prophylaxis, respectively (RRR 91%, 95% CI 30–99%, $P = 0.003$). The rate of bleedings was similar (0.9% in the two groups).

Conclusions: After laparoscopic surgery for colon-rectal cancer, extended antithrombotic prophylaxis is safe and reduces the risk for VTE, as assessed by cCUS, compared to 1 week prophylaxis (NCT01589146).

OC 59.2

Increased risk of venous thrombosis after arterial thrombosis: causal or explained by common risk factors?

Flinterman LE[1], Lind C[2], Severinsen MT[3], Cannegieter SC[1], Hansen JB[2] and Overvad K[4]

[1]Leiden University Medical Center, Leiden, the Netherlands; [2]University of Tromsø, Tromsø, Norway; [3]Aarhus University Hospital, Aarhus; [4]Aalborg University Hospital, Aalborg, Denmark

Background: Venous and arterial thrombosis are traditionally considered as two different diseases. However, recently associations between the two entities have been described.

Aim: We aimed to investigate explanations for the increased risk of venous thrombosis (VT) after an arterial event (AT), such as presence of common risk factors or immobilisation during the acute phase of a myocardial infarction or stroke.

Methods: The study was performed in two large cohorts from Denmark and Norway, i.e. the Diet, Cancer and Health cohort (DCH) and the Tromsø study. The DCH cohort included individuals recruited between 1993 and 1997 aged 50–64 years and without prior cancer at the time of recruitment. The Tromsø study is a population-based cohort conducted between 1994 and 1995. Both cohorts were regularly linked to their national registries by means of the civil registration number. Incidence rates of VT were calculated for the overall cohorts and for subjects with arterial thrombosis, starting from the date of the arterial event, to study the overall risk and the effect of time on the incidence. The ratios between the two events were calculated using a time-dependent Cox regression model. To investigate the mechanism we adjusted for the following common risk factors: sex, age, Body Mass Index, smoking, alcohol intake, hypertension, diabetes, and education level. All participants gave informed consent, and both studies were approved by their local ethical committee.

Results: Out of 6200 patients with an arterial thrombosis, 108 developed a venous thrombosis, leading to an overall incidence of VT of 4.0 (CI95 3.3–4.8) per 1000 person years in this group, compared to an incidence of 1.2 (CI95 1.1–1.3) per 1000 person years in subjects without AT. This led to an overall 2.7-fold (CI95 2.2–3.3) higher risk of VT in patients with AT. When we studied the time-trend between the two events we found an incidence rate for VT of 39.8 per 1000 person years (CI95 24.7–64.0) in the first 2 months after arterial thrombosis compared with an incidence of 1.1 per 1000 person years (CI95 1.0–1.2) in those without AT. This incidence rate decreased over time to 1.9 per 1000 person years in the period of more than 6 years after the arterial event. When we adjusted the overall hazard ratio for common risk factors, it attenuated from 2.7 to 1.5 (CI95 1.2–1.9), indicating that common risk factors partly explained the increased risk. Patients in whom the VT occurred within 2 months after AT were less likely to

have common risk factors for arterial and venous thrombosis than those who had a VT more than 2 months after an AT.
Conclusion: In the first 2 months after an arterial thrombosis, the risk of a venous event was strongly increased. This risk decreased over time but remained higher also the long term. The long-term association was partly explained by common risk factors. However, in the high-risk period shortly after AT, the role of common risk factors seemed to be limited.

OC 59.3

Arthroscopy of the knee and risk of venous thrombosis: results from the MEGA study

Van Adrichem RA, Nelissen GHH, Schipper IB, Rosendaal FR and Cannegieter SC

Leiden University Medical Center, Leiden, the Netherlands

Background: Knee arthroscopy is the most common orthopaedic procedure performed worldwide. In contrast to most other orthopaedic surgeries, guidelines generally recommend against the use of thromboprophylaxis, because the reported estimates vary widely and the exact risk of venous thrombosis (VT) after knee arthroscopy remains unclear. Furthermore, the influence of genetic and acquired risk factors, as well as the indication for knee arthroscopy on this risk is not known, even though identification of such high-risk groups can individualise prophylactic treatment.
Aims: To estimate the risk of venous thrombosis after knee arthroscopy and to identify high risk groups.
Methods: We used data from a large population based case-control study (MEGA-study) into the aetiology of venous thrombosis (4418 cases, 6150 controls, consent and ethical approval obtained). Odds ratios (OR) with 95% confidence intervals (CI95) were calculated and adjusted for age, sex, body mass index, regular exercise and rheumatic disease. We used varying exposure time windows for reasons of statistical precision. Absolute risks were estimated from the ORs, assuming an incidence of VT of 1–2 per 1000 person years in the general population. Analyses of joint effect all have those with none of the risk factors in the analysis as reference group.
Results: Knee arthroscopy (105 cases, 24 controls) was associated with an almost sevenfold increased risk of VT in the following year (OR 6.7 [CI95; 4.3–10.5]) and an 18-fold increased risk over a 3 months period (OR 18.3 [CI95; 8.8–37.8]). This corresponds to an incidence of VT of 0.5–0.9% in the 3 months after the procedure.
Considering events during 1 year after knee arthroscopy showed that chondroplasty, meniscal surgery and diagnostic knee arthroscopy resulted in a sixfold increased risk (OR 6.1 [CI95; 3.8–9.7]) whereas ligament reconstructions led to a 20-fold increased risk (OR 20.3 [CI95; 2.6–157]). An even more pronounced risk was found in those with genetic or other acquired risk factors. The combination of knee arthroscopy and oral contraception use led to a 64-fold elevated risk over the following year (CI95; 8.5–481); with carriership of the factor V Leiden mutation, prothrombin G20210A mutation or a non-O blood type the OR was 16.6 (CI95; 8.9–30.7). There was no excess risk conferred by obesity (BMI > 30 kg/m^2 and arthroscopy: OR 7.4 [CI95; 2.5–21.5]). No information was available on thromboprophylaxis, while a proportion of the patients most likely did receive this. Therefore our results are most likely an underestimation of the true risk.
Conclusion: Knee arthroscopy strongly increases the risk of venous thrombosis, especially in the first months after the procedure. Patients with genetic predispositions or who have other acquired risk factors have an additionally increased risk. Prophylactic treatment can be individualised and optimised when the indication for knee arthroscopy and the presence of genetic and acquired risk factors are taken into account. This will substantially reduce thrombosis morbidity, especially considering the high frequency of the procedure.

OC 59.4

Optimal risk estimation for DVT requires measurement of coagulation protein concentrations

Bakker B[1], Reitsma PH[2], Van Ooijen HJ[1], Van Den Ham R[1], Rosendaal FR[2] and Lijfering WM[2]

[1]Philips Research, Eindhoven; [2]Leiden University Medical Center, Leiden, the Netherlands

Background: he risk of developing deep venous thrombosis has been linked to a number of separate risk factors, ranging from clinical risk factors like leg injury or immobility to genetic factors like SNPs and plasma coagulation protein concentrations such as the concentration of Factor (F)VIII. In a recent publication, de Haan et al. (Blood, 2012) presented a risk score based on clinical and genetic risk factors, which showed good discrimination results between the high (such as hospitalized patients) and low risk individuals in the MEGA (Blom et al., JAMA, 2005) and LETS (van der Meer et al., Thromb Haemost, 1997) studies. The inclusion of coagulation protein concentrations may further improve the discrimination power of these risk models however.
Aims and Methods: To this end, we applied neural network machine learning methods to the data that has been collected in the MEGA study and constructed an algorithm to translate clinical risk factors (recent surgery, leg injury, immobility, recent travel, pregnancy, use of oral contraceptives, obesity, cancer and family history of thrombosis), genetic risk factors (FV Leiden, blood group non-O, prothrombin G20210A and mutations in FXI and fibrinogen) and coagulation protein concentrations (antithrombin, FII, FVII, FVIII, FIX, FX, FXI, fibrinogen, protein C, protein S) into one risk score. In order to test the robustness of our method, we validated the risk score algorithm that was optimized on the MEGA data on the independent LETS data set.
Results: The machine learning methods based on the complete set of inputs (including coagulation protein concentrations) outperformed the published method based on clinical risk factors and SNPs alone (area under the ROC curve of 0.86, 95% confidence interval 0.84–0.87 vs. 0.81 (0.79–0.82) in a cross-validation study on MEGA). The validation on LETS required the exclusion of cancer patients from the MEGA cohort, since these patients were excluded from the original LETS study. Without malignancies as a discriminative factor, the AUC on MEGA dropped to 0.82 (0.80–0.84) with and 0.78 (0.76–0.80) without coagulation protein concentrations. Without further adaptation of the algorithm, the discriminative power when applied to the LETS cohort remained high with an AUC of 0.81 (0.77–0.85) and 0.78 (0.74–0.82) for the same method with clinical and genetic risk factors only. All increases in AUC upon inclusion of protein concentrations were statistically significant (p-values > 0.05).
Conclusion: These results indicate that including concentration measurements of coagulation proteins holds a strong, additional value over current methods. We showed that earlier published results can be improved when concentrations of coagulation proteins into the thrombosis risk estimation are included.

OC 59.5

Validation study of the IMPACT-ILL venous thromboembolism risk assessment model in the acutely ill medical patient

Mahan CE[1], Vu J[1] and Spyropoulos AC[2]

[1]University of New Mexico, Albuquerque, NM; [2]North Shore/LIJ Health System, Lenox Hill Hospital, Hofstra School of Medicine, New York, NY, USA

Background: For Venous Thromboembolism (VTE) prevention, American College of Chest Physicians (ACCP) and International Union of Angiology (IUA) guideline recommendations are primarily based off of risk factors utilized for entry into randomized controlled trials (RCT) or post-hoc analysis of these RCTs. These guidelines rec-

ommend a group-based, as opposed to an individualized risk assessment, approach. It is currently unknown how these risk factors interact in a quantitative manner.

A recent retrospective VTE risk assessment model (RAM) (IMPACT-ILL) was derived from the multinational IMPROVE registry in hospitalized medical patients. The '*VTE-VALOURR*' is a retrospective, multi-center, case-control, validation study of this RAM and is also assessing other VTE and bleeding risk factors. Many RAMs are available with none being appropriately externally validated in the acutely ill medical patient.

Methods: Reports from ICD-10 coding and the McMaster Transfusion Registry for Utilization Surveillance and Tracking (TRUST) database, which contains demographics, transfusion data, and approximately 50 clinical variables including thrombotic outcomes of inpatients, were used as the data source at three hospitals. Inclusion criteria were hospitalized medical patients ≥ 18 years with ≥ 3 days length of stay (LOS) while exclusion criteria were patients with pregnancy, mental health disorders, atrial fibrillation/flutter, trauma, spinal cord injury, surgery within 90 days, VTE within 24 h of admission, treatment dose anticoagulants (including warfarin) within 48 h of admission, or transferred from a non-McMaster acute care facility. Pulmonary embolism and lower extremity deep vein thrombosis (DVT) within 3 months of admission were the outcomes of interest and verified by chart review. Upper extremity DVT was excluded. Descriptive statistics, including proportions and frequencies, were used to summarize binary variables. A VTE cohort and a VTE free control cohorts' receiver operator curves will be compared assessing the validity of the IMPACT-ILL RAM.

Results: From January 1st, 2005 to February 28th, 2011, 247,241 hospitalizations occurred at three McMaster hospitals. After exclusionary criteria were applied, 779 VTE events were identified. Of these, 419 were excluded because they were VTE events not related to a previous hospitalization (i.e. community-acquired), leaving a VTE cohort of 139 patients. A VTE-free control cohort at a 2:1 ratio was also evaluated for VTE and bleeding risk factors. Approximately 80% of the current VTE cohort appears to have a score of 2 or above and be at moderate to high risk of VTE. Final results of the validity of the IMPACT-ILL VTE RAM will be presented.

Conclusions: Testing for validity of the IMPACT-ILL VTE RAM will be useful and may help identify medical patients at risk of VTE that do not readily fit into group-specific VTE risk categories. Further, validation may identify subsets of medical patients at especially high risk of VTE and focus future randomized controlled trials. Other VTE risk factors may be identified with the study.

OC 59.6

Impact of incident atrial fibrillation on future risk of venous thromboembolismthe Tromsø study

Enga KF, Mathiesen EH, Løchen ML, Mathiesen EB, Njølstad I, Wilsgaard T, Braekkan SK and Hansen JB

University of Tromsø, Tromsø, Norway

Background: Epidemiological and clinical studies have provided strong evidence that atrial fibrillation is associated with thrombus formation in the left atrium with subsequent increased risk of systemic embolism, particularly ischemic stroke. Previous autopsy and retrospective studies have shown that pulmonary embolism may originate from right arterial thrombi. Similarly, a retrospective cohort reported higher prevalence of pulmonary embolism in subjects with atrial fibrillation than without atrial fibrillation. Although these observations support the concept that atrial fibrillation is associated with risk of pulmonary embolism, no prospective cohort study has investigated the association between incident atrial fibrillation and future risk of venous thromboembolism (VTE).

Aims: We wanted to investigate whether incident atrial fibrillation is associated with future risk of incident VTE in a prospective cohort study with subjects recruited from a general population.

Methods: A total of 29 774 men and women participated in at least one survey of the Tromsø study (1994–95, 2001–02 or 2007–08), where information was obtained by questionnaires, blood samples and a physical examination. The study participants were followed from date of enrolment until December 31, 2010, and all events of atrial fibrillation and VTE were recorded and validated. Cox proportional hazard regression models, using age as time scale and atrial fibrillation as a time-dependent variable, were used to obtain crude and multivariable hazard ratios (HR) for VTE with 95% confidence intervals (CI). The analyses were adjusted for sex, body mass index, smoking, physical activity, cholesterol, self-reported arterial cardiovascular disease and diabetes. The study was approved by the regional committee for research ethics, and all participants gave their informed written consent to participate.

Results: Of the study participants, 1604 (5.4%) were diagnosed with atrial fibrillation and 621 (2.1%) had an incident VTE event during a median of 15.6 years follow-up. Among those with atrial fibrillation, 65 (4.1%) developed a subsequent VTE yielding an age-adjusted incidence rate (IR) per 1000 person-years of 9.17 (95% CI: 7.19–11.17), whereas the corresponding IR in subjects without atrial fibrillation was 6.39 (95% CI: 5.69–7.18). Subjects diagnosed with atrial fibrillation had increased risk of VTE compared to subjects without atrial fibrillation in crude (HR: 2.09, 95% CI: 1.60–2.73) and multivariable adjusted analyses (HR: 1.95, 95% CI: 1.48–2.56). Atrial fibrillation was associated with risk of both pulmonary embolism and deep vein thrombosis, but as expected, the risk estimates for pulmonary embolism were higher (multivariable HR: 2.54, 95% CI: 1.74–3.72) than for deep vein thrombosis (multivariable HR: 1.50, 95% CI: 1.01–2.23). The risk of VTE was highest during the first 6 months after the atrial fibrillation diagnosis (age-adjusted IR: 32.06, 95% CI: 21.27–48.32).

Conclusion: We found that atrial fibrillation was associated with increased risk of VTE, and pulmonary embolism in particular. Our findings support the concept that pulmonary embolism may originate from right atrial thrombi formed in an environment of atrial fibrillation.

OC 60 – Novel Platelet Receptors

OC 60.1

Syk is essential for anti-CLEC-2 antibody-induced thrombocytopenia, but not receptor depletion

Lorenz V[1], Stegner D[2], Kiefer F[3] and Nieswandt B[1]

[1]*University Hospital and Rudolf Virchow Center;* [2]*University Hospital, Wuerzburg;* [3]*Max Planck Institute for Molecular Biomedicine, Muenster, Germany*

Background: The C-type lectin-like receptor 2 (CLEC-2) plays an important role in haemostasis and thrombosis. Ligation of CLEC-2 induces phosphorylation of the hemITAM motif of the receptor and the recruitment of Syk, thereby initiating a signalling cascade that involves the adapter LAT and culminates in the activation of phospholipase (PLC) gamma 2. We have previously shown that treatment of mice with the CLEC-2 specific INU1 antibody leads to a transient thrombocytopenia and depletion of CLEC-2 in circulating platelets. Such CLEC-2 depleted mice are protected from occlusive thrombus formation but do not show a major bleeding defect. The mechanisms underlying these anti-CLEC-2 antibody induced effects have not been identified.

Aims: By the use of mouse lines deficient in central molecules in the CLEC-2 signalling pathway the mechanisms underlying anti-CLEC-2 antibody-induced thrombocytopenia and receptor depletion were assessed *in vivo*.

Methods: Mice were treated with the monoclonal antibody INU1 (anti-CLEC-2, 200 μg i.v.) to deplete CLEC-2 in circulating platelets. Platelets were analysed up to 7 days after injection using flow cytometry, biochemical methods and functional assays.

Results: INU1-treatment induced severe thrombocytopenia in wild-type and *Lat*−/− mice to the same extent and this was not altered by

pre-treatment with integrin αIIbβ3-blocking antibodies. In sharp contrast, no thrombocytopenia was observed in INU1-treated mice lacking either CLEC-2 or Syk in platelets demonstrating that binding of INU1 to platelet CLEC-2 directly induces platelet depletion *in vivo* through a Syk-dependent mechanism that does, however, not require αIIbβ3-dependent aggregation. Strikingly, INU1 induced the irreversible loss of CLEC-2 in wild-type, *Lat*−/− and Syk-deficient mice to the same extent and irrespective of αIIbβ3 blockade. In Syk-deficient platelets, the INU1-induced CLEC-2 loss occurred through internalisation and intracellular clearing demonstrating for the first time an active mechanism of CLEC-2 down-regulation in platelets.

Summary/Conclusions: Our results reveal that anti-CLEC-2 antibody induced thrombocytopenia and receptor depletion can be mechanistically uncoupled and that the latter occurs independently of Syk. These findings may have important implications for the possible development of therapeutic agents that modulate CLEC-2 function.

OC 60.2

Expression of exogenous proteins in platelets: all you need is Yop

Prevost N[1], Wölke S[2], Kurata S[1], Morioka Y[1], Heesemann J[2] and Cornelis G[3]

[1]Kyoto University, Kyoto, Japan; [2]Max von Pettenkofer Institute, Munich, Germany; [3]University of Basel, Basel, Switzerland

Background: While primarily known for their role in hemostasis, platelets are also essential components of the innate immune system. Their ability to detect and capture blood-born bacterial pathogens, in particular, is well established. These interactions are varied in nature and depend on the specie and strain a given bacterium belongs to. Yersinia enterocolitica is one of three pathogenic Yersinia species capable of injecting large amounts of plasmid-encoded cytotoxins known as Yops into immune cells, a defense mechanism that is known to disrupt the phagocytic and lytic responses of leukocytes. The injection of Yops into mammalian cells is dependent on the type III secretion system (T3SS) of Yersinia and requires both a *N*-terminal secretion domain and the co-expression of a chaperone protein.

Aims. Because blood platelets are known to bind virulent strains of Yersinia enterocolitica, we hypothesized that these bacteria could be used as a vector to inject proteins into platelets.

Methods: Attenuated, Yop-deficient Yersinia enterocolitica strains were engineered to produce massive amounts of fusion proteins bearing the N-terminal secretion domain of YopE along with the chaperone protein SycE. Expressed proteins included, amongst others, fluorescent proteins and intracytoplasmic epitopes-targeted peptides. Ex vivo infection of blood platelets with fusion protein-expressing Yersinia enterocolitica strains was performed on both activated and resting platelets. After bacteria removal, the amount of injected material present in platelets was quantified by western blotting, immunofluorescence and flow cytometry. Simultaneously, platelets were tested in various assays to ascertain any altered functional response.

Results: Yersinia enterocolitica was able to bind to both resting and activated platelets. Protein injection was very successful in both cases with success rates ranging from 98% to 100%. Within 1 h of infection, fluorescent proteins such as eGFP could be readily detected by immunofluorescence and flow cytometry, demonstrating the efficiency of protein transfer. The infection procedure had no detectable effect on platelet responsiveness. As for inhibitory peptides: platelets that were injected with a peptide spanning part of the talin-1 FERM domain presented with impaired integrin aIIbb3 responses; platelets injected with a peptide targeting calcium channels had normal intracytoplasmic calcium oscillations in their resting state but impaired calcium mobilization when treated with thrombin.

Conclusion: In nucleated cells, expression of exogenous proteins, fluorescent reporters or bioactive peptides is just a transfection step away, a sadly unattainable commodity to all platelet biologists. Bearing this mind, we have sought a methodology that would allow us to overcome this limitation. Our studies show that Yersinia enterocolitica can be engineered to rapidly deliver proteins and peptides into blood platelets without affecting their responsiveness. This new tool should prove especially useful to anyone interested in studying platelet intracytoplasmic signaling.

OC 60.3

A novel double heterozygous substitution p.(Val207Ala; Thr223Arg) in the P2Y12 receptor is associated with reduced receptor expression and platelet dysfunction

Nisar SP[1], Jones ML[1], Murden SL[1], Norman JE[1], Watson SP[2], Mundell SJ[1] and Mumford AD[1]

[1]University of Bristol, Bristol; [2]University of Birmingham, Birmingham, UK

Background: The Genotyping and Phenotyping of Platelets consortium (GAPP) has developed an approach for rapidly identifying and characterizing rare function disrupting variations in genes encoding platelet proteins, including GPCRs which are critical regulators of platelet function and are anti-thrombotic drug targets. This has yielded two novel thromboxane receptor variants (Mumford et al., 2010; Mumford et al., 2013) and three novel $P2Y_{12}$ variants (Nisar et al., 2011; Daly et al., 2009; Patel et al., in preparation) which result in reduced platelet responsiveness. We now report a novel double heterozygous $P2Y_{12}$ receptor variant associated with reduced platelet responsiveness to ADP.

Aims: To characterise the functional effect of the double heterozygous p.[(Val207Ala; Thr223Arg)] $P2Y_{12}$ variant in platelets and cell lines.

Methods: Platelet function was assessed by measuring platelet aggregation responses in platelet rich plasma (PRP). The candidate $P2Y_{12}$ variations were identified by capture of the *P2Y12R* coding exons from genomic DNA using an Agilent-SureSelect targeted array of 216 platelet genes and sequencing on an Illumina GA-II. For the cell expression studies, HA-tagged wild type (WT), V207A, T223R and V207A/T223R constructs were generated and transiently expressed in HEK293 cells and stably expressed in human 1321N1 astrocytoma cells.

Results: The 41 year old female subject with no history of pathological bleeding displayed diminished aggregation responses to 2 and 5 μM ADP compared to healthy controls, but similar aggregation responses to high concentrations of other agonists. Analysis of *P2Y12R* showed heterozygous non-synonymous variations predictive of V207A and T223R substitutions in the 5th transmembrane domain and the 3rd intra-cellular loop respectively. A family study showed that both variations p.([Val207Ala; Thr223Arg]) were present on the same *P2Y12R* allele. Immunoblotting and imaging experiments in both HEK293 and 1321N1 cells showed that total expression of the double mutant V207A/T223R was significantly reduced and accompanied with a loss of receptor function. Surface and total expression of the single mutants, however, was comparable to WT.

Conclusions: We have identified a novel double heterozygous mutation within the $P2Y_{12}$ receptor, associated with reduced ADP-induced platelet aggregation. This is the first description of a naturally occurring double variant in the same $P2Y_{12}$ allele. Our data suggest that it is the combination of the V207A and T223R substitutions that causes reduced total receptor expression, resulting in reduced platelet responsiveness to ADP.

OC 60.4

Endothelial protein C receptor is expressed on activated platelets and contributes to FVIIa binding

Hoffman M[1] and Monroe D[2]

[1]Duke University, Durham; [2]University of North Carolina, Chapel Hill, NC, USA

Background: At pharmacologic concentrations recombinant Factor VIIa (rFVIIa, NovoSeven®) binds to activated platelets and mediates activation of FX directly on the platelet surface. We originally proposed that this binding was mediated by surface-expressed phosphatidyl serine (PS). More recently, Lismann et al. demonstrated that rFVIIa can also bind to the platelet surface glycoprotein (GP) Ib/IX/V complex. However, binding to GPIb/IX/V on other membrane surfaces did not recapitulate the pattern of rFVIIa binding to activated platelets. Therefore, we sought other possible contributors to platelet rFVIIa binding.

Aims: Our unpublished data show that Protein C can partially compete with rFVIIa and rFVIIa variants for binding to activated platelets. The group of Pendurthi and Rao have shown that rFVIIa binds to endothelial protein C receptor (EPCR) and that binding to EPCR modulates the proteolytic activity of rFVIIa against cell-surface targets. The goal of our current work is to determine whether EPCR is expressed on platelets and whether it contributes to rFVIIa binding (and activity) on platelets.

Methods: Human platelets were isolated from blood samples collected from normal donors after obtaining informed consent. The binding of rat monoclonal (Santa Cruz) and goat polyclonal (Affinity Biologicals) antibodies raised against human EPCR was assessed by flow cytometry. EPCR was also immunoprecipitated from platelet lysates using the monoclonal antibody and detected on PAGE followed by Western blotting with the polyclonal antibody.

Results: We found that EPCR could not be detected on the surface of unactivated platelets, and activation with thrombin alone resulted in a low level of EPCR expression. By contrast, activation with the combination of thrombin and convulxin (a collagen receptor agonist) resulted in the appearance of a discrete population of platelets with high expression of EPCR and a residual population of platelets that are negative for EPCR. The population of EPCR-positive platelets is the same as the platelets that bind high levels of rFVIIa, and comprise from 30% to 60% of the platelets, depending on the blood donor. Kjalke et al. have previously reported that COllagen And Thrombin activated (COAT) platelets preferentially bind rFVIIa. An anti-EPCR antibody was able to partially block FVIIa binding to activated platelets. A protein with the correct molecular weight for full length EPCR could be immunoprecipitated from thrombin + convulxin-activated platelets.

Conclusion: EPCR is expressed on the population of highly procoagulant COAT platelets induced by dual stimulation with thrombin and a collagen agonist. EPCR plays a role in mediating binding of rFVIIa to activated platelet surfaces.

OC 60.5

Regulation of the hemostatic and inflammatory responses triggered by ligands of Toll like receptor 2 and 4 is another non-genomic role of nuclear factor-?B in platelets

Rivadeneyra L[1], Carestia A[1], Fondevila C[2], Negrotto S[1] and Schattner M[1]

[1]Institute of Experimental MedicineNational Academy of MedicineCONICET; [2]Bazterrica Clinic, Buenos Aires, Argentina

Background: Platelets express toll like receptors (TLRs), a family of proteins that recognize molecular components of pathogens. Although several studies reported platelet activation mediated by activation of TLR2 and 4, the data are controversial and the molecular mechanisms are not fully elucidated. In nucleated cells, one of the downstream molecules of the TLRs signaling pathway is the transcription factor nuclear factor-κB (NF-κB), a major regulator of inflammatory genes transcription. We have previously shown that activation of NF-κB mediates platelet activation triggered by classical platelet agonists, indicating that this transcription factor exerts non-genomic functions in platelets.Whether NF-κB is involved in the signaling pathway of TLR2 and 4 have not yet been investigated.

Aim: To further examine platelet activation mediated by TLR2 and TLR4 stimulation and determine if activation of NF-κB is a downstream signal.

Methods: Washed human platelets were stimulated with Pam(3)CSK (4) or lipopolysaccharide (LPS) (agonists for TLR2 or 4 respectively) in the absence or presence of BAY11-7082 and Ro106-9920, two non-structurally related inhibitors of NF-κB. Aggregation and ATP release were measured using a Lumi-aggregometer and platelet-leukocyte aggregates were enumerated by cytometry. Activation of NF-κB was examined by the degradation of its inhibitor, I-kB, and the phosphorylation of the p65 subunit, by Western Blot. The release of IL-1b was determined by ELISA. Results are expressed as X ± SEM (Student T test $*P > 0.05$ vs. C and ANOVA $\#P > 0.05$ vs. Pam(3)CSK(4), LPS or Thrombin (Thr) $n = 4–5$).

Results: Stimulation of platelets with Pam(3)CSK(4) (0.1–15 μg/mL) triggered platelet aggregation, ATP release, as well as proinflammatory responses such as IL-1b secretion (C: 51 ± 13, Pam(3)CSK(4) (1 μg/mL): 288 ± 96* pg/mL) and the formation of platelet-leukocyte aggregates (C: 17 ± 2, Pam(3)CSK(4): 38 ± 4*% of PMN associated with platelets). All Pam(3)CSK(4)-mediated responses were completely inhibited by preincubation of the platelets with BAY11-7082 or Ro106-9920. LPS (10 μg/mL) did not have a direct effect but potentiated aggregation and ATP release induced by threshold Thr concentrations (0.01 U/mL). This synergism was partially blocked by the NF-κB inhibitors (BAY11-7082: 39 ± $3^{\#}$, Ro106-9920: 37 ± $5^{\#}$% of inhibition). While platelet-leukocyte aggregates were no triggered by LPS, it efficiently induced IL-1b release that was prevented in platelets pretreated with BAY11-7082 or Ro106-9920 (C: 51 ± 13, LPS: 460 ± 110*, LPS+BAY11-7082: 24 ± $16^{\#}$, LPS+Ro106-9920: 32 ± $17^{\#}$ pg/mL). Stimulation of platelets with 1 μg/mL of Pam(3) CSK(4) or LPS resulted in the degradation of I-kB and the phosphorylation of the p65 subunit of NF-κB (Pam(3)CSK(4): 5 ± 1*, LPS: 6 ± 1*, fold increase). Both responses elicited by Pam(3)CSK(4) or LPS were completely inhibited by an antibody against TLR2 or 4 respectively, and synergized by threshold concentrations of Thr (phosphorylation of p65: Thr: 4 ± 1, Thr+Pam(3)CSK(4): 9 ± $1^{\#}$, Thr + LPS: 12 ± $4^{\#}$).

Conclusion: Activation of TLR2 and 4 trigger platelet hemostatic and inflammatory responses that are mediated by the transcription factor NF-κB. These data reinforce the notion of the relationship between the immune response and platelets, reveal another non-genomic function of NF-κB in platelets and highlight this molecule as a potential target to prevent platelet activation in inflammatory and infectious diseases.

OC 60.6

The newly identified platelet receptor DCBLD2 is involved in platelet activation and thrombus formation

Nuyttens BP[1], Broos K[1], Sadeghi M[2], Nie L[2], De Meyer SF[1], Vanhoorelbeke K[1] and Deckmyn H[1]

[1]KU Leuven Kulak, Kortrijk, Belgium; [2]Yale University School of Medicine, New Haven, CT, USA

Background: Recent genome wide association and -omics studies revealed new platelet proteins potentially related to platelet disorders. One of these is the discoidin, CUB and LCCL domain containing 2 protein (DCBLD2), a transmembrane receptor which we previously found to be involved in thrombus formation in a zebrafish model [1].

Aim: Our aim is to further characterize the role of DCBLD2 in thrombosis and haemostasis and to uncover its platelet-specific function.
Methods: To study the *in vivo* role of DCBLD2 in thrombosis and haemostasis, DCBLD2 knock-out (KO) mice were subjected to well established models of $FeCl_3$-induced thrombosis, tail clipping bleeding and ischemic stroke (transient middle cerebral artery occlusion, tMCAO). *In vitro* agonist-induced platelet aggregation experiments and flow cytometric analysis of murine and human platelets provided further clues about the mechanisms responsible for the effects observed *in vivo*.
Results: Although DCBLD2 KO mice have normal platelet counts and no distinct phenotype, the absence of DCBLD2 clearly resulted in a significant decrease in the time to occlusion upon arterial vessel damage in the $FeCl_3$-induced thrombosis model. These data confirm our earlier findings in zebra fish and point towards an attenuating effect of DCBLD2 on thrombus formation. Interestingly, absence of DCBLD2 did not affect tail-clipping times. It is known that certain platelet receptor-ligand interactions contribute to stroke progression after reperfusion of previously occluded major arteries. This is however not the case for DCBLD2 as the infarct volume and functional outcomes after ischemic stroke in DCBLD2 KO mice were not significantly different from those in wild-type animals. Involvement of DCBLD2 in platelet activation was further validated by *in vitro* agonist-induced platelet aggregation experiments. Aggregation of platelet rich plasma (PRP) from DCBLD2 KO mice showed a significant increase of $13 \pm 0.5\%$ ($n = 5$; $P > 0.01$) and $10 \pm 1\%$ ($n = 3$; $P > 0.01$) compared to controls when stimulated with ADP or collagen respectively. When stimulated with threshold concentrations of thrombin, the maximum aggregation level of DCBLD2 KO platelets was up to $40 \pm 4\%$ ($n = 4$; $P > 0.01$) higher. In addition, flow cytometric analysis of washed platelets from the DCBLD2 KO mice, activated with threshold concentrations of thrombin, showed increased expression of both P-selectin and activated $\alpha_{IIb}\beta_3$, further demonstrating the dampening effect of DCBLD2 on platelet activation. Aggregation of platelets in human PRP was found to be stronger in response to several agonists in the presence of recombinant human DCBLD2-extracellular domain (ECD) indicating not only a similar role for DCBLD2 in man as in mice, but also suggesting that the recombinant domain is competing with the receptor for an extracellular ligand.
Conclusions: Our data demonstrate a down-regulating function of DCBLD2 in platelet activation and platelet-dependent thrombus formation. Our experiments also suggest the presence of an extracellular ligand for DCBLD2, which remains to be identified.

OC 61 – Pregnancy and Coagulation

OC 61.1
Qualitative changes in VWF are acquired during pregnancy

Johnsen JM[1], Drury-Stewart D[1], Lannert KW[1], Gammill HS[2], Zimring JC[1] and Konkle BA[1]
[1]*Puget Sound Blood Center;* [2]*University of Washington, Seattle, WA, USA*

Background: Levels of the critical clotting protein von Willebrand Factor (VWF) increase markedly during pregnancy. The VWF changes observed during pregnancy have long been thought to be the result of direct hormonal stimulation of VWF production. We hypothesized that pregnancy also induces qualitative changes in VWF.
Aims: To test this hypothesis, we investigated molecular properties of VWF in healthy pregnancies.
Methods: Plasma samples were obtained from a healthy pregnancy repository; all pregnancies exhibit increased VWF:Ag levels, consistent with the literature, and all have stable ADAMTS13 activities. For this study, subjects who had samples available from multiple trimesters and a > 6 week postpartum sample were selected. Samples were normalized for VWF:Ag (ELISA, GTI Diagnostics) in VWF-deficient plasma (Affinity Biologicals). VWF multimers were examined by 1% agarose gel electrophoresis, blotted to PVDF, and detected by immunoblotting (HRP-conjugated rabbit anti-human VWF, Dako). Isoelectric focusing (IEF) of native plasma was performed in precast 5% acrylamide gels pH range 3–7 (Invitrogen), blotted to PVDF, and detected by immunoblotting (HRP-conjugated rabbit anti-human VWF, Dako). VWF blood group A glycan burden was determined by ELISA (mouse anti-A primary antibody, Immucor; HRP-conjugated donkey anti-mouse secondary antibody, Jackson ImmunoResearch).
Results: VWF multimer patterns shifted over the course of pregnancy towards higher order multimers by the third trimester. These higher order multimers were no longer detectable in postpartum samples. IEF analysis of native VWF demonstrated two distinct bands which focused at pH ~5.6 and 5.7 in normal plasma and early pregnancy samples. The VWF upper band (pH 5.7) became less distinct, shifted focus towards the lower band (pH 5.6), and the ratio of top band density to lower band density decreased in the third trimester. The VWF focusing pattern returned to two distinct bands at pH 5.6 and 5.7 in the postpartum sample. Blood group A glycan burden on VWF shifted to a progressively to higher detectable A glycan over the course of two pregnancies and returned to a lower A glycan burden postpartum. However, this pattern of increased A glycan burden was not consistent among several other blood group A pregnancies tested.
Conclusions: VWF multimer structure and isoelectric point changed over the course of these pregnancies. These shifts were most evident in the third trimester and resolved postpartum. Interestingly, VWF blood group A carbohydrate burden also demonstrated a capacity to shift over the course of pregnancy, but this finding was not consistent in other pregnant blood group A subjects. We conclude that VWF can acquire complex molecular qualitative changes during gestation. These data support a new model in which VWF shifts both quantitatively and qualitatively as a result of pregnancy. We speculate that pregnancy-induced qualitative changes correspond with differences in VWF function. The shift towards higher order VWF multimers later in pregnancy suggests greater VWF hemostatic activity. This new model may have significant clinical implications for pregnant women, particularly in the assessment of patients at risk for bleeding or thrombotic complications.

OC 61.2
Aspirin or anticoagulants for treating recurrent miscarriage in women without antiphospholipid syndrome: an updated systematic review

De Jong PG[1], Kaandorp SP[1], Di Nisio M[2], Goddijn M[1] and Middeldorp S[3]
[1]*Academic Medical Center Amsterdam, Amsterdam, the Netherlands;* [2]*University "G. D'Annunzio" of Chieti-Pescara, Chieti, Italy;* [3]*Academic Medical Center, Amsterdam, the Netherlands*

Background: Approximately 5% of women attempting to conceive experience two or more miscarriages (recurrent miscarriage, RM). RM is associated with thrombophilia and anticoagulant therapy appears to increase the chance of live birth in subsequent pregnancies in women with antiphospholipid syndrome. Whether this is also true in women with unexplained RM or women with RM and inherited thrombophilia is uncertain.
Aims: To evaluate the efficacy and safety of aspirin and anticoagulant agents in women with a history of at least two miscarriages without apparent causes, other than inherited thrombophilia.
Methods: We searched the Cochrane Pregnancy and Childbirth Group's Trials Register (30 April 2012) and scanned bibliographies of all located articles for any unidentified articles.

Randomised and quasi-randomised controlled trials that assessed the effect of anticoagulant treatment on live birth in women with a history of at least two miscarriages without apparent causes other than inherited thrombophilia were eligible. Interventions included aspirin, unfractionated heparin, and low-molecular-weight heparin (LMWH) for the prevention of miscarriage. One treatment could be compared with another or with placebo. Two authors assessed the studies for inclusion in the review and extracted the data. If necessary they contacted study authors for more information.

Result: Nine studies, including data of 1238 women, were included in this review evaluating the effect of either LMWH or aspirin or a combination of both, on the chance of live birth in women with recurrent miscarriage, with or without inherited thrombophilia. Studies were heterogeneous with regard to study design and treatment regimen and three studies were considered to be at high risk of bias. Two of these three studies showed a benefit of one treatment over the other, but in sensitivity analyses (in which studies at high risk of bias were excluded) anticoagulants did not show a beneficial effect on live birth. Obstetric complications such as preterm delivery, preeclampsia, intrauterine growth restriction and congenital malformations were not significantly affected by any treatment regimen. Treatment with LWMH combined with aspirin increased the risk of bleeding significantly in one study. Local skin reactions to LMWH were reported in almost 40% of patients in the same study. Subgroup analyses in women with inherited thrombophilia were underpowered for firm conclusions.

Conclusion: There is a limited number of studies on the efficacy and safety of aspirin and heparin in women with a history of at least two miscarriages without apparent causes other than inherited thrombophilia. Of the nine reviewed studies quality varied, different treatments were studied and of the studies at low risk of bias only one was placebo-controlled. No beneficial effect of anticoagulants in studies at low risk of bias was found. Therefore, the use of anticoagulants in women with unexplained recurrent miscarriage is not recommended. The effect of anticoagulants in women with unexplained recurrent miscarriage and inherited thrombophilia needs to be assessed in randomised placebo controlled trials; at present there is no evidence of a beneficial effect.

OC 61.3

Calibrated automated thrombography does not reveal hypercoagulability in women with unexplained recurrent pregnancy loss

Bennett AS[1], Bagot C[2], Appiah A[3], Johns J[3], Ross J[3], Roberts L[1], Patel R[1] and Arya R[1]

[1]King's Thrombosis Centre, London; [2]Department of Haematological Medicine, Glasgow; [3]Department of Maternal Medicine, King's College Hospital NHS Foundation Trust, London, UK

Background: Unexplained recurrent pregnancy loss (RPL) is often attributed to an underlying maternal prothrombotic state. Consequently it is common practice for such patients to receive antenatal thromboprophylaxis despite randomized controlled trials (RCTs) demonstrating no benefit of aspirin ± heparin over placebo for live birth rate.

Aims: To ascertain whether a global assay of coagulation, calibrated automated thrombography (CAT) could discriminate between women with a history of RPL when compared with parous controls who have never experienced pregnancy loss.

Methods: Between March 2011 and September 2012 we prospectively recruited 50 consecutive women from the recurrent miscarriage clinic at King's College Hospital. Those with ≥ 3 losses prior to 14 weeks' gestation or 1 loss after 14 weeks that remained unexplained were eligible, and were compared to 41 controls. Exclusion criteria comprised prior venous thromboembolism, antiphospholipid syndrome, inherited thrombophilia, previous placenta mediated pregnancy complication, use of hormonal contraception, anticoagulants and immunosuppressants. Venous blood was collected (> 6 weeks after a miscarriage) with minimal stasis and the second draw divided into BD vacutainers containing 0.109 M trisodium citrate. Each participant also provided a sample to which corn trypsin inhibitor (CTI) at a final concentration of 18.3 μg/mL was added. Platelet poor plasma (PPP) prepared following double centrifugation at 4750 *g* for 10 min was stored at −40°C. Hemker's thrombin generation method was carried out utilising manufacturer reagents (Thrombinoscope BV, the Netherlands). PPP was tested alone (5 pM) and with thrombomodulin (5 pMTM) at a final concentration of 6 nM (5 pM TF and 4 μM PL) and with 1 pM TF for samples containing CTI at a mean ± SD time period of 5.3 ± 1.3 weeks following freezing. Peak thrombin and estimated thrombin potential (ETP) are expressed as normalised ratios against NHCP (Technoclone, Austria) which was run in tandem with each assay as a reference plasma. Velocity index (peak thrombin/[time to peak thrombin-lag time]) and percentage suppression of both peak thrombin and ETP in the presence of TM were also determined ([variable in the absence of TM-variable in the presence of TM]/variable in the absence of TM).

Results: Normalised ratios for peak thrombin (5 pM: 0.88 vs. 0.83, $P = 0.42$; 5 pMTM: 0.79 vs. 0.69, $P = 0.19$; 1 pM: 0.43 vs. 0.36, $P = 0.11$) and ETP (5 pM: 0.81 vs. 0.75, $P = 0.27$; 5 pMTM: 0.67 vs. 0.57, $P = 0.19$; 1 pM: 0.68 vs. 0.61, $P = 0.17$) were comparable between subjects and controls in all assays respectively. There was no statistical difference in velocity index (5 pM: 104.7 nM/min vs. 100.1 nM/min, $P = 0.93$; 5 pMTM: 85.2 nM/min vs. 73.9 nM/min, $P = 0.37$; 1 pM: 28.1 nM/min vs. 24.8 nM/min, $P = 0.65$) or TM-related suppression of peak thrombin (34.6 vs. 38.5, $P = 0.63$) and ETP (46.7 vs. 49.8, $P = 0.86$) between subjects and controls respectively. *P* values adjusted for potential confounding factors of age, ethnicity, smoking status, phase of menstrual cycle, BMI, factor VIII:C and antithrombin levels.

Summary: Calibrated automated thrombography was not able to identify an underlying prothrombotic state in women with unexplained RPL. These results do not provide a rationale for use of prophylactic anticoagulation to safeguard pregnancy in such women and support the findings of recently published RCTs which failed to show the benefit of such an approach.

OC 61.4

Risk of recurrence during pregnancy after a first VTE: a french cohort

Le Moigne E[1], Delluc A[1], Daoudal A[1], Nowak E[2], Mottier D[2] and Le Gal G[2]

[1]Brest University Hospital; [2]Clinical Investigations Center, Brest, France

Background: Pregnancy is a high risk period for venous thromboembolism (VTE) especially for women with previous VTE. However, risk stratification is difficult and recommendations for prophylaxis are of low grade of evidence because randomized studies are lacking during pregnancy.

Aims: We aimed to study the risk of recurrent VTE during pregnancy after a first VTE.

Methods: We studied the risk of recurrent VTE during pregnancy in a cohort of young women under 50 years with first proved VTE, admitted from 1992 to 2010 in BrestUniversityHospital. Follow-up information was collected annually about medical events and thrombosis risk factors. In case of pregnancy, we collected information about prophylaxis with low-molecular-weight heparin (LMWH).

Results: Of the 338 women under 50 years with a first VTE, 62 had a total of 96 pregnancies starting before January 2011. At beginning of pregnancy, median age was 29 years and 29% of women were obese. Initial VTE was associated with hormones (pregnancy, postpartum or contraception) in 92%. We observed recurrent VTE in 7.3% of

pregnancies. Women received prophylaxis with LMWH in 79% of pregnancies. Dose and duration of prophylaxis were consistent with international recommendations in 65% of cases. Recurrent VTE occurred in early pregnancy, before starting prophylaxis, and postpartum sometime despite LMWH. Risk factors for recurrence were obesity, varicose veins and hormone-related initial VTE.
Conclusion: Risk of recurrent VTE during pregnancy is high, which would justify early prophylaxis in pregnancy, especially for women with initial hormone-related VTE. Discontinuation of anticoagulants for delivery and LMWH dosage may explain failures of prophylaxis during postpartum. Risk stratification and randomized trials would solve this issue.

OC 61.5

Risk factors for acute VTE in pregnancy and the postpartum period: a retrospective case control study of 14 years at National Women's Health, Auckland, New Zealand

Emmett SC[1] and McLintock C[2]

[1]BC Women's Hospital, Vancouver, BC, Canada; [2]National Womens' Hospital, Auckland, New Zealand

Background: This was a retrospective study of acute venous thromboemboli (VTE) occurring during pregnancy or within 8 weeks postpartum, from 1998 to 2011, at National Women's Health, New Zealand.
Aim: The assessment of the risk factors for acute pregnancy associated VTE (PA-VTE).
Methods: Medical ethics approval was obtained. The study group included women who received enoxaparin for the treatment of acute PA-VTE. The control group was women who delivered before and after study group patients. Data was collected from patients' records.
Results: Seventy-eight events occurred in 76 women and 123 controls were identified. The incidences of age > 35 years, parity ≥ 3, multiple pregnancies, smoking, BM > 30, comorbidities or preeclampsia were not statistically increased in this study group compared to the control group but the incidence of antiphospholipid syndrome was statistically higher in the study group. There was a history of previous VTE in 12.8% of the study group, of which 80% were hormone related. A family history of VTE was present in 21% of the women and half of the VTEs in mothers or sisters were pregnancy related. Of those tested, Protein S deficiency was confirmed in two patients (3%), four patients (6.3%) were FVL heterozygous and 9 (15.3%) were PGM heterozygous. The incidence of emergency caesarian deliveries was significantly greater in those with postpartum VTEs than the control group. Of the 21 postpartum VTEs, three patients had received thromboprophylaxis. Postpartum prophylaxis may have prevented six of eighteen VTE. There was associated systemic infection in 11 cases, surgery in one case and severe varicose veins in two cases. Twelve women were immobilized for ≥ 3 days. Of the 29 women with first trimester VTEs, six (20.7%) experienced hyperemesis. Regional anaesthesia was not significantly different between the postpartum VTE and control groups. There was a higher incidence of VTE in those of European ethnicity and a lower incidence in those of Asian ethnicity. The ACCP[3] and RANZCOG[2] guidelines were assessed for thromboprophylaxis recommendations in women with a personal history of VTE, those with inherited thrombophilias and in the postpartum setting. Eight patients had previous pregnancy or COC related VTE and should have received thromboprophylaxis according to both guidelines. Postpartum thromboprophylaxis may have prevented 6 (33%) of the postpartum VTEs. Of the three patients with a known thrombophilia and a family history of VTE, the VTE may have been prevented by thromboprophylaxis in accordance with the ACCP guidelines in one case and with the RANZCOG guidelines in two cases. None of the ten women, with known thrombophilias but no personal or family history of VTE, would have received thromboprophylaxis according to either guideline.
Conclusion: A family history of VTE is highlighted as a risk factor for PA-VTE. Testing for heritable thrombophilias should be considered if there is a history an unprovoked or hormone-related VTE in a first degree relative. A third of the postpartum VTE occurred within 7 days of delivery and may have been prevented by thromboproprophylaxis. There was a significant association between emergency caesarean deliveries and postpartum VTE.

OC 61.6

Tranexamic acid inhibits fibrinolysis-induced coagulopathy associated with post-partum hemorrhage

Susen S[1], Tournoys A[1], Duhamel A[2], Elkalioubie A[3], Dupont A[3], Debize G[4], De Prost D[5], Huissoud C[6], Jude B[3] and Ducloy-Bouthors AS[7]

[1]Haematology Transfusion Department; [2]Pole de santé publique, CHRU de Lille; [3]Univ Lille Nord de France, UDSL, IFR114, EA2693, Faculté de Médecine, Lille; [4]Pole d'Hématologie, Hopitaux civils de Lyon, Lyon; [5]Pole d'Hématologie, CHU Louis Mourrier, APHP, Paris; [6]Pole d'Obstétrique, Hopitaux civils de Lyon, Lyon; [7]Pole d'Anesthésie-Réanimation, CHRU de Lille, Lille, France

Background: Beneficial effects of the preventive use of tranexamic acid (TA) have been established in major surgery and trauma. In ongoing post-partum haemorrhage (PPH), a high dose of TA reduced blood loss, duration of bleeding and transfusion needs in the French randomized controlled EXADELI trial. During this study (Controlled Trials ISRCTN09968140), markers of fibrinolysis were investigated.
Aims: To investigate the biological effects of tranexamic acid on hemostasis in post partum haemorrhage.
Methods: women with PPH > 800 mL following vaginal delivery were assigned to receive either TA (loading dose4 g over 1 h, then infusion of 1 g/h over 6 h) (TA [n = 72]), or no prohaemostatic treatment (untreated controls [n = 72]). At four time-points (T1 inclusion, T2 30 min, T3 2 h, T4 6 h), blood loss and biological coagulation parameters (D Dimers, factor II (FII), factor V (FV) and plasmin antiplasmin complexes [PAP]) were recorded. Results are expressed as median and quartiles.
Results: In the control group, D Dimers were increased at T1 (3730 ng/mL [2468–8493]) as soon as the PPH began and became maximal at T3 (7495 [4400–15,772]; P = 0·001 T1 vs. T3). Fibrinogen, FII and FV levels decreased from T1 to T4 with the lowest values at T3 (fibrinogen 3.34 g/L [2.6–4], FII 78 UI/mL [68–88], FV 77 UI/mL [66–90]; P > 0.0001 when compared to T1 values). In the TA group, the increase in D Dimers was blunted and T3 levels were kept as low as T1 (3888 ng/mL [2688–6172] vs. 3645 ng/mL [2222–6223]; T3 and T1 values respectively) and were significantly reduced when compared to controls (P > 0.0001). PAP complexes were significantly reduced in the TA group compared to controls (902 μg/mL [516–1289] vs. 2254 μg/mL [1113–3394] respectively; P = 0.03 at T2, trend for T3). The time course of fibrinogen, FII and FV was not significantly modified by the use of TA.
Summary/Conclusions: This study provides a biological evidence of hyperfibrinolysis-induced coagulopathy associated with PPH and its improvement by the use of Tranexamic acid.

OC 62 – Rare Bleeding Disorders – II

OC 62.1

First report of a CalDAG-GEFI gene (RASGRP2) mutation in humans that affects platelet function and causes severe bleeding

Canault M[1], Ghalloussi D[2], Grosdidier C[2], Morange PE[2], Pillois X[3], Nurden AT[3], Kuijpers TW[4], Tregouet DA[5] and Alessi M-C[2]
[1]UMR Inserm 1062INRA 1260; [2]UMR Inserm1062INRA 1060Aix-Marseille University, Marseille; [3]LIRYC, Plateforme Technologique et d'Innovation BiomédicaleHopital X. Arnoza, Pessac, France; [4]Sanquin Research and Landsteiner LaboratoryUniversity of Amsterdam, Amsterdam, the Netherlands; [5]Inserm UMR_S 937, ICANPierre and Marie Curie University, Paris, France

Background: Inherited platelet disorders are rare diseases that give rise to bleeding when platelets fail to fulfill their hemostatic function upon vessel injury. Study of these pathologies provides an unique opportunity to delineate mechanisms of platelet signal transduction by highlighting defects in specific pathways.
Aims: To investigate the molecular basis of an inherited platelet disorder in three siblings affected by severe bleeding and a platelet aggregation defect in the absence of mutations in *ITGA2B* and *ITGB3* genes coding $\alpha II_b\beta 3$
Methods: Exome sequencing; Genotyping; Protein sequence modeling; Flow cytometry; Platelet function testing (aggregation, adhesion and spreading); GTPases activation assays; Thrombin generation; Leukocyte phenotyping.
Results: Exome sequencing of two affected siblings and three non-affected relatives (focusing on single nucleotide or ins/del variants affecting coding regions) revealed 114 candidate variants following the recessive hypothesis. Only four candidates were absent or at low frequency (> 1‰) in public databases. Among these one stood out, a non-synonymous cG742T mutation (exon 8) in the *RASGRP2* (RAS guanyl releasing protein 2) gene leading to p.G248W in the encoded protein, Calcium and DAG-regulated Guanine Exchange Factor I (CalDAG-GEFI). Modeling a closely related structure, SOS-2, reveals that the mutation causes the formation of a protrusion within the cavity of the catalytic domain of the GEF. The mutation affects platelet's ability to effect proper $\alpha II_b\beta 3$ integrin inside-out signaling. In homozygous carriers, maximal aggregation in response to all tested doses of ADP or low doses of any other agonists was reduced except for ristocetin and PMA (phorbol 12-myristate 13-acetate). Dense and alpha granule numbers and content were normal and procoagulant properties were moderately affected. The mutation strongly dampened the activation of the CalDAG-GEFI prototypical substrate in platelets, Rap1, induced by low and intermediate doses of ADP and TRAP-6. PMA induces the same Rap1 activation in patients and controls highlighting, the existence of CalDAG-GEFI bypassing pathways dependent on protein kinase C (PKC). An ADP-mediated pathway able to overcome CalDAG-GEFI dysfunction was also shown.
Under arterial flow and over fibrillar collagen, the surface covered by homozygous platelets was strongly reduced. Although there was no obvious defect in aggregation, the adhesion kinetics were also strongly altered for obligate heterozygotes whose have normal tethering but defective ability to form thrombi.
On immobilized fibrinogen, homozygous and heterozygous platelets exhibit a reduced number of filopodia and failed to form lamellipodia. Accordingly, Rac1 activation was decreased. Stimulation with high doses agonists only partially reversed the spreading defect indicating that CalDAG-GEFI activity is required for full spreading. The functional deficiency induced by the *RASGRP2* mutation is confined to platelets and has only little impact on leukocyte functions.
Conclusion: We report the first case of a *RASGRP2* mutation in humans causing severe bleeding without affecting leukocytes. Remarkably, the functional deficiency was found to be confined to platelets and can be bypassed under some conditions. We observed that the presence of only one normal allele is sufficient to support normal aggregation but not adhesion under flow and spreading. This makes CalDAG-GEFI an interesting therapeutic target to prevent thrombosis without causing bleeding.

OC 62.2

A comprehensive approach for the study of a rare bleeding disorder: factor VII deficiency, the IRF7 and STER experiences.

Mariani G and For the IRF7 and STER
University of Ferrara, Rome, Italy

Background: Understanding clinical features and assessing optimal treatment for the Rare Bleeding Disorders (RBD) is hampered by their rarity and, in general, by the lack of specific treatment tools. The latter issue is not true for FVII deficiency, a bleeding disorder for which several replacement options are available: Recombinant, activated FVIIa (rFVIIa), Plasma Derived FVII concentrates, Fresh Frozen Plasma and the four factor Prothrombin Complex Concentrates.
Methods: We have evaluated a large series of patients with FVII deficiency within the International Registry for FVII (n = 514) and the Seven Treatment Evaluation Registry (STER) (n = 225) initiatives, using novel approaches to evaluate homogeneous clinical phenotypes and to assess the optimal management. Genotype assessment was available for 332 individuals of whom 104 (31.3%) were homozygous, 86 (25.9%) compound heterozygous and 142 (42.8%) heterozygous for mutations. The *Age at disease presentation* and the *type of first symptom* were the elements used to assess the disease severity; FVII coagulant activity levels (FVIIc) were employed to further refine patients' categorization.
Results: Three main phenotypes were identified: asymptomatic (≈30%), mild (55–60%) characterized by muco-cutaneous bleeds and the severe, life and limb threatening bleeding phenotype (10–15% characterized by CNS, GI and joint bleeds), with a good clinical consistency over time. Treatments were followed up prospectively through an online protocol.
Surgical interventions were 136 in total, 69 'major', 67 'minor' (including eight adeno-tonsillectomies). For the major interventions three doses of at least 13 μg/Kg of rFVIIa on the day of operation were suggested; because of the lack of events, no data concerning the optimal overall post-surgical RT duration is available. As for the minor surgeries (dental extractions and invasive & diagnostic procedures) a single dose of 20 μg/Kg was found sufficient to avoid bleeding.
For most of the spontaneous bleeding episodes (n = 101), apart from the life-threatening bleeds, a single, intermediate dose of rFVIIa (60 μg/Kg) was proven efficacious. Prophylaxis courses were reported in 37 cases, mostly subsequent to life- and limb-threatening bleeds, and rFVIIa was shown to be very effective when 'frequent' schedules (at least three times weekly) and doses of 90 μg/Kg were used. This appears to be in contrast with the pharmacokinetic (PK) data obtained for rFVIIa, characterized by very low *in vivo* recoveries (n = 116 evaluations), half-life (n = 10, median 1.97 h) and AUClast (214.3 Uh/dL); however, the high volume of distribution on the terminal phase, much higher than the plasma volume, indicate that a large extravascular diffusion of FVIIa and binding to extravascular receptors takes place, a fact that may well explain a prolonged pharmacodynamic effect. The latter finding is particularly evident when PK is evaluated using the Prothrombin Time ratio instead of the FVIIc assay. Treatment adverse events, as reported in the 225 STER patients, were the occurrence of inhibitors to FVII 3/225 (1.3%) and of thrombotic episodes 4 (1.7%), the latter clearly related to surgery and replacement therapy.
Conclusions: We have prospectively evaluated the clinical and management features of FVII deficiency providing settings and treatment schedules focused on disease severity.

OC 62.3

The ThromboGenomics Next Generation Sequencing Platform for the DNA-based diagnosis of known inherited rare bleeding and platelet disorders

Kiddle GR[1], Poudel P[1], Bray PF[2], Van Geet C[3], Goodeve AC[4], Kunicki T[5], Reitsma PH[6], Ouwehand WH[1] and Rendon A[1]

[1]NHSBT/University of Cambridge, Cambridge, UK; [2]Thomas Jefferson University, Philadelphia, PA, USA; [3]KU Leuven, Leuven, Belgium; [4]University of Sheffield, Sheffield, UK; [5]CHOC Children's Hospital Research Institute, Orange, CA, USA; [6]Leiden University Medical Center, Leiden, the Netherlands

Background: There are over 140 Bleeding and Platelet Disorders (BPDs) registered in OMIM. For many BPDs, diagnostic laboratory algorithms are cumbersome or inconclusive. Molecular diagnosis is often missing in many cases, preventing targeted treatments and family counselling. Next Generation Sequencing Technologies (NGSTs) have resulted in the development of fast, accurate and cost effective DNA tests to diagnose several inherited disorders. For BPDs, NGSTs enable the exciting opportunity to use DNA testing early on in the diagnostic algorithm, rather than as a final confirmatory step, thereby reducing time to diagnosis and healthcare costs. To achieve this goal, ISTH experts under the umbrella of the ThromboGenomics working group (http://www.isth.org/group/genomics) are collaborating on a set of 97 genes harbouring mutations underlying most known BPDs.

Aims: Bringing NGST-based diagnostics to healthcare delivery requires: (i) gene annotation to clinical standards providing a widely accessible, stable and sustainable frame of reference for cataloguing clinically significant mutations; (ii) proof of principle that the BPD gene panel can substantially improve the diagnosis of rare inherited BPDs.

Methods: LRG (www.lrg-sequence.org) records entailing the DNA sequence, transcripts and clinically relevant variants of all 97 genes are agreed through curation by ISTH-ThromboGenomics gene-specific experts and given an immutable ID. The guiding principle for the creation of an LRG record is that the ISTH-ThromboGenomics community will have the final say in defining the sequences and their annotation. In parallel, a Roche/Nimblegen custom panel capturing nearly one million bp has been designed to contain all transcribed sequences, the 2000 bp centred around transcription start sites, and all BPD variants present in the Human Gene Mutation Database (www.hgmd.cf.ac.uk). To validate the platform and assess its diagnostic performance, 500 idiopathic BPDs and 500 BPDs with known causative variants are being sequenced with it.

Results: So far 12 ISTH experts have agreed to join the curation effort. The curation for four disorders is complete and LRGs have been created for the following genes: ITGA2B, ITGB3, GP1BA, GP1BB, GP9, WAS, and MYH9. BPD-causative variants have been agreed for these genes.A first generation platform has been tested with 12 DNA samples, achieving 940X average coverage across BPD gene regions. This level of coverage ensures that multiplexing 96 samples in a single HiSeq2000 lane results in 92% of the target been covered at > 30X, and 98% of the 'capturable' regions. Less than 2% of the 8740 HGMD mutations in the panel wouldbe covered at > 30X. To improve the design even further, baits have been rebalanced toimprove capture uniformity.

Summary/Conclusions: Early sequencing results are extremely promising in terms of panel coverage, capturehomogeneity, and potential level of multiplexing. This means that a low-cost, comprehensivegenetic test for BPDs seems achievable. At the meeting we will share the analysis of thesequencing of at least 500 samples in the validation experiment. The gene curation processalready underway will be accelerated and LRG records for 2/3 of the genes will have beendeposited prior to the ISTH conference.

OC 62.4

Constitutive activation of integrin alphaIIb-beta3 due to an inherited mutation of integrin beta3 leads to defective receptor function and impaired thrombopoiesis

Bury L[1], Corazzi T[1], Giannini S[1], Falcinelli E[1], Savoia A[2], Italiano JE[3] and Gresele P[1]

[1]University of Perugia, Perugia; [2]IRCCS ''Burlo Garofolo'', Trieste, Italy; [3]Brigham and Women's Hospital, Boston, MA, USA

Background: Mutations of integrin alphaIIbbeta3 lead to Glanzmann Thrombasthenia (GT), an autosomal recessive bleeding disorder characterized by absent platelet aggregation associated with a normal platelet count and volume. We have recently described a novel autosomal dominant hereditary macrothrombocytopenia with platelet dysfunction and mucocutaneous bleeding associated with a heterozygous mutation (2134+1 G>C) of the ITGB3 gene, leading to the deletion of the entire exon13 and consequently to del647-686 of integrin beta3 (Gresele P et al. Haematologica. 2009; 94:663–9): a variant form of GT.

Aims: Aim of the present study was to unravel the mechanism by which a heterozygous mutation of integrin beta3 induces the phenotype of a typical autosomal recessive GT and to clarify the role of this mutation in the generation of macrothrombocytopenia.

Methods: CHO cells expressing the wild type alphaIIbbeta3, the mutant form or both were generated. Integrin expression and receptor internalization were studied by Western blotting and flow cytometry. AlphaIIbbeta3 activation was studied by aggregation in the presence of fibrinogen, PAC-1- and fibrinogen-binding. Outside-in signaling was investigated by spreading assay, protein phosphorylation and clot retraction. Additional studies on patient's platelets were also carried out. The wild type and the mutant alphaIIb-beta3 receptor were also transduced by retrovirus in fetal liver-derived murine megakaryocytes on which spreading and proplatelet formation were studied.

Results: Studies in CHO cells reveal that the mutation exerts a dominant negative effect and induces constitutive activation of alphaIIb-beta3. The co-expression of the mutant beta3 subunit together with the normal protein decreases the number of alphaIIb-beta3 receptors expressed on the cell surface. Mutant integrin-bearing CHO cells bind fibrinogen and PAC-1 without the need of stimulation and aggregate spontaneously in the presence of fibrinogen, thus showing constitutive activation of the receptor. The mutant, activated receptor is internalized without the need of agonist activation, and this explains its reduced surface expression. Beta3 cytoplasmic tail and Focal Adhesion Kinase are constitutively phosphorylated in CHO cells expressing the mutant beta3 subunit, spreading on fibrinogen is faster while clot retraction is defective, all results compatible with defective alphaIIb-beta3 mediated outside-in signalling. Patients' platelets show constitutive activation of outside-in signalling with increased actin polymerization in resting platelets and spontaneous spreading on Von Willebrand factor.

Fetal liver-derived murine megakaryocytes expressing the mutant beta3 show abnormal proplatelet formation, with tips decreased in number and larger in size than those of controls, and abnormal spreading on fibrinogen. In addition, platelet maturation from preplatelets is impaired, with the generation of asymmetric barbell-proplatelets and consequently the formation of platelets of heterogeneous dimensions.

Summary/Conclusions: Taken together these data show that a defective outside-in signaling generated by a constitutively activated alphaIIb-beta3 receptor is the cause of both macrothrombocytopenia and defective platelet function in our GT variant.

OC 62.5

A new type of hereditary bleeding disorder resulting from a premature stop codon in thrombomodulin (p.Cys537*)

Langdown J[1], Luddington R[1], Huntington JA[2] and Baglin TPT[1]
[1]Cambridge University Hospitals NHS Foundation Trust, Cambridge; [2]University of Cambridge, Cambridge, UK

Background: Thrombomodulin is a single pass type-1 transmembrane protein with key roles in the regulation of haemostasis and inflammation. We describe a novel thrombomodulin variant within a family with an undiagnosed autosomal dominant phenotype of delayed post traumatic bleeding.
Aims: Investigations were performed to identify and characterise the previously observed clinical haemostasis defect within an individual prior to scheduled abdominal surgery such that an appropriate treatment plan could be devised.
Methods: Coagulation screening tests (prothrombin time, APTT, thrombin time), coagulation factor assays (fibrinogen, factor II, V, VII, VIII, IX, X, XI, XII, XIII, von Willebrand factor antigen/activity), platelet function tests, endogenous thrombin potential (ETP), antithrombin, protein S and protein C assays were performed. Plasma thrombomodulin levels were quantified by ELISA and genomic DNA was screened for thrombomodulin mutations by polymerase chain reaction amplification followed by direct DNA sequencing.
Results: All coagulation screening tests, coagulation factor assays and platelet function test results were within normal limits. The ETP using 5 pM tissue factor (TF) was normal (1300 nmol/min, normal range 1114–2272 nmol/min), but markedly reduced using 1 pM TF (354 nmol/min, normal range 851–1759 nmol/min). Addition of normal plasma failed to correct the ETP, indicating the presence of a coagulation inhibitor. Addition of 10-fold excess of protein C abolished thrombin generation in the patient plasma but left normal plasma unaffected. The plasma thrombomodulin level was elevated (130 ng/mL, normal range 2–8 ng/mL). A heterozygous c.1611 C>A mutation was detected within the thrombomodulin gene sequence (THBD) which coded for a change from cysteine 537 to a premature stop codon (p.Cys537*). The mutations lies within the transmembrane region of thrombomodulin (p.Cys537*) and results in a truncated thrombomodulin molecule lacking the *C*-terminal cytoplasmic domain. The same thrombomodulin mutation and laboratory findings have been identified in two close family members who share the same bleeding predisposition.
Summary/Conclusions: We have identified a new thrombomodulin mutation (c.1611 C>A) associated with a decrease in thrombin generation at low tissue factor concentration, elevated plasma thrombomodulin levels and an accompanying increase in protein C activation. We predict that one of the consequences of the p.Cys537* truncated thrombomodulin molecule would be a reduction of its binding to the endothelial membrane and its shedding into the plasma. This would facilitate protein C activation, factor Va/VIIIa cleavage and early cessation of thrombin generation within a developing haemostatic clot. The likely consequence of this scenario would be the formation of smaller and weaker haemostatic clots, thus explaining the phenotype of delayed post traumatic bleeding observed within this family. To our knowledge this is the first case of a thrombomodulin mutation causing a bleeding disorder.

OC 62.6

Characterization of four novel β3 integrin defects associated with Glanzmann's thrombasthenia

Sabi EM, Stockley J, Al-Marwani A, Kiss-Toth E, Makris M and Daly ME
University of Sheffield, Sheffield, UK

Background: Glanzmann's thrombasthenia (GT) is a recessively inherited bleeding disorder characterized by quantitative and, or, qualitative abnormalities of αIIbβ3, an integrin receptor for adhesive proteins that mediates platelet aggregation. The α- and β-subunits of αIIbβ3 are encoded by *ITGA2B* and *ITGB3* respectively, and many genetic defects resulting in reduced expression or dysfunction of αIIbβ3 have been described. As part of a study to investigate the molecular basis of GT in a cohort of UK patients, we identified four novel *ITGB3* mutations predicting amino acid substitutions in the ligand binding domain (E200K, W264L, S317F) and signal peptide (W11R) of β3. We have now used *in silico* and *in vitro* methods to characterise these defects further.
Aims: To confirm the pathogenicity of four *ITGB3* mutations using *in silico* methods to predict their effects on αIIbβ3, and by analysing αIIbβ3 receptor levels after expression of the corresponding β3 variants in heterologous cells.
Methods: b3 integrin sequences from 12 vertebrate species were aligned with the human sequence using the ClustalW2 tool available at http://www.ebi.ac.uk. The effects of candidate mutations were predicted using the Polymorphism Phenotyping v2 (http://genetics.bwh.harvard.edu/pph2/), Sorting Intolerant from Tolerant (http://sift.jcvi.org/), Align Grantham Variation Grantham Deviation (http://agvgd. iarc.fr/agvgd_input.php) and SNPs&GO (http://snps-and-go.biocomp.unibo.it/snps-and-go/) tools. The SignalP 4.0 tool (http://www.cbs.dtu.dk/services/SignalP) was used to examine the effect of the W11R substitution on signal peptide cleavage. Site-directed mutagenesis was used to introduce *ITGB3* mutations into pcDNA3.1(-)neo-ITGB3 expression construct. Chinese Hamster Ovary (CHO) cells were then co-transfected with recombinant *ITGB3* and WT-*ITGA2B* expression vectors and expression of the recombinant αIIbβ3 receptors assessed by flow cytometry.
Results: Alignment of β3 integrin sequences revealed conservation of tryptophan (W) 264 and serine (S) 317, while tryptophan (W) 11 was conserved in seven of the 10 species where sequence was available, suggesting an important role for these amino acids in β3 integrin. Supporting this, the W264L and S317F substitutions were predicted to significantly affect protein function. The W11R substitution was not expected to disrupt signal peptide cleavage but was predicted to affect protein function. In contrast, glutamate (E) 200 is not conserved and is replaced by lysine (K) in eight of 12 species examined and the E200K substitution was predicted to be benign by three of the tools used. There was an almost complete loss of cell surface expression of αIIbβ3 levels in CHO cells expressing the W11R, W264L and S317F variants ($P > 0.0006$), and 37% and 23% reductions in intracellular expression of the W264L ($P > 0.005$) and S317F ($P > 0.05$) variants, while the intracellular expression of the W11R variant was reduced to 99% of that of WT ($P > 0.0005$). In contrast, cells expressing the E200K variant showed similar cell surface and intracellular expression to those cells expressing the WT receptor ($P = 0.39$).
Conclusion: Our findings confirm the pathogenicity of the W264L, S317F and W11R mutations in GT. Assessment of the functional consequences of the E200K substitution is required to confirm whether it is responsible for the diagnosis of GT in the patient with this defect.

OC 63 – Recurrent Venous Thrombosis – II

OC 63.1

Current statin use and its association with recurrent venous thrombosis

Smith NL[1], Harrington LB[1], Blondon M[1], Wiggins KL[1], James FS[1], Sitlani C[1], McKnight B[1], Rosendaal FR[2], Heckbert SR[1] and Psaty B[1]
[1]University of Washington, Seattle, WA, USA; [2]Leiden University Medical Center, Leiden, the Netherlands

Background: Evidence from randomized clinical trials suggest that the use of statin therapy is associated with a decreased risk of incident

venous thrombosis (VT), particularly in the setting of use for primary prevention of cardiovascular disease (CVD). The association of statins with risk of recurrent VT is not known.

Aims: The aim of this study is to assess the relationship between current statin use and the risk of recurrent VT. We hypothesize that current statin use is associated with a decreased risk of VT recurrence, especially among those without CVD.

Methods: In a population-based study, we identified an inception cohort of adults 30–89 years of age who were members of a large health maintenance organization (HMO) and who suffered an incident VT (deep vein thrombosis or pulmonary embolism) from 2002 through 2010. Participants were followed for VT recurrence by reviewing the full medical record. A recurrent VT was defined as a physician-diagnosed recurrence more than 2 weeks after the incident event and with clinical and/or imaging evidence of a new or expanded clot. Statin use was identified from prescription fills within the HMO. Using failure time models with baseline (age, BMI, sex, race, idiopathic incident event, estrogen use in women) and time-varying follow-up covariates (cancer, smoking, prevalent CVD, vitamin K antagonist [VKA] and aspirin use), we estimated the relative hazard of a recurrent VT comparing current statin users and recent statin stoppers (≤ 2 years) with never or past (> 2 years) statin users. Time scale was time since incident event and censoring occurred at last follow-up or death. The study is expected to include 2600 participants with incident VT. Preliminary, cleaned data on 1854 participants (71%) with incident VT were available at the time of abstract submission.

Results: The average age was 65.6 years and 45% were male. Among the incident events, 57% were idiopathic. At cohort entry, 23% of participants were using statin therapy; during follow-up, 22% initiated treatment while 57% of users permanently stopped therapy. Among users, simvastatin was used by 54% and lovastatin by 43%. We identified 275 recurrent events during an average of 3.2 years of follow-up. A recurrent VT occurred in the first 2 years in 10% of the cohort. Male sex (hazard ratio [HR] = 1.3), idiopathic status of incident event (HR = 1.3), and cancer (HR = 3.9) were associated with higher risk of a recurrent event, and VKA use (HR = 0.2) was associated with a lower risk. Compared with never or past (> 2 years) use, current statin use was associated with a 20% lower risk of recurrent VT (HR = 0.8; 95% CI: 0.6–1.1); recent discontinuation of statins was not associated with risk (HR = 1.0; 95% CI: 0.6–1.6). When participants with CVD (myocardial infarction, stroke, or angina) at baseline were excluded (n = 408), the HR was 0.6 (95% CI: 0.4–0.9).

Summary/Conclusion: In interim analyses of observational data, we found a lower risk of recurrent VT associated with current statin use but confidence intervals were wide. Additional data collection is underway and subgroup analyses by drug type and dose will be performed.

OC 63.2

The risk of recurrent venous thromboembolism among women in relation to estrogen intake: results from a prospective cohort study

Eischer L, Eichinger S and Kyrle PA

Medical University of Vienna, Wien, Austria

Background: Women have a lower risk of recurrent venous thromboembolism (VTE) than men. The risk of recurrence among women with VTE in association with female hormone intake is not well studied.

Aim: to investigate the risk of recurrent VTE among women who had their incident VTE associated with estrogen use.

Methods: The Austrian Study on Recurrent Venous Thromboembolism (AUREC), is a large prospective cohort study. Patients with a first objectively confirmed deep vein thrombosis (DVT) of the leg and/or pulmonary embolism (PE) who had received anticoagulants for 3–18 months were included. Exclusion criteria were: age > 18 years; VTE associated with surgery, trauma, cancer or pregnancy; long-term anticoagulation; natural inhibitor deficiency; lupus anticoagulant; homozygousity or double heterozygousity for factor V Leiden and/or the prothrombin mutation. Women were advised to refrain from further estrogen use and were excluded in case of non-adherence. The study end point was recurrent symptomatic DVT and/or PE verified by imaging. The local ethics committee approved the study and all patients gave written informed consent.

Results: 1179 patients (54% females) were followed for a mean of 63 months. Recurrent VTE was recorded in 72 of the 631 females (11%) and in 186 of the 548 males (33%). Compared to men, women had a relative risk of recurrence of 0.3 (95%CI 0.2–0.4) after adjustment for age, location of VTE and factor V Leiden mutation.

Two hundred and seventy-four women used combined contraceptives and 72 used estrogen containing hormone replacement therapy (HRT) at time of initial thrombosis. Recurrent VTE was seen in 15 contraceptive users. Women using contraceptives were at lower risk of recurrence than non-users (adjusted RR 0.3 (95% CI 0.2–0.7, P = 0.01). After 5 years the probability of recurrence was 4% (95% CI 1–7) among contraceptive users and 16% (95% CI 8–23) among non-users (P = 0.002).

Ten of the 72 women with HRT had recurrent VTE. Women using HRT were at lower risk of recurrence than those in the same age group with idiopathic VTE (adjusted RR 0.6 [95% CI 0.3–1.4] P = 0.2). After 5 years the probability of recurrence was 13% (95% CI 3–23) among HRT users and 18% (95% CI 12–24) among non-users (P = 0.1).

Conclusion: The risk of recurrent VTE is lower in women than in men. The risk of recurrence is particularly low among women with VTE during combined contraceptive use. In these women extended anticoagulation is not justified provided that they refrain from further estrogen use.

OC 63.3

Safety of dabigatran vs. warfarin for acute venous thromboembolism: pooled analyses of RE-COVER and RE-COVER II

Schulman S[1], Eriksson H[2], Goldhaber SZ[3], Kakkar A[4], Kearon C[1], Mismetti P[5], Schellong S[6], Feuring M[7], Peter N[7] and Friedman J[8]

[1]McMaster University, Hamilton, ON, Canada; [2]Sahlgrenska University Hospital-Östra, Gothenburg, Sweden; [3]Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; [4]Thrombosis Research Institute and University College London, London, UK; [5]Bellevue Hospital, St Etienne, France; [6]Municipal Hospital Friedrichstadt, Dresden; [7]Boehringer Ingelheim GmbH & Co KG, Ingelheim am Rhein, Germany; [8]Boehringer Ingelheim Pharmaceuticals Inc, Ridgefield, CT, USA

Background: In the RE-COVER and RE-COVER II trials, patients with acute venous thromboembolism (VTE) were started on parenteral therapy and were then randomized to receive overlapping warfarin (W) or warfarin-placebo (single-dummy). After discontinuing parenteral therapy, they either continued warfarin or received dabigatran etexilate (DE), respectively (double-dummy). Safety may be assessed from the start of randomization on any study drug (scenario 1); thus, bleeding events related to parenteral therapy alone (before administration of DE) will be included in the dabigatran arm. Alternatively, to assess safety of DE itself, scenario 2 is to count bleeding from the first intake of active study drug (W in single-dummy, DE in double-dummy period), thus excluding events associated with parenteral therapy. Scenario 3 is to count events from the start of the double-dummy period to compare DE with W at its full pharmacological potential (but omitting the W/parenteral overlap). DE is not currently approved for this indication.

Aims: Using the pooled trial data we investigated the impact of counting bleeding events by the three different approaches on the safety comparison between DE and W.

Methods: Patients with acute VTE received parenteral anticoagulation and were randomized to the addition of W or placebo for ≥ 5 days until INR or sham INR was ≥ 2.0 on two consecutive days followed by continued W (INR range 2.0–3.0) or DE 150 mg twice daily, respectively, with corresponding placebos for 6 months. Major bleeding events (MBE) and the composite of MBE or clinically relevant non-major bleeding events (CRBE) were counted from three starting points until 6 days after the last intake of any study drug.
Results: Scenario 1: MBE for DE in 37 patients (1.4%) vs. 51 (2.0%) for W; hazard ratio (HR) 0.73 (95% CI 0.48, 1.11). There were 13 patients who had not yet taken DE and 11 taking W in the single-dummy period with MBE; 5 and 3 of these, respectively, continued into the double-dummy phase. Scenario 2: MBE (DE vs. W) in 24 patients (1.0%) vs. 51 (2.0%); HR 0.48 (95% CI 0.29, 0.78). Scenario 3: MBE in 24 patients (1.0%) vs. 40 (1.6%), respectively; HR 0.60 (95% CI 0.36, 0.99). All three analyses favored DE and were statistically significant in scenarios 2 and 3. The HR for MBE/CRBE favored DE and for all comparisons the upper bounds of the CIs were below 1.0. There was no difference in symptomatic VTE or VTE-related mortality (counted from the start of randomization on any study drug) between DE and W: 2.7% vs. 2.4%, HR 1.09 (95% CI 0.77, 1.54).
Conclusions: Three safety comparisons were made: from the start of the two treatment regimens, from the start of each active study drug (excluding bleeds caused by heparin in the absence of DE), and from the start of the double-dummy period (after W had reached therapeutic levels). Regardless of the calculation, pooled data from RE-COVER and RE-COVER II consistently showed a profile of numerically or even statistically significant lower major bleeding rates with DE than with W.

OC 63.4
Risk factors for recurrent venous thromboembolism: VTE Epidemiology Group (VEG) Study

Martinez C[1], Katholing A[1] and Cohen A[2]
[1]*Im Dinkelfeld 32, Frankfurt, Germany;* [2]*King's College Hospital, London, UK*

Background: Recurrence of venous thromboembolism (VTE) has important implications for VTE management and outcomes. Only a few risk factors for recurrence have been recognized consistently. To simplify decision making, these factors must be assessed allowing for the presence or absence, and quality, of anticoagulant therapy.
Aims: To explore potential risk factors for recurrent VTE.
Methods: Patient data were retrieved from the subset of general practices in England contributing to the Clinical Practice Research Datalink (CPRD) linked to data from the Hospital Episodes Statistics (HES) and to the Office for National Statistics (ONS). From January 2001 to October 2011, all VTE cases in the CPRD were verified with an algorithm based on review of medical records and notes, hospital diagnoses, cause of death and anticoagulation therapy. We conducted a nested case-control study defining all patients with recurrent VTE as cases and those without recurrence as controls; the date of VTE recurrence was recorded as the index day. For each case we selected five patients without recurrence on the index day with the same duration of observation as the respective case. Patients with a record indicating vitamin K antagonist (VKA) use before the first VTE were excluded. The independent association between the prevalence of potential risk factors at the first VTE and at the index day, and the recurrent VTE were derived from conditional multivariate logistic regression models and presented as adjusted odds ratios (ORs) with 95% confidence intervals (CIs). Adjustment included the type of antithrombotic therapy: VKA, low molecular weight heparin or antiplatelet.
Results: A total of 24,795 patients with first VTE were at risk of recurrent VTE. The mean age of patients was 63.4 years and 46.0% were male. Of these, 3678 cases of recurrent VTE occurred during the entire observational period. The risk of VTE recurrence was greater in the following groups: age > 30 years (OR = 1.43; 95% CI 1.20–1.71), males (OR = 1.26; 95% CI 1.17–1.36), body mass index ≥ 30 kg/m^2 (OR = 1.14; 95% CI 1.05–1.25) and current smokers (OR = 1.12; 95% CI 1.01–1.24). Deep vein thrombosis with pulmonary embolism compared with deep vein thrombosis alone was associated with an increased risk (OR = 1.51; 95% CI 1.30–1.75). When compared with provoked VTE, patients with active cancer or with unprovoked VTE at the time of the first VTE had an increased risk of recurrence (OR = 1.59; 95% CI 1.38–1.83, and OR = 1.52; 95% CI 1.39–1.65, respectively). The new occurrence of a provoking event after the initial VTE augmented the risk of recurrence, e.g. for a new active cancer (OR = 5.60; 95% CI 4.51–6.96), new major trauma (OR = 2.89; 95% CI 1.83–4.54) or new pregnancy (OR = 2.09; 95% CI 1.27–3.44) compared with those without a new provoking event. Other predictors for recurrent VTE were renal disease (OR = 1.17; 95% CI 1.04–1.32) and superficial thrombophlebitis (OR = 3.50; 95% CI 1.97–6.21).
Summary/Conclusions: The recognition of risk factors for recurrent VTE should guide decisions on the duration of anticoagulation therapy.

OC 63.5
Mortality following Venous thromboembolism. Risk factors from a large cohort. VTE Epidemiology Group (VEG) Study

Cohen AT[1], Rietbrock S[2] and Martinez C[2]
[1]*King's College Hospital, London, UK;* [2]*Pharmaepi.com, Frankfurt, Germany*

Background: Mortality is the commonest outcome at 5 and 10 years following both pulmonary embolism (PE) and deep vein thrombosis (DVT). Mortality remains higher following index PE but is significant following DVT also. The recognition of risk factors and the use of a risk score may help to evaluate high risk groups and guide therapy type and duration. To simplify decision making these factors for mortality must be assessed allowing for the presence, quality and absence of anticoagulant therapy.
Aim: To explore potential risk factors for mortality following VTE.
Methods: Patient data were retrieved from the subset of general practices in England contributing to the Clinical Practice Research Database (CPRD) that has been linked to data from the Hospital Episodes Statistics (HES) and to the Office for National Statistics (ONS).From January 2001 to October 2011, all VTE cases in the CPRD were verified with an algorithm based on review of medical records and notes, hospital diagnoses, cause of death and anticoagulation therapy. We conducted a nested case-control study in patients with a first VTE. Deaths during the entire observational period from any cause during the entire observational period were defined as cases and the date of death as the index day. For each case we selected five patients alive on the index day and with the same duration of observation as the respective case. The independent association between the prevalence of potential risk factors associated with first VTE for all-cause mortality was derived from conditional multivariate logistic regression models and presented as adjusted odds ratios (ORs) with 95% confidence intervals (CIs). Adjustment included age, gender, socioeconomic risk factors, components of the Charlson index, and the type of antithrombotic therapy (VKA, low molecular weight heparin or antiplatelet therapy).
Results: Of 35,373 patients with first VTE 29,550 patients survived more than 7 days and had 81,906 person-years of observation were at risk of mortality following the acute presentation. Over the observational period and after at least 90 days following first VTE 6714 deaths were identified.
The adjusted odds ratio for all-cause mortality was increased for the following VTE-related risk factors: having both PE and DVT, OR 1.21 (1.031.43) compared to a primary DVT; recurrent DVT, OR 1.51 (1.291.76) and recurrent PE, 1.52 (1.281.82) compared to no recurrence, severe post-phlebitic syndrome, OR 1.73 (1.272.37) and new

onset of chronic pulmonary hypertension 2.44 (1.733.43). The odds of mortality were lower in the following conditions: TTR > 60%, OR 0.47 (0.370.60); TTR 40 ≤ 60%, OR 0.80 (0.641.01) both compared with TTR > 40%.

Summary/Conclusions: The recognition of risk factors for mortality should facilitate decisions for managing therapy in VTE patients.

OC 63.6

Red cell distribution width and blood monocytes are associated with an increased risk of venous thrombosis

Rezende SM[1], Lijfering WM[2], Rosendaal FR[2] and Cannegieter SC[2]
[1]*Universidade Federal de Minas Gerais, Belo Horizonte, Brazil;*
[2]*Leiden University Medical Center, Leiden, the Netherlands*

Background: Recent studies have suggested that leukocytes and erythrocytes play a role in the process of coagulation and their presence is clearly observed in the anatomy of a venous clot. Furthermore, leucocytosis is a predictor of venous thrombosis during follow-up of patients with polycythemia vera and essential thrombocytemia.

Aim: The aim of this study was to investigate whether peripheral leukocytes, erythrocytes and other hematological variables (hematocrit, hemoglobin and red cell indices) are associated with the risk of venous thrombosis.

Methods: To study this, we used data from 2473 patients with venous thrombosis and 2935 controls from the MEGA study. The MEGA (Multiple Environmental and Genetic Assessment of risk factors for venous thrombosis) study is a population-based case-control study on risk factors for venous thrombosis. The variables assessed were: total leukocytes, granulocytes, lymphocytes, monocytes, hematocrit, hemoglobin, erythrocytes and red cell indices (mean corpuscular volume [MCV], mean hemoglobin volume [MCH], mean corpuscular hemoglobin volume [MCHC] and red cell distribution width [RDW]). Odds ratios and their 95% confidence intervals (95% CI) were calculated for erythrocytes and leukocytes counts, hematocrit, hemoglobin and red cell indices and adjusted for age, sex, malignancy, co-morbidities and CRP using logistic regression. Cut-off points of variables were established at the 1st, 5th, 95th, 97.5th and 99th percentilesin the control subjects.

Results: We found a strong dose-response relation for higher RDW and monocytes with risk of venous thrombosis, with odds ratios of 3.1 (95% confidence interval [CI], 2.0–4.8) and 2.8 (95%CI, 1.3–5.8), respectively, after adjustment for age, sex, C-reactive protein, malignancy and co-morbidities. A low monocyte count (> 0.12 × 109/L) was associated with a lower venous thrombosis risk after full adjustment (odds ratios 0.6; 95%CI, 0.4–0.8). In our study, RDW was associated with an increased risk for venous thrombosis, even when RDW was still within the usual reference range (above 14.1%). This association was held after full adjustment (OR 3.1; 95% CI 2.0–4.8 for percentile above 99) and for all subgroup analyses. Further adjustments for anemia did not reduce the odds ratio. Recently, an elevated RDW was reported to be associated with an increased risk for all-cause mortality and cardiovascular disease. To our knowledge, this is the first study to report an association between venous thrombosis and higher RDW.

Conclusion: High RDW and blood monocytes, two unexpensive and easily obtainable tests, are associated with increased risk of venous thrombosis. Future studies should evaluate the underlying mechanism and the use of these variables in prediction models for first and recurrent thrombosis.

OC 64 – Thrombin Generation Tests

OC 64.1

Quantitative imaging of thrombus formation under shear

Baker S, Phillips KG, Leung PY, Tucker I, Gruber A and McCarty OJT
Oregon Health and Science University, Portland, OR, USA

Background: When vessel walls are damaged, exposed extracellular matrix proteins and tissue factor (TF) trigger a series of events that lead to the formation of a hemostatic plug through platelet recruitment and concurrent blood coagulation. The extrinsic pathway of blood coagulation initiates thrombin generation that clots fibrinogen and activates platelets, coagulation cofactors, and factor XI (FXI) of the intrinsic pathway, which can further enhance thrombin formation and assist in the development of a stable hemostatic plug. Under pathological conditions, platelet and coagulation activation pathways can extend into the lumen of the blood vessel, resulting in the formation of a thrombus that can occlude the vessel. How these pathways relate to the mass, volume, and density of the growing thrombus inside blood vessels remains ill-defined. This is in part due to a lack of a quantitative technique to measure the physical parameters of thrombus formation.

Aims: To create a measurement technique for determining the relative roles of the intrinsic and extrinsic coagulation pathways in regulating the basic physical parameters of mass, volume, and density of platelet aggregates and thrombi formed under shear, using whole blood in an *ex vivo* model.

Methods: Citrate-anticoagulated whole blood with or without added calcium was perfused through a flow chamber at a shear rate of 200/s over immobilized fibrinogen, collagen, and/or TF (0.1 or 1 nM). In selected experiments, whole blood was pretreated with inhibitors of FXIIa (CTI, 40 μg/mL), FXIIa activation of FXI (14E11, 20 μg/mL), or FXIa activation of FIX (1A6, 20 μg/mL). Non-interferometric quantitative phase microscopy (NI-QPM) and Hilbert transform differential interference contrast (HT-DIC) microscopy were used to determine mass and volume, respectively, of formed aggregate or thrombi.

Results: Platelet aggregates formed on surfaces of fibrinogen and collagen, but not on TF alone, under shear in the absence of coagulation. The extent of platelet adhesion and aggregation remained constant when fibrinogen or collagen was coated in combination with TF. Recalcification of the sodium-citrate anticoagulated blood resulted in fibrin formation on both fibrinogen and collagen surfaces. Mean volume of platelet aggregates and thrombi did not significantly differ on the surfaces. However, the mean mass and density dramatically increased for thrombi formed on surfaces of fibrinogen or collagen that had been coated in combination with TF. For instance, mean mass of thrombi increased from 122.8 ± 14.1 pg to 325.0 ± 10.7 pg and density increased from 30 ± 0.002 to 70 ± 0.003 fg/μm^3 (p-value ≤ 0.01) when TF was immobilized in combination with collagen. The presence of FXIIa and FXIa inhibitors abrogated fibrin formation on fibrinogen and collagen surfaces only in the absence of TF, resulting in a corresponding reduction in mass and density.

Conclusion: We have developed a quantitative imaging platform to measure the mass, volume and density of platelet aggregate and thrombus formation under shear. This platform may provide a novel screening method for rapid quantitative efficacy/safety assessments of various antithrombotic or pro-hemostatic agents.

OC 64.2

Delayed and decreased thrombin generation is associated with stroke in the elderly: results from the prosper study associate

Loeffen R[1], Winckers K[1], Ford I[2], Jukema JW[3], Robertson M[2], Stott DJ[2], Spronk HMH[1], Lowe GDO[2] and Ten Cate H[1]
[1]Maastricht University Medical Center, Maastricht, the Netherlands; [2]University of Glasgow, Glasgow, UK; [3]Leiden University Medical Center, Leiden, the Netherlands

Background/Aim: Experimental as well as clinical data suggest a contribution of hypercoagulability to the pathophysiology of atherosclerosis and -thrombosis. As thrombin fulfills a central role in the coagulation process and links to several mechanisms involved in arterial vascular disease and (models) of ischemic brain damage, we investigated the association between thrombin generation (TG) and ischemic stroke in the elderly.
Method: We studied the relationship between TG and stroke in the PROspective Study of Pravastatin in the Elderly at Risk (PROSPER), a multi-center prospective cohort study including 5804 individuals aged 70–82 years with known cardiovascular risk factors or previous cardiovascular disease. TG was measured in platelet poor plasma with addition of 1 and 5 pM tissue factor, using the calibrated automated thrombogram. The associations between TG and incident stroke were investigated using Cox proportional hazard models adjusted for country, treatment, age, sex, conventional cardiovascular risk factors, interleukin-6, and CRP levels. Subjects on warfarin ($n = 105$) were excluded from analysis.
Results: Plasma samples for TG were available from 4932 (85%) subjects of whom 227 subjects (4.6%) had incident stroke within the 3.2 years of follow-up. In 156 strokes (69%) ischemic etiology was confirmed. TG was lower in patients who developed stroke than in control patients; normalized peak height (nPH): 71 ± 41% vs. 82 ± 45% and normalized endogenous thrombin potential (nETP): 79 ± 23% vs. 87 ± 25%; means and SDs. Moreover TG showed an independent and inverse relationship with stroke risk. Hazard ratios (95% confidence intervals) for the highest vs. the lowest tertile for nPH, nETP, log lag time and log time to tail were 0.71 (0.60–0.85), 0.68 (0.58–0.79), 1.27 (1.09–1.47) and 1.32 (1.13–1.54), respectively. Hazard ratios did not change when analysis were restricted to confirmed ischemic strokes.
Conclusion: In elderly people at increased risk of cardiovascular disease, a delayed and decreased potential to generate thrombin is an independent risk factor for stroke. Although the role of thrombin formation in the pathogenesis of stroke remains unknown, these data support an effect of plasma coagulation activity on progression of arterial vascular disease, related to stroke.

OC 64.3

Evaluation of the thrombin generation potential of a recombinant factor VIII Fc fusion protein (rFVIIIFc) in a phase III multi-national clinical trial

Buyue Y, Jiang H, Luk A, Pierce GF and Sommer J
Biogen Idec, Waltham, MA, USA

Background: The recombinant coagulation factor VIII Fc (rFVIIIFc) consists of a single molecule of human factor VIII covalently linked to the dimeric Fc domain of human immunoglobulin G1 (IgG1). The rFVIIIFc fusion protein utilizes the FcRn receptor-mediated immunoglobulin cycling pathway to extend plasma half-life. In a global phase 3 clinical study (A-LONG), rFVIIIFc demonstrated effective prevention and control of bleeding episodes with a longer prophylactic dosing interval than current short acting FVIII products. In addition to the one-stage and chromogenic clotting assays, pharmacokinetics (PK) samples were analyzed by a thrombin generation assay (TGA) in order to gain additional insights into the coagulation potential of rFVIIIFc in a potentially more relevant physiological setting.
Aims: To compare the *ex vivo* thrombin generation potential of rFVIIIFc to a currently marketed rFVIII product (Advate®) in post-infusion patient plasma samples by a standardized TGA in a Phase 3 multi-center clinical trial.
Methods: A total of 1207 samples from 137 subjects were collected from 48 clinical study sites in 15 countries for TGA analysis. Blood samples were collected into special tubes containing 3.2% citrate and 50 μg/mL corn trypsin inhibitor (CTI), followed by centrifugations to produce platelet-poor plasma. The TGA was performed at a central laboratory using a modified calibrated automated thrombogram (CAT®) method. Before testing, the thawed samples were centrifuged to remove any remaining cell debris or microparticles. Each assay contained 80 μL sample, 20 μL 1:6000 dilution of Innovin®+4 μM synthetic phospholipids and 20 μL fluorogenic substrate with calcium. This study was approved by local site medical ethics committees and informed consent was obtained from all participating subjects.
Results: Results of 643 samples (29 subjects) from sequential PK profiling for both rFVIIIFc and rFVIII were included for this report. The responses of major TGA parameters (peak thrombin and endogenous thrombin potential) were proportional to the one-stage and chromogenic FVIII activity throughout the measurable range. At early time points post-dosing, rFVIIIFc demonstrated comparable thrombin generation responses to rFVIII, and the decay of thrombin generation activity post-dosing was markedly slower for rFVIIIFc than that of rFVIII. The average thrombin generation profile for rFVIIIFc compared to rFVIII correlated well with the half-life extension observed for plasma rFVIIIFc activity by the one-stage and chromogenic assays. Regression analysis of the thrombin generation profiles vs. FVIII activity indicated comparable thrombin generation responses for rFVIIIFc and rFVIII at equivalent FVIII activities.
Summary/Conclusions: Our large scale, global clinical evaluation of rFVIIIFc by TGA using a standardized sample collection procedure and an optimized and validated assay performed at a central laboratory demonstrated that, despite inherent patient-to-patient differences in thrombin generation potential, (i) The TGA results confirmed the longer duration of activity of rFVIIIFc relative to rFVIII. (ii) The pooled patient data showed comparable TGA responses for rFVIIIFc and rFVIII at equivalent FVIII activities. (iii) The comparable *ex vivo* thrombin generation potential of rFVIIIFc and rFVIII observed in this study supports our method for rFVIIIFc potency assignment against the WHO FVIII concentrate standard.

OC 64.4

Whole blood thrombin generation in aging mice

Ninivaggi M[1], Kelchtermans H[1], Kuijpers MJE[1], Hemmeryckx B[2], Heemskerk JWM[1], Lindhout T[1], Hoylaerts MF[2] and De Laat B[1]
[1]CARIM, Maastricht University, Maastricht, the Netherlands; [2]Katholieke Universiteit Leuven, Leuven, Belgium

Background: Thrombin generation (TG) is increasingly being recognized as a versatile diagnostic tool in the field of thrombosis and haemostasis. TG in plasma is most accurately measured with the Calibrated Automated Thrombogram assay (CAT) and is sensitive in detecting conditions of hyper- and hypocoagulabilty. By modification of the classic plasma CAT assay, we were able of measuring TG in whole blood (WB-CAT assay). The advantage of using this assay in mice is that only small amounts of blood are needed (> 100 μL) to perform triplicate measurements including calibration. As a result there is no need to sacrifice the mice and TG can be measured in one mouse repeatedly in time. As a proof of principle, we studied the TG in Bmal1-knock out (KO) and wild type (WT) mice. Bmal1-KO mice were known to have a prothrombotic phenotype due to accelerated aging compared to WT mice. However, standard coagulation tests reveal opposite results (e.g. decreased prothrombin time and prolonged activated partial thromboplastin time).

Aims: To technically validate the WB-CAT assay in mice and to investigate TG in prothrombotic Bmal1-KO mice compared to WT mice.
Methods: Mice blood samples were taken from the orbital sinus using a capillary coated with a dimethyldichlorosilane solution. Blood was anticoagulated with citrate (3.8%) and reactivated during the experiment with a solution containing calcium, tissue factor (TF) and the substrate. Hirudin was also added to the calibrator wells to prevent any TG that could disturb the calibrator signal.
Results: When activating the blood using different TF concentrations, we found that 0.5 pM TF was sufficient to start coagulation. Addition of corn trypsin inhibitor (CTI) to prevent contact activation did not have a profound effect indicating that contact activation does not play a significant role in the initiation phase. The mean intra-assay variation ($N = 24$) of the peak height, lagtime, time-to-peak and velocity index revealed to be fairly precise as the coefficient of variation (CV) was 10% or less. The CV of the ETP was higher (12%). Studying TG in the Bmal1-KO mice revealed that the mean ETP of Bmal1-KO mice (ETP [SD] = 437 [78]) was significantly higher ($P > 0.001$) than measured in WT mice (ETP [SD] = 220 [45]). We found comparable differences for the peak height ($P = 0.027$). No difference was observed in lagtime, TTP and velocity index (p-values were respectively 0.45, 0.15 and 0.74).
Conclusion: We have developed a reproducible assay to monitor TG in whole blood of mice using only minimal amounts of blood. In addition, with this method we have established an increased TG in Bmal1-KO mice compared.

OC 64.5

A systematic review to evaluate thromboelastography for characterization of bleeding patients with advanced liver diseases

Chan HW, Li X, Lau K and Chan AK
McMaster University, Hamilton, ON, Canada

Background: The liver produces clotting proteins, but thrombocytopenia commonly occur in patients with advanced liver disease. Traditional coagulation tests, such as PT or aPPT, only measure the interactions of clotting proteins without evaluating the roles of cellular components during clot formation. In contrast, thrombelastography (TEG) monitors real-time clot formation of whole blood, thereby allowing global evaluation of the hemostatic system and providing more information regarding the integrity of hemostasis in patients with liver diseases and concomitant thrombocytopenia.
Aims: To evaluate whether patients with bleeding complications due to advanced liver diseases have distinctive TEG abnormalities as compared with those without bleeding.
Method: The OVID MEDLINE and EMBASE databases from 1946 to 2012 were searched with keywords 'thromboelastography' and 'liver disease'. 113 studies were obtained from OVID MEDLINE and 216 studies from EMBASE. Duplicates, non-English, non-primary articles such as reviews, meta-analysis and animal studies were excluded. We only included studies that evaluated the association between TEG parameters and objective bleeding outcomes. Data regarding study design, number of subjects, TEG settings, TEG values, clinical outcomes, and results of other conventional coagulation test were extracted. The data from both bleeders and non-bleeders were standardized to the normal values given in each study to adjust for the variations in study design and TEG methodology. To account for different sample sizes, normalized values were weighted according to each study's sample size. Weighted means and weighted standard deviations were calculated for each of the 4 TEG parameters (R, K, α, MA) and Student's *t*-test was conducted to compare the bleeders with non-bleeders. A *P*-value of ≤ 0.05 was considered statistically significant.
Results: Three prospective and one retrospective studies involving a total of 172 patients with 21 bleeders and 151 non-bleeders were identified. Three studies assessed bleeding following an invasive procedure, while one assessed recurrence of bleeding. All bleeding outcomes were evaluated independently of TEG measurements. Of the four studies, one study used kaolin-activated TEG, one used native TEG, while the other two were unstated.
The R in the patients with bleeding was $132.3 \pm 37.2\%$, significantly longer than $93.2 \pm 4.0\%$ in those without bleeding. The K of the bleeders was $228.4 \pm 168.7\%$; again, significantly higher than the value of $132.23 \pm 29.16\%$ among the non-bleeders. Those with bleeding also had a significant lower α of $68.5 \pm 36.1\%$, as compared with the value of $92.1 \pm 8.5\%$ in those without bleeding. In contrast, there was no significant difference in the MA between the patients with or without bleeding; the values were $83.9 \pm 11.0\%$ and $85.69 \pm 11.96\%$ respectively.
Summary/Conclusion: The results suggested that patients with clinical bleeding took longer to initiate clotting and the clot propagated slower, but the clot achieved similar maximum strength once it formed. Patients suffering from severe liver diseases with bleeding complications have a distinctively different TEG profile as compared with those without bleeding complications. These abnormal TEG parameters are compatible with coagulopathy mainly due to insufficient procoagulant proteins for hemostasis. Yet, the advantages of using TEG, instead of traditional plasma-based coagulation tests, in predicting bleeding in patients with advanced liver diseases warrant further investigation.

OC 64.6

Increased thrombin generation in patients with premature myocardial infarction is linked to tissue factor microparticles in the circulation

Alsahli MA, Popat B, Wright JR, Singh RJ, Samani NJ and Goodall AH
University of Leicester, Leicester, UK

Background: The extent of the haemostatic response may determine the risk of forming an occlusive thrombus, particularly in patients who suffer MI at an early age, when the atherosclerotic burden is relatively low. While levels of individual haemostatic factors have been linked to increased risk of MI, measurement of the endogenous thrombotic potential (ETP) may better indicate the overall haemostatic response of an individual. Previously we have shown, using a thrombin generation assay sensitive for plasma coagulation factor levels (triggered with 5 pM tissue factor [TF] and 4 μM phospholipid [PL]) that the ETP in plasma from individuals with an MI > 50 years was significantly higher than that in age/sex-matched controls with no history of CHD. Moreover there was a significantly higher level of TF in the cases compared to the controls and levels of TF were strongly correlated between the ETP in the MI cases and the level of TF in their plasma which was not seen in the control subjects.
Aims: Here we sought to determine whether the higher level of TF seen in the MI cases was predominantly in the form of microparticles (MPs).
Methods: Plasma from 198 individuals with an MI under the age of 50 years and 194 age/sex-matched controls with no history of CHD was analysed for thrombin generation by the Calibrated Automated Thrombogram (CAT) MP assay triggered with 4 μM PL that is designed to measures the activity of endogenous TF+ve MPs. The plasma samples were also passed through a 0.22 μm filter (Ceveron) to remove MPs and reanalysed in the same assay.
Results: All four parameters from the CAT MP assay were significantly different in the cases compared to the controls. The lag time (LT) and time to peak (ttP) were faster in the patients (for LT 32.31 ± 1.45 vs. 38.5 ± 1.62 min; $P = 0.005$ and for ttP 34.78 ± 1.42 vs. 40.95 ± 1.51 min; $P = 0.0032$), indicative of higher numbers of TF+ve MPs in the patients' samples. As previously the ETP levels were higher in the patients (980 ± 45 vs. 697 ± 42 nM.min; $P > 0.0001$) as was the level of peak thrombin (PT; 160.2 ± 8.3 vs. $105.0 \pm$

7.0 nM.min; $P > 0.0001$). Following filtration to remove MPs the LT and ttP (which are the most sensitive parameters to detect MP-derived TF in the assay) increased significantly (p£0.03) and after filtration there was no difference in these parameters between the patients and the controls (for LT 37.56 ± 1.76 vs. 41.54 ± 1.81 min; $P = 0.01159$ and for ttP 39.50 ± 1.66 vs. 43.36 ± 1.70 min; $P = 0.1058$). Filtration also caused the mean ETP and PT to fall slightly for both patients and controls but for both measures the patients still generated significantly more thrombin that the controls (for ETP 824 ± 49 vs. 643 ± 45 nM.min^{-}; $P = 0.0070$ and for PT 145.2 ± 9.4 vs. 109.1 ± 8.5 nM.min; $P = 0.0047$).

Conclusions: These data are consistent with a higher level of TF+ve MPs in the plasma of patients who have suffered an MI at an early age compared to matched controls. Although the cellular source of the TF +ve MPs was not determined these prothrombotic MPs may be a contributing factor the increased thrombotic risk in the patients.

Accelerated uptake of VWF/platelet complexes in macrophages contribute to VWD-type 2B associated thrombocytopenia

Casari C[1], Christophe OD[1], Denis CV[2] and Lenting PJ[1]
[1]Inserm, Le Kremlin-Bicetre; [2]Inserm U 770, Le Kremlin-Bicêtre, France

Background: Von Willebrand Disease (VWD)-type 2B is caused by so-called *gain-of-function* mutations, clustered in exon 28 of von Willebrand factor (*VWF*) gene and results in spontaneous binding to glycoprotein (GP)Ib. Bleeding tendency is associated with heterogeneous clinical manifestations such as the decrease of high molecular weight-VWF multimers, presence of giant platelets and/or platelet aggregates, and moderate to severe thrombocytopenia.

Aims: One of the major predictor of the bleeding risk in VWD-type 2B patients is the severity of the thrombocytopenia, the causes of which have not yet been identified. An *in vivo* mouse model of VWD-type 2B obtained via hydrodynamic gene transfer of plasmids to express murine VWF carrying type 2B mutations was applied. This model was used to investigate the molecular mechanism underlying the thrombocytopenia.

Methods and Results: Mutation-specific conformational changes in the VWF molecule increase its affinity for the platelet receptor GPIb, allowing spontaneous VWF-platelets interactions. Indeed, VWF-type 2B mutants but not wild type (wt)-VWF were adsorbed to platelets, as assessed via immunofluorescence analysis. Moreover, the presence of VWF-type 2B/platelet complexes and aggregates was associated with the occurrence of thrombocytopenia.

Given that liver and spleen macrophages have already been identified as important actors in the clearance of VWF and platelets, we studied their possible involvement in the elimination of VWF-type 2B/platelet complexes. *In vivo* chemical depletion of macrophages was successfully obtained through liposome-clodronate injection and converted thrombocytopenia in VWD-type 2B mice to near normal platelet counts. Furthermore, CMTMR-*in vivo* cell tracker was used to localize exogenous type-2B platelets infused in VWD-type 2B mice. Microscopical qualitative evaluation of liver and spleen cryo-sections revealed that the vast majority of type 2B-platelets co-localized with Kupffer cells (CD68+) in the liver and with marginal metallophilic macrophages (CD169+) in the spleen. Quantitative analysis confirmed that significant more platelets are directed to liver and spleen in VWD-type 2B mice than in wt-mVWF expressing mice.

Finally, platelet half-life was determined in our mouse model of VWD-type 2B and proved significantly shorter (34 ± 4 h) compared to the half-life of platelets in wt-mVWF-expressing mice (53 ± 7 h, $P > 0.0001$), possibly contributing to the lower platelet counts in VWD-type 2B mice.

Conclusions: Our data indicate that VWF-type 2B/platelet complexes are rapidly targeted to macrophages, which could contribute to the thrombocytopenia in patients with VWD-type 2B.

OC 65.2

The vicinal disulphide bond and calcium coordination site of the von Willebrand factor A2 domain have distinct and additive roles in domain stabilisation that govern proteolysis by ADAMTS13

Lynch CJ, Lane DA and Luken BM
Imperial College London, London, UK

Background: Rheological shear forces in the blood trigger von Willebrand factor (VWF) unfolding which exposes the Y1605-M1606 scissile bond within the A2 domain for cleavage by ADAMTS13. The VWF A2 domain contains two main structural features that influence its ability to unfold: a calcium coordination (Ca^{coord}) site and a vicinal disulphide bond (VicCC) between C1669-C1670.

Aim: To investigate the functional dependency of Ca^{coord} and VicCC in the unfolding of the VWF A2 domain and subsequent proteolysis by ADAMTS13.

Methods: VWF A2 domain variants with point mutations in the Ca^{coord} site (D1498A, D1596A, N1602A) were combined with deletion (ΔCC) and substitution mutations (C1669G/C1670G) of the VicCC and expressed in HEK293 cells both as VWF A2 domain fragments and full-length VWF protein. Differential scanning fluorimetry assays were used to determine T_m of the VWF A2 domain variants during thermodynamic unfolding to assess protein stability. ADAMTS13 cleavage assays in the absence/presence of denaturing agent were used to assess susceptibility to proteolysis.

Results: The expression and secretion of the isolated VWF A2 domain containing the VicCC (A2VicCC) was unaffected by mutation of Ca^{coord} residues. The presence of calcium ions stabilised the WT A2VicCC domain, causing a shift in T_m of 19.2 °C from 1 mM EDTA (46.3 °C) to 5 mM $CaCl_2$ (65.5 °C). The T_m of the Ca^{coord} mutants was not affected by addition of calcium/EDTA and these fell into two distinct groups: 'stabilising mutations' that had a similar stability to the WTA2VicCC in the presence of calcium (T_m in the range of 60–65 °CD1596A, D1596A/N1602A), and 'destabilising mutations' that had a similar stability to WTA2VicCC in the absence of calcium (T_m in the range of 46–51 °CD1498A, N1602A, D1498A/D1596A, D1498A/N1602A, D1498A/D1596A/N1602A). When these Ca^{coord} mutants were introduced into the A2ΔCC, all the 'destabilising mutations' prevented secretion and resulted in intracellular retention of the A2ΔCC protein. In contrast, the WTA2ΔCC and A2ΔCC containing 'stabilising mutations' were successfully secreted. Introduction of the Ca^{coord} mutants into the full length VWF protein in both the presence (WT) and absence (VicGG) of the VicCC did not prevent secretion. In cleavage assays with ADAMTS13 in the absence of denaturant, the presence of either the VicCC or 'stabilised' Ca^{coord} prevented cleavage. Substitution of VicCC and 'destabilisation' of the Ca^{coord} site (VWF VicGG D1498A or VicGG N1602A) resulted in cleavage of full length VWF in the absence of denaturant or shear.

Conclusions: Mutation of both the VicCC and specific residues of the Ca^{coord} site destabilises the isolated A2 domain to such extent that it is no longer secreted. Secretion of A2 domain is recovered in the full length protein. VWF with a substituted VicCC and 'destabilised' Ca^{coord} site is proteolysed by ADAMTS13 without a need for induced unfolding, whereas VWF containing either the VicCC or the Ca^{coord} site is resistant to proteolysis in the absence of induced unfolding. The distinct and additive effects of both the VicCC and Ca^{coord} provide the VWF A2 domain with stability, whilst allowing it to unravel and expose its cleavage site for ADAMTS13 under high shear.

OC 65.3

Comprehensive characterization of loss and gain-of-function von Willebrand factor collagen binding variants and the role of GPVI using a mouse model system

Shida Y, Rydz N, Brown C, Mewburn J, Sponagle K, Danisment O, Crawford BA, Vidal B, Hegadorn C and Lillicrap D
Queen's Univeristy, Kingston, ON, Canada

Background: von Willebrand factor (VWF) is a multifunctional multimeric protein that plays an important role in primary hemostasis where binding of VWF to exposed subendothelial collagens is the first step towards thrombus formation at the site of injury. To date, four point mutations within the VWF A3 domain affecting collagen-binding have been described in 11 patients: S1731T, W1745C, S1783A, and H1786D. However, given the rarity of collagen-binding mutants and the heterogeneous genetic backgrounds of the affected subjects, the analysis of these aberrant VWF-collagen interactions has been relatively limited.
Aims: To characterize VWD collagen binding defects and analyze the role of collagen, we developed a comprehensive inbred mouse model system. In addition to the analysis of collagen binding via the VWF A3 domain, we further analyzed the impact of the direct collagen binding of platelets by knocking down GPVI.
Methods: Full-length murine VWF cDNA was cloned into the pCIneo plasmid to produce recombinant mouse VWF (r-mVWF) and into the pSC11 plasmid with the liver-specific Enhanced murine Transthyretin (ET) promoter for hydrodynamic delivery. Mutagenesis was performed to introduce the gain-of- function mutation (L1757A) and loss-of-function mutations (S1731T, W1745C, S1783A, H1786D, A3 deletion). All these amino acids are conserved between human and mouse. r-mVWF was obtained by calcium phosphate transient transfection. The function of r-mVWF was analyzed by the following methods a static collagen binding assay, flow chamber assay and *in vivo* intravital thrombosis analysis. The collagen binding assay is a conventional ELISA based assay. In the flow chamber assay, whole blood from VWF knockout mice was perfused into a collagen/r-mVWF coated flow chamber and real-time thrombus formation was analyzed by Quorum WaveFX- X1 spinning disk confocal system. In the intravital experiments, VWF cDNA was delivered to VWF knockout mice by hydrodynamic injection. GPVI knockdown was performed by intraperitoneal injection of anti-GPVI antibody. After rhodamine 6G infusion, injury was induced on arterioles in the cremaster muscle by 10% ferric chloride for 3 min. Following injury, a single arteriole in the injured area was observed for 40 min.
Results: The gain-of-function (L1757A) variant showed consistent enhanced collagen binding. Collagen binding assay demonstrated 2.7- and 2.0-fold-binding to collagen type I and III and the flow chamber experiment showed 3.0- and 1.5-fold-increase in thrombus size. The loss-of-function mutants showed variable degrees of functional deficit (10–88% reduction compared to wild type VWF). In the intravital experiment, the wild type and gain-of-function (L1757A) variant showed 100% occlusion at 30 and 25 min respectively, while a loss of function mutant (H1786D) showed 66% occlusion at 40 min and did not fully occlude. VWF, GPVI and combined VWF/GPVI knockout mice showed significant loss of thrombus formation (28.8%, 34.1%, 33.8% occlusion at 40 min, respectively).
Summary/Conclusion: We have performed a comprehensive evaluation of the collagen binding variants described in patients. Our results are consistent with an important role for collagen binding in thrombus formation. Nevertheless, VWF/GPVI double knockout mice still demonstrated significant amounts of thrombus formation, suggesting the role of alternative pathway(s) for thrombogenesis, independent of collagen binding.

OC 65.4

The role of platelet von Willebrand factor in mice

Verhenne S, Libbrecht S, Vandenbulcke A, Deckmyn H, Vanhoorelbeke K and De Meyer SF
KU Leuven Kulak, Kortrijk, Belgium

Background: von Willebrand factor (VWF) is a large adhesive multimeric glycoprotein that mediates binding of platelets to sites of vascular injury and protects clotting factor VIII from degradation in circulation. VWF is constitutively secreted from endothelial cells in plasma and subendothelium but is also stored as ultra-large VWF multimers in endothelial Weibel-Palade bodies and platelet a-granules. The exact role of ultra-large platelet VWF is still not completely understood.
Aim: Given the fact that ultra-large VWF has been reported to contribute to both thrombosis and inflammation, we aimed to study the role of platelet VWF in hemostasis, thrombosis and thrombo-inflammatory disorders such as stroke.
Methods: To determine the role of platelet VWF, we transplanted bone marrow mononuclear cells from wild-type (WT) mice in VWF knockout (KO) mice and *vice versa*, resulting in chimeric mice with only platelet VWF and chimeric mice that lack platelet VWF. To study the role of platelet VWF we used our chimeric mice to perform tail clipping bleeding assays, $FeCl_3$-induced carotid artery thrombosis models and a stroke model of transient focal cerebral ischemia.
Results: The bleeding time in chimeric mice with only platelet VWF was prolonged and was not different from the one in VWF KO mice (> 600s). Chimeric mice that lack platelet VWF on the other hand had bleeding times similar to those of WT mice (148 $\pm$ 60 vs. 155 $\pm$ 48 s, respectively). These studies suggest that (i) platelet VWF alone is not able to support normal hemostasis and (ii) lack of platelet VWF does not induce a bleeding phenotype in mice. After injury of the carotid artery, arterial occlusion times in chimeric mice with only platelet VWF were prolonged, similar to VWF KO mice (> 60 min), thus indicating that platelet VWF alone cannot support normal thrombus formation, corroborating the bleeding assay results. Thrombosis experiments with chimeric mice lacking platelet VWF are still ongoing. Interestingly, using a mouse model of transient middle cerebral artery occlusion, we observed that cerebral infarct sizes in chimeric mice with only platelet VWF (79.6 $\pm$ 32.3 mm^3) were similar as in WT mice (71.3 $\pm$ 38.3 mm^3). These results are surprising and point towards the contribution of platelet VWF in cerebral ischemia/reperfusion injury. Stroke studies using mice lacking platelet VWF are in progress.
Conclusion: Our data suggest that whereas platelet-derived VWF does not play a crucial role in thrombosis and hemostasis, it might aggravate thrombo-inflammatory diseases such as stroke. Further studies will assess how platelet VWF mediates stroke progression.

OC 65.5

Common and rare VWF coding variants are associated with von Willebrand Factor and Factor VIII phenotypes in African Americans: the NHLBI Exome Sequencing Project

Johnsen JM[1], Auer P[2], Cushman M[3], O'Donnell C[4], Rich S[5], Green D[6], Morrison AC[7], Reiner AP[8] and NHBLI GO[9]
[1]Puget Sound Blood Center; [2]Fred Hutchinson Cancer Research Center, Seattle, WA; [3]University of Vermont, Burlington, VT; [4]National Institutes of Health, Bethesda, MD; [5]University of Virginia, Charlottesville, VA; [6]Northwestern University, Chicago, IL; [7]University of Texas Health Science Center at Houston, Houston, TX; [8]University of Washington, Seattle, WA; [9]NIH, Bethesda, MD, USA

Background: von Willebrand Factor (VWF) is a critical clotting protein which stabilizes Factor VIII (FVIII), adheres at sites of vascular

injury, and binds platelets. VWF and FVIII levels vary widely among individuals and are generally higher in individuals of African ancestry (AA) than European ancestry (EA). Differences between AAs and EAs may be partly due to genetic factors, but large studies of the effects of *VWF* gene variants have not been reported in AA.

Aims: To study the association of *VWF* coding variants with VWF and FVIII levels in AA.

Methods: Using *VWF* sequence data from 6515 individuals (4298 EA, 2217AA) in the NHLBI Exome Sequencing Project (ESP), we employed genotype imputation to study the association of *VWF* coding variants with VWF and FVIII levels in 4468 AA from four population-based cohorts: the Atherosclerosis Risk in Communities (ARIC), Coronary Artery Risk Development in Young Adults (CARDIA), Multi-Ethnic Study of Atherosclerosis (MESA), and Women's Health Initiative (WHI). In ESP, 452 EA and 409 AA *VWF* variants were identified. In AA, 147 *VWF* variants had a minor allele frequency (MAF) > 0.1%. Of these, 114 were successfully imputed (30 missense, 28 synonymous, 56 intronic). Genetic association analysis was performed using the 30 missense variants and data in the four cohorts for VWF:Ag (n = 2989, mean 132 ± 58 IU/dL) and FVIII:C (n = 4450, mean 155 ± 64 IU/dL).

Results: Eight of 30 *VWF* missense variants, including a novel variant (Ser1486Leu), were significantly associated with levels of VWF, FVIII, or both, in AA after Bonferroni correction ($P > 0.0017$). Five>/i> VWF variants were common (MAF > 10%), three were rare (MAF > 1%), and in ESP all were more common in AA than EA. The variant Thr789Ala (rs1063856, MAF = 43.2%) was associated with higher VWF and FVIII levels ($P = 10^{-9}$ and 10^{-6}, respectively), with each additional copy of the G allele (Ala789) associated with ~8 IU/dL higher VWF and FVIII levels. The variants Ile1380Val (rs11063988, MAF = 10.6%) and Asn1435Ser (rs11063987, MAF = 10.3%) were in strong linkage disequilibrium ($r^2 = 0.89$) and associated with ~6–9 IU/dL higher FVIII and VWF levels. Conversely, Arg2185Gln (rs2229446, MAF = 19.9%), was associated with lower VWF and FVIII levels ($P = 10^{-13}$ and 10^{-17}, respectively); each additional copy of the A allele (Gln2185) was associated with ~13 IU/dL lower VWF and FVIII levels. His817Gln (rs57950734, MAF = 11.7%) was associated with lower FVIII levels ($P = 10^{-21}$) but no difference in VWF; each A allele (Gln817) was associated with ~18 IU/dL lower FVIII. The three rare missense variants (Met1439Val [rs150077670], Ser1486Leu [rs149424724], Arg2287Trp [rs61750625]) were each significantly associated with lower VWF ($P = 10^{-4}$, 10^{-7}, 10^{-6}, respectively) but not FVIII level. The presence of a single copy of each of these rare variants were associated with an average per allele difference of 35–40 IU/dL lower VWF.

Conclusions: Using an exome sequencing and genotype imputation approach in a large AA population sample, we identified several common and rare *VWF* coding sequence variants which were associated with effects on VWF and FVIII levels in AAs. These *VWF* variants may contribute to the genetic complexity underlying ethnic differences in VWF and FVIII.

OC 65.6
High density lipoprotein and apolipoprotein A1 modulate VWF secretion and self-association

Chung DW[1], Ling M[2], Chen J[1], Fu X[1], Parsons S[1], Harris J[1], Le J[1] and Lopez JA[2]

[1]Puget Sound Blood Center; [2]University of Washington, Seattle, WA, USA

Background: Several studies have shown that VWF multimers in solution can homotypically associate with VWF multimers immobilized onto collagen, and endothelial and platelet surfaces. Association of newly secreted ultra-large VWF multimers into strands and cables on the endothelial surface, and adsorption of VWF to artificial surfaces represent additional forms of VWF self-association. While working on the properties of purified VWF, we observed that VWF disappeared from the solution rapidly. Through steps of fractionation and inactivation, we identified apolipoprotein A1 (ApoA1), the primary component of high density lipoprotein (HDL), as one possible VWF stabilizer in plasma.

Aim: To characterize the effect of ApoA1 and HDL on VWF self-association.

Methods: VWF self-association was studied by two Methods (i) adsorption to and selective elution from artificial surfaces, and (ii) formation of ULVWF strings on the surface of endothelial cells. Purified VWF was exposed to surfaces with or without stabilizing proteins. At specified times, the following fractions were analyzed by Western blotting or ELISA: VWF remaining in solution, VWF eluted from surfaces by 2% sodium dodecyl sulfate, and VWF eluted by 4% CHAPS-5 mM DTT-8M urea. Confluent endothelial cells in flow chambers were stimulated with phorbol myristate acetate (50 ng/mL), with or without HDL (2 mg/mL). ULVWF was visualized by binding to platelets that were perfused over the stimulated cells with or without HDL. The cells were then fixed and imaged. Platelet-decorated VWF strings on the endothelial surface exceeding 25 mm were counted.

Results: Substantial amounts of purified VWF adsorbed to plastic and glass surfaces through VWF-surface interactions (~15%), followed by VWF self-association (~70%). Human ApoA1 and HDL stabilized VWF in solution (~90%) and prevented its adsorption to surfaces. While pre-treating surfaces with ApoA1 or HDL moderately reduced adsorption, maximal stabilization required the continued presence of ApoA1 or HDL during incubation. These results suggest that ApoA1 or HDL not only prevented surface adsorption, but also prevented self-association of solution VWF with surface-bound VWF. In cultured endothelial cells, the presence of HDL during stimulation by phorbol myristate acetate significantly reduced the amount of secreted and cell surface-bound ultra-large VWF (ULVWF), suggesting that HDL modulates VWF secretion and self-association of the secreted VWF into ULVWF. The binding of platelets to ULVWF was slightly affected by the presence of HDL. Fluorescence depolarization studies showed that ApoA1 and HDL bound to a specific sequence in VWF, suggesting that exposure and interaction of this region with ApoA1 and HDL regulate VWF self-association. Further, we observed that the levels of ApoA1 were below normal in patients with thrombotic complications in the microvasculature, including thrombotic thrombocytopenic purpura, sickle cell disease, and sepsis.

Summary: These results show that ApoA1 or HDL may modulate platelet adhesion by modulating both VWF secretion from endothelial cells and self-association into ULVWF strands on the endothelial surface. This may be another mechanism by which HDL protects against cardiovascular disease and extends its protective effects from large arteries to the microvasculature.

OC 66 – Alternative Treatments of Haemophilia A

OC 66.1
Fusion of two TFPI inhibitory peptides yields in total inhibition of human TFPI even at highly elevated TFPI levels

Dockal M[1], Hartmann R[1], Polakowski T[2], Brandstetter H[3], Kammlander W[1], Panholzer E[1], Redl C[1], Osterkamp F[2] and Scheiflinger F[1]

[1]Baxter Innovations GmbH, Vienna, Austria; [2]3B Pharmaceuticals, Berlin, Germany; [3]University of Salzburg, Salzburg, Austria

Background: TFPI is a Kunitz (K)-type protease inhibitor that inhibits both, FXa and TF-FVIIa and is an important physiological inhibitor of the extrinsic coagulation pathway. Direct inhibition of TFPI in hemophilia models alleviates bleeding challenges and may become an

important approach in hemophilia treatment. Recently we presented *de novo* peptide inhibitors of TFPI that enhance coagulation in hemophilia models. Two optimized peptides JBT-A7 and JBT-B5 efficiently blocked inhibitory activity of TFPI and bind to K1 and K1-K2, respectively, which was shown by crystallography. The X-ray structures offered starting points for peptide optimization and provided atomic details for linking the two single peptides to generate a fusion peptide that maximally blocks TFPI activities.

Aims: We aimed to generate a TFPI 'super-inhibitory' fusion peptide, which totally blocks TFPI activity even at high TFPI plasma levels.

Methods: The interaction of TFPI inhibitory peptides to TFPI fragments was assessed by Biacore. Recently we showed the crystal structure of JBT-A7 bound to K1 of TFPI. Moreover, JBT-B5 was co-crystallized with K1-K2 of recombinant human (h)TFPI. The structure of K1 in the K1-K2/JBT-B5 and the NTermK1/JBT-A7 complex were overlayed. The TFPI inhibitory potential of the peptides was tested in model systems (FXa inhibition and TF-FVIIa catalyzed FX activation) and in plasma (TF-triggered thrombin generation). The assays were carried out at TFPI concentrations up to 10 nM, which is 50-fold higher than the physiological flTFPI plasma concentration.

Results: Overlay of the structure of K1 in the K1-K2/JBT-B5 and the NTermK1/JBT-A7 complex revealed no significant differences between the two crystal structures of the Kunitz domain. This implies that the peptides do not induce conformational changes on the domains of TFPI responsible for the antagonistic effect. The model confirms non-overlapping epitopes and close proximity of the termini of both peptides. The distance could be bridged by an approximately ten amino acid linker. A fusion peptide with a 10-serine-linker was synthesized. The fusion peptide showed highly improved dissociation in Biacore experiments and fully inhibited TFPI activity in the model assays. In contrast, single peptides are partial inhibitors of high TFPI concentrations. In thrombin generation assays, the fusion peptide showed a substantially higher ability to increase the thrombin peak even at elevated TFPI compared with the single peptides. Although a mixture of the single peptides showed an improved response over each monomeric peptide, it did not reach the effect of the fusion peptide. Thus, we provide clear evidence that a molecular fusion is required for most efficient inhibition of TFPI activity.

Summary/Conclusions: The fusion of two single peptides binding to different epitopes on TFPI can inhibit the interaction of TFPI with both, FXa and FVIIa resulting in a full inhibitor of TFPI activity even at highly elevated TFPI. The fusion peptide has the potential to block local high TFPI concentrations as it occurs during platelet activation. Thus, the fusion peptide can be useful to prevent bleeding in hemophilia patients. Moreover, this FVIII and FIX independent approach would allow treatment of inhibitor patients via a non-i.v. route of application.

OC 66.2

Influence of TFPI levels on the different parameters of thrombin generation and impact of a TFPI neutralization on the correction of thrombin generation in haemophilic patients

Tardy-Poncet B[1], Piot M[2], Chapelle C[1], Mismetti P[1] and Tardy B[1]

[1]CHU Saint-Etienne; [2]Université Jean Monnet, Saint-Etienne, France

Background: TFPI is a potent direct inhibitor of factor Xa, inhibiting the factor VIIa/TF complex in a factor Xa-dependent manner. TFPI feedback inhibition of factor VIIa/TF is consistent with a deficient factor Xa production in haemophilic plasma. It has already been shown that TFPI is involved in haemorrhagic manifestations in haemophilia and that blocking TFPI can restore haemostasis.

Aim of the study: To evaluate prospectively the influence of TFPI on the different parameters of TG and to evaluate the impact of TFPI neutralization on the correction of thrombin generation (TG).

Patients and Methods: Twenty-four haemophilic patients (14 HA and 10 HB). TG assay (TGA) was evaluated using the CAT system described by C Hemker on platelet poor plasma (PPP) and on platelet rich plasma (PRP) at low TF concentration (1 pM) before and after adding anti human TFPI antibody (R &D System) at different concentrations. Blood was taken on citrated tubes containing CTI. Free TFPT (fTFPI) levels were measured by ELISA (Asserachrom free TFPI, Asnières France).

Results: When all haemophilic patients are taken together, the correlation (evaluated with R^2 Spearman correlation; * if $P > 0.05$) between Lag Time (LT) and fTFPI is much better in PRP ($R^2 = 0.247$*) than in PPP ($R^2 = 0.07$). In PRP, the correlation between LT and fTFPI is much better in haemophilia A ($R^2 = 0.440$*) and in severe haemophilia ($R^2 = 0.503$*). This correlation does not exist in PPP. When all haemophilic patients are taken together, the correlation between endogenous thrombin potential (ETP) and fTFPI is much better in PPP ($R^2 = 0.239$*) rather than in PRP ($R^2 = 0.022$). However, in haemophilia A patients the correlation between ETP and fTFPI in PRP is high ($R^2 = 0.486$*) but still better in PPP ($R^2 = 0.655$*). The same correlation is obtained in PPP between free TFPI and the Thrombin Peak.

We demonstrated that blocking TFPI by an anti-TFPI Antibody (Ab) allows a complete correction of the TG profile in PRP and in PPP; the correction depends on the anti TFPI Ab concentration that was used. Anti TFPI Ab (1 μg/mL) induced a 70% reduction of the LT when TG is performed in PRP.

With 1 μg/mL of anti TFPI Ab, the correction of ETP expressed as ETP + Ab/initial ETP is better in PPP (3.7) than in PRP (2.5) ($P = 0.02$). The correction of the Peak expressed as Peak + Ab/initial Peak is better in PPP (6.6) than in PRP (3.9) ($P = 0.05$).

Conclusion: A major influence of fTFPI is observed on LT in PRP and on ETP in PPP. There is a good correlation between fTFPI and ETP and Peak especially in haemophilia A. Anti TFPI are able to restore thrombin generation in haemophilic patients; their efficacy should be evaluated by TGA *ex vivo* rather in PRP to take into account platelet TFPI fraction.

OC 66.3

Effect of bypassing agent therapy with and without tranexamic acid in haemophilia A patients with inhibitors, a prospective crossover study using thromboelastography and thrombin generation assay

Tran HTT[1], Sørensen B[2], Rea C[2], Bjørnsen S[1], Ueland T[3], Pripp AH[4], Tjønnfjord G[5] and Holme PA[5]

[1]Oslo University Hospital, Oslo, Norway; [2]Haemostasis Research Unit, London, UK; [3]Research Institute of Internal Medicine; [4]Department of Biostatistics and Epidemiology; [5]Institute of Clinical Medicine, Oslo, Norway

Background: Activated prothrombin complex concentrate (aPCC) and recombinant activated factor VII (rFVIIa) are the only two drugs that are available to treat bleeds in haemophilia A patients with high titer inhibitors. The haemostatic response to treatment is widely variable and often difficult to predict. The antifibrinolytic agent tranexamic acid (TXA) may improve the haemostatic outcome but has been little studied due to a lack of standardized methods to monitor the effect.

Aims: The objective of the present study is to evaluate the effect of aPCC and rFVIIa with and without TXA, clot stability and thrombin generation capacity, using thromboelastography (TEG) and thrombin generation assay (TGA), respectively, and to assess the risk of thrombosis and disseminated intravascular coagulation (DIC) following these treatment regimens.

Methods: We conducted a prospective *in-vivo* crossover study including haemophilia A patients with high titer inhibiors ($n = 6$), age between 22 and 61 that had signed informed consent. The study was approved by the Regional Committee for Medical and Health

Research Ethics. On the first study day the participants received aPCC (75 IU/kg intravenously) while on the second study day aPCC was given concomitantly with TXA (20 mg/kg orally). Blood sampling was performed at baseline, 15, 30, 60, 120, 180 and 240 min post-treatment on both days for TEG, TGA analysis and DIC monitoring. After a washout period of 14 days the subjects were crossed over to rFVIIa (90 μg/kg intravenously) without and with TXA. Blood sampling and experimental set up was repeated as for the aPCC study arm.

Endogenous thrombin potential (ETP) was the main parameter used for evaluating the coagulable state whereas maximum clot firmness (MCF) and area under the curve (AUC) assessed clot stability. Comparisons between different treatment regimens were analysed with linear mixed models due to the crossover study design with repeated measurements. Post hoc comparisons were done with Bonferroni correction. A value of $P > 0.05$ was considered to indicate statistical significance.

Results: We found that both MCF and AUC increased by threefold ($P > 0.05$) following the combined treatment of aPCC or rFVIIa with TXA compared to aPCC or rFVIIa alone. There was no significant difference in ETP for the treatment with and without TXA ($p > 0.05$). In addition, DIC parameters were within normal range following all treatment regimens.

Conclusion: The results from our study suggest that the combined treatment strategy of aPCC/rFVIIa and TXA provides a beneficial haemostatic effect by increasing clot stability without increasing the thrombin generation potential and thereby the risk of thrombosis. There was no laboratory or clinical signs implying the occurrence of DIC. Moreover, the study also demonstrated that TEG and TGA seemed to be valuable methods in monitoring the therapeutic effects of bypassing agents. These findings may have important implications for the management of haemophilia A patients with inhibitors as they add evidence regarding the efficacy and safety of this novel treatment regimen.

RISE- response to DDAVP in moderate/mild haemophilia A patients: in search for determinants

Loomans JI[1], Van Velzen AS[1], Kruip JHA[2], Santagostino E[3], Eckhardt CL[1], Castaman G[4], Hart DP[5], Peters M[1], Van Der Bom JG[6] and Fijnvandraat KJ[1]

[1]Emma Children's Hospital, Amsterdam; [2]Erasmus Medical Center, Rotterdam, the Netherlands; [3]IRCCS Maggiore Hospital Foundation and University of Milan, Milan; [4]San Bortolo Hospital, Vicenza, Italy; [5]Royal London Hospital, London, UK; [6]Leiden University Medical Centre, Leiden, the Netherlands

Background: Large inter-individual variation in DDAVP response is observed in moderate/mild haemophilia A (MHA) patients. Identification of determinants of the DDAVP response may support optimal use of DDAVP and increase our understanding of the biological mechanisms associated with the release of VWF and rise in FVIII:C.

Aim: We aim to identify clinical and genetic determinants of the DDAVP response in MHA patients.

Methods: RISE is an international multicenter cohort study which aims to include 800 MHA patients (baseline (b)FVIII:C 0.02–0.40 IU/mL) who have received DDAVP between 1980 and 2013. Data on potential determinants were collected: ethnicity, family history of DDAVP response, age at receiving DDAVP, blood group, *F8* mutation, bVWF:Ag and bFVIII:C. Main outcome is the response 1 h after DDAVP administration, classified as complete (CR; FVIII:C > 0.50 IU/mL), partial (PR; FVIII:C 0.30–0.50 IU/mL) or no response (NR; FVIII:C > 0.30 IU/mL). Data were analyzed by univariate/multivariate analyses (adjusted for age, CR in family members, bFVIII:C, Body Mass Index) or Chi-Square test where appropriate.

Results: Data on the first 311 patients are presented. Median age was 31 years (IQR 1746) and median bFVIII:C and bVWF:Ag levels were 0.16 IU/mL (IQR 0.11–0.24) and 0.97 IU/mL (IQR 78122) respectively. The majority ($n = 260$; 84%) of patients received intravenous administration of DDAVP (0.3 μg/kg). *F8* genotype, known in 233 patients (75%), displayed 67 different missense mutations. Most prevalent were Arg593Cys ($n = 74$), Asn618Ser ($n = 20$) and Arg2150His ($n = 11$).

CR was observed in 200 patients (64%) and associated with bFVIII:C level (adjusted relative risk for 0.01 IU/mL rise in bFVIII:C (aRR) 1.2; 95% CI 1.081.43) and CR in family members (aRR 16.05; CI 3.867.1). CR was achieved in 33% ($n = 1$) with bFVIII:C level > 0.05 IU/mL, in 26% ($n = 13$) with bFVIII:C level 0.05–0.09 IU/mL, in 43% ($n = 33$) with bFVIII:C level 0.1–0.14 IU/mL and in 85% ($n = 153$) with bFVIII:C level ≥ 0.15 IU/mL. CR in family members was present in 75 of the 122 patients (62%).

Differences in the proportion of patients achieving CR in the three most prevalent mutations were observed. The best response was observed for Asn618Ser (median bFVIII:C = 0.24 IU/mL; IQR 0.170.32): 95% achieved CR. CR was present in 66% of the Arg593Cys patients (median bFVIII:C = 0.16 IU/mL; IQR 0.12–0.21). Patients with Arg2150His (median bFVIII:C = 0.08 IU/mL; IQR 0.06–0.09) had a significantly lower response than the rest of the population ($P > 0.043$): only 36% achieved CR, possibly explained by the FVIII secretion and VWF binding defect of this mutation.

None of the patients with the following four of the 14 most prevalent mutations achieved CR: Pro130Arg, Gly1960Val, Trp2229Cys and Pro2300Leu (median bFVIII:C = 0.07 IU/mL; IQR 0.06–0.10). Structural defects of FVIII are likely present in Gly1960Val and Trp2229Cys. Pro2300Leu causes a FVIII secretion and VWF binding defect. The defect caused by Pro130Arg is still unclear.

Conclusion: The response to DDAVP is associated with FVIII mutation, baseline FVIII:C levels and the response in family members.

OC 67 – Coagulation Factor XIII

OC 67.1

Major roles for FXIII-A and transglutaminase 2 in maintaining cardiovascular tissue integrity

Pease RJ[1], Newell LM[2], Standeven KF[1], Grant PJ[1] and Jackson CL[2]

[1]University of Leeds, Leeds; [2]University of Bristol, Bristol, UK

Introduction: In addition to its key role in cross-linking fibrin to stabilize blood clots, factor FXIII-A may be involved in tissue repair. This function is also undertaken by the closely homologous enzyme, transglutaminase 2 (TG2). TG2 is widely expressed while FXIII-A is expressed in cells of the megakaryocyte, monocyte and chondrocyte lineages. Both enzymes are expressed in cardiac tissue and arterial wall. Besides tissue repair, FXIII-A and TG2 have been suggested to play overlapping roles in pathways that are essential for normal development, including bone deposition and macrophage function.

Aim: To determine the roles of these transglutaminases in cardiovascular repair by breeding mice deficient in one or both enzymes upon an apoE negative background.

Methods: Basal expression of mRNA levels in tissues from saline-perfused mice ($n = 10$ per genotype) was assessed in animals at 8–10 weeks. Starting at 6–8 weeks, male mice ($n = 30$ per genotype) were fed a rodent diet containing 21% lard and 0.15% cholesterol for 12 weeks. Female mice at 6–8 weeks ($n = 12$ per genotype) were subjected to left carotid artery ligation or to sham ligation for a period of 28 days. At termination, fat-fed and ligated mice were perfusion fixed with buffered formalin.

Results: Mice of all genotypes, including apoE/FXIII-A/TG2 triple knockout mice, displayed normal skeletal development as assessed by dual energy X-ray absorption measurements. No compensatory induction of mRNA encoding other transglutaminases was observed in the hearts, spleens, bones or livers of transglutaminase knockout mice. Increased expression of mRNAs encoding haeme oxygenase and CD163 was observed in the hearts of apoE/FXIII-A/TG2 triple

knockout mice, suggesting an influx of macrophages. Upon fat feeding, there was no difference between genotypes in plaque area in the aortic sinus or in buried fibrous caps per unit plaque area in the brachiocephalic artery, the latter being an index of plaque rupture. However extensive cardiac fibrosis (averaging 17% of ventricular volume) was observed in the hearts of 20/28 surviving apoE/FXIII-A/TG2 triple knockout mice, while milder fibrosis (4% of ventricular volume) was detected in 3/30 apoE/FXIII-A double knockout mice, but not in mice of other genotypes, ($P > 0.0001$). Fibrosis appeared to be secondary to extravasation of blood. Carotid ligation led to frequent arterial rupture (6/12 by 10 days) in apoE/FXIII-A/TG2 triple knockout mice, but not in mice of other genotypes, ($P = 0.004$). Although frequent elastic lamellar breakages and vessel dilation occurred in apoE/TG2 double knockout mice, these lesions did not progress to rupture.

Conclusions: Neither FXIII-A nor transglutaminase 2 protects against atherosclerotic plaque expansion and rupture in a mouse atherosclerosis model. However both transglutaminases maintain the integrity of the cardiac microvasculature against leakage and protect the arterial wall against mechanical damage.

OC 67.2

Functional characteristics of coated platelets

Mattheij N[1], Berny-Lang MA[2], Van De Vijver P[1], Hackeng TM[1], McCarty OJT[3], Cosemans JMEM[1] and Heemskerk JWM[1]

[1]Maastricht University, Maastricht, the Netherlands; [2]Harvard Medical School, Boston, MA; [3]Oregon Health and Science University, Portland, OR, USA

Introduction: Collagen and thrombin stimulate platelets into a population known as 'coated' platelets, which have been characterized in three distinct ways: (i) irreversible binding of factor V, fibrinogen and other proteins via transglutaminase-mediated cross-linking; (ii) high $\alpha_{IIb}\beta_3$-independent binding of fibrinogen; (iii) surface exposure of phosphatidylserine (PS). Functional studies suggest roles for coated platelets in the local assembly of α-granular proteins and in the stimulation of thrombin generation. However, it is unclear how 'coated' platelets differentiate from 'procoagulant', PS-exposing platelets formed under different conditions.

Aim: Investigate the functional characteristics of 'coated' and 'procoagulant' platelets.

Methods: Washed human platelets in $CaCl_2$-containing buffer were stimulated with combinations of thrombin, PAR1/PAR4 peptides, convulxin (collagen receptor agonist) or ionomycin (Ca^{2+} ionophore). Platelets in partially fibrinogen-depleted plasma were triggered with tissue factor plus $CaCl_2$. Subpopulations of activated platelets were identified by dual-color flow cytometry, using labeled fibrinogen, coagulation factors and a fluorescently labeled transglutaminase-dependent probe, A14 α2-antiplasmin (A14-αAP). Thrombin generation was measured using the calibrated automated thrombogram (CAT) assay.

Results: Stimulation with convulxin/thrombin resulted in a platelet population binding annexin A5, factor Va and factor Xa. These platelets persistently showed high fibrinogen binding (the level of which increased with concentration of thrombin), but gradually decreased PAC1 mAb binding, indicating inactivation of $\alpha_{IIb}\beta_3$. The same platelets stained positively for fibrin with an anti-fibrin mAb, and readily incorporated A14-αAP via transglutaminase activity, as indicated by specific inhibition of either factor XIIIa or tissue-type transglutaminase. Platelet stimulation in plasma with tissue factor/$CaCl_2$ resulted in a large platelet population with the same characteristics. Formation of these platelets correlated with the extent of thrombin generation. Addition of factor XIII increased fibrinogen binding to these platelets, but was without effect on thrombin generation.

Platelet stimulation with the Ca^{2+}-elevating agonists, convulxin/PAR1 peptide, convulxin/PAR4 peptide or ionomycin provoked high binding of annexin A5 and coagulation factors. These agonists again enhanced thrombin generation, but did not produce high fibrinogen binding, fibrin staining or A14-αAP incorporation. Finally, platelet stimulation with convulxin or thrombin alone resulted in minimal binding of annexin A5, low binding of fibrinogen and PAC1 mAb, and no binding of coagulation factors nor A14-αAP.

Summary/Conclusion: These findings indicate that A14-αAP, incorporated via factor XIIIa and tissue-type transglutaminase, specifically detects platelets with high fibrinogen binding and fibrin staining, which are generated by collagen/thrombin co-stimulation. By implication, 'coated' platelets should be considered as platelets with a fibrin coat, collecting multiple functional proteins. These platelets are highly active in supporting thrombin generation.

OC 67.3

Pharmacokinetics of recombinant FXIII at steady-state in patients with congenital FXIII A-subunit deficiency

Kerlin B[1], Brand B[2], Inbal A[3], Halimeh S[4], Nugent D[5], Lundblad M[6] and Tehranchi R[6]

[1]Nationwide Children's Hospital, Columbus, OH, USA; [2]University Hospital Zurich, Zurich, Switzerland; [3]Tel Aviv University, Tel Aviv, Israel; [4]Medical Thrombosis and Haemophilia Treatment Center, Duisburg, Germany; [5]Hematology, CHOC Children's Hospital/UC Irvine Medical School, California, USA; [6]Novo Nordisk A/S, Søborg, Denmark

Background: A comprehensive understanding of the steady state pharmacokinetics (PK) of recombinant FXIII (rFXIII) has been obtained in patients with congenital FXIII A-subunit deficiency, and the haemostatic coverage during long-term prophylaxis is described in detail.

Aims: The objective of this investigation was to obtain and thoroughly describe the PK of rFXIII at steady-state in patients with congenital FXIII A-subunit deficiency, as part of a once monthly prophylaxis dosing schedule.

Methods: Steady-state PK has been investigated in this on-going, multi-centre, multi-national, open-label, single-arm, repeat dose phase 3b, safety and efficacy trial in patients with congenital FXIII A-subunit deficiency. Each patient is participating for at least 52 weeks during which they are receiving monthly (28 ± 2 days) intravenous (i.v.) injections of rFXIII (35 IU/kg).

All patients were offered to participate in the steady-state PK sampling and in total 23 out of 55 patients consented. Blood samples for PK assessments were collected at the following time points: Pre-dose (immediately prior to dosing), 1, 2 h, 3, 7, 14, 21 and 28 days post-dose. The Berichrom® FXIII activity assay was used for measurement of FXIII activity and thus the method used for the primary PK evaluation. The PK parameters were calculated using non-compartmental statistical methods, without prior baseline adjustment. At each PK sampling time point information regarding adverse events and bleeding episodes were collected and additional blood samples for FXIII enzyme linked immunosorbent assay were drawn. Furthermore, antibody assessments were performed pre-dose and and at day 28 post-dose (prior to the subsequent rFXIII administration).

Results: The PK results show a mono-exponential decline in FXIII levels, following first-order elimination with a mean half-life of 13.9 days. The mean FXIII activity levels for the cohort were above 0.1 IU/mL throughout the 28-day PK period, including pre-dose. The mean clearance was 0.15 mL/h/kg, with a C_{max} level of 0.89 IU/mL and mean C_{trough} value of 0.17 IU/mL. From the total of 139 individual activity measurements obtained during the PK session, all but two were above 0.1 IU/mL throughout the entire dosing interval. One of the two low activity levels occurred at day 28, in a patient with a few previous occasions of low activity levels, and the other occurred at day 14 in another patient. The subsequent activity levels in this patient were well above 0.1 IU/mL. Bleeding episodes did not occur in any of the patients during the PK session and no antibodies against rFXIII were detected during the entire trial period. The participating patients had all received at least 10 doses of rFXIII prior to the PK session and C_{max}

and C_{trough} activities were demonstrated to be constant over time when compared to the previously obtained activities in the same patients.
Summary: These data indicate that the clearance of rFXIII is unaffected over time and monthly prophylaxis with 35 IU/kg rFXIII is sufficient to achieve adequate FXIII activities to prevent spontaneous hemorrhage in patients with congenital FXIII A-subunit deficiency.

OC 67.4
Spatial distribution and co-localization of fibrinogen and platelet-derived factor XIIIa on the activated platelet subpopulations

Obydennyy SI, Kotova YN, Ataullakhanov F and Panteleev MA
Center for Theoretical Problems of Pharmacology, Moscow, Russia

Background: Activated platelets include three different subpopulations: (i) uncoated platelets, ameboic-shaped platelet with low intracellular calcium (Ca-), active integrin $\alpha_{IIb}\beta_3$, absence of phosphatidylserine (PS-) and low quantity of fibrin(ogen) on the surface (Ca-/PS-); (ii) coated platelets, balloon-shaped platelets with high intracellular calcium (Ca+), inactive integrin $\alpha_{IIb}\beta_3$, presence of PS and high quantity of fibrinogen on the surface (Ca+/PS+); (iii) recently discovered platelets with low intracellular calcium, active integrin $\alpha_{IIb}\beta_3$, and presence of PS on the surface (Ca-/PS+), with unstudied morphology.
Aims: Our research is aimed to better characterize the third subpopulation and localization of adhesive proteins and factor XIIIa on their surface.
Methods: Washed gel-filtered platelets were activated with 100 nM thrombin and/or CRP at 20 μg/mL. The cells were stained with different fluorescent dyes for identification of the subpopulations (PAC1 for integrin $\alpha_{IIb}\beta_3$ condition and/or Annexin V for PS presence/absence on the surface and/or fura red for intracellular calcium level), with specific antibodies, and then examined with the Zeiss Axio Observer Z1 confocal microscope on the surface covered with fibrinogen or collagen in order to see the morphology for alive and fixed subpopulations. In addition, all samples were analysed using Accuri C6 flow cytometer.
Results: The images showed both adherent Ca-/PS+ and Ca-/PS- cells with filopodia. The experiment with fixed cells in suspension (before platelet adhesion) demonstrated that Ca-/PS+ and Ca-/PS- also looked alike. The total fibrinogen levels on the coated platelets were increased, while those of factor XIIIa were not. However, both fibrinogen and factor XIIIa on the surface of the coated platelets were co-localized and concentrated on a single spot instead of a uniform distribution. Every coated platelet had only one such spot, and its size was several-fold smaller than the full size of the cell. Both CRP and thrombin induced the spot formation, although thrombin was required to obtain high total fibrinogen coating. The concentration of PS was higher in the spot than in other parts of the cell. In every case of aggregate formation involving Ca-/PS- with Ca+/PS+ platelets, they demonstrated location of the spot in the area of cells' contact. The 3D reconstruction of a typical coated platelet with the fibrin(ogen) spot and of the platelet aggregate were obtained.
Conclusions: The main aggregation mediator fibrinogen is co-localized with the major crosslinking enzyme factor XIII in a small area of the balloon-shaped Ca+/PS+ platelet surface, where it mediates aggregation of the coated platelets. The Ca-/PS+ and Ca-/PS- cells are similar in their morphology suspension and on the surface.
The study was supported by the Russian Foundation for Basic Research grants 12-04-31401, 12-04-31788, 12-04-32246, 12-04-31873, 12-04-33055.

OC 68 – Coagulation Factor: Structure and Function

OC 68.1
Molecular and structural determinants of high affinity membrane binding in coagulation factor V

Kumar S[1], Stayrook S[2], Huntigton JA[3], Camire RM[1] and Krishnaswamy S[1]
[1]Children's Hospital of Philadelphia; [2]University of Pennsylvania, Philadelphia, PA, USA; [3]Cambridge University, Cambridge, UK

In mammalian coagulation, high affinity membrane binding of factor Va is vital for facilitating the assembly of prothrombinase and the enhanced formation of thrombin at the site of vascular damage. In contrast, the venom of Pseudonaja textilis contains a non-hemostatic, constitutively active factor Va-like protein (V_{Ptex}) which can tightly bind to a factor Xa-like venom protein in a membrane independent fashion. Membrane-independent thrombin formation by this complex may lead to disseminated and consumptive coagulopathy after envenomation. V_{Ptex} shares high sequence identity (53%) to human factor V (hV) and has a common A1-A2-B-A3-C1-C2 domain organization. Our high-resolution (1.95 Å) x-ray structure of recombinant V_{Ptex} closely mimics those seen at a lower resolution for inactivated bovine factor Va lacking the A2 domain and full length B-domainless human factor VIII (hVIII). Surprisingly, despite having all the critical membrane binding structures in the C-domains, V_{Ptex} showed negligible binding to membranes with an estimated 10^3-fold weaker affinity than that of hV. Expecting that this non-hemostatic feature was unlikely to be replicated in FV from the plasma of the snake, we compared the C-domain sequences of the two different forms of FV and found nine differences (5 in C1 and 4 in C2-domains) that were closely spaced in the crystal structure. Substitution of these residues in V_{Ptex} yielded a derivative (V_{Ptex}C1C2) that bound to membranes with high affinity in a manner equivalent to hFV. The newly acquired function of membrane binding in V_{Ptex}C1C2 does not affect its ability to function in solution, suggesting that membrane binding and solution-phase function are controlled independently. Surprisingly, the individual C-domain mutants (V_{Ptex}C1 and V_{Ptex}C2) also retained significant membrane binding ability. However, we observed a lack of additivity of the binding energy contributions from the individual C-domains in V_{Ptex}C1C2. The large energetic loss (−8.7 Kcal/mole) implies that a significant conformational rearrangement accompanies membrane binding. This corroborates well with the higher thermal factor observed in the C-domains of structures of V_{Ptex}C1C2 and V_{Ptex}C2 as compared to V_{Ptex}, suggesting that disorder in these domains is intrinsic to membrane binding. This is also supported by the fact that in stopped-flow light scattering studies V_{Ptex} showed an association rate constant identical to hV and V_{Ptex}C1C2. This suggests that the membrane binding defect in V_{Ptex} lies in a faster dissociation rate of the protein-membrane complex. This is also in line with the finding that substitution of Leu for Pro_{2070} in V_{Ptex}C1C2 completely abolished membrane binding. Pro_{2070}, a key residue in C2-domain was found to be mutated to Leu in Paul Owren's original patient that caused severe clotting deficiency and several episodes of unexplained bleeding. Close proximity of $Pro_{2070}$to some of the residues introduced in V_{Ptex}C1C2 explains why individual mutations in this area have severe consequences for membrane binding. Our findings provide new structural and functional insights into how high affinity membrane binding is achieved by coagulation factor V.

OC 68.2

Cleavage of factor V by thrombin at Arg709 is dependent on the integrity of amino acid region 1000–1008 of the procofactor

Na M, Wiencek JR and Kalafatis M

Cleveland State University, Cleveland, OH, USA

Background: The desirable process of hemostasis is the direct consequence of the generation of thrombin by the prothrombinase complex. Prothrombinase is a stoichiometric complex between factor Va (fVa) and factor Xa (fXa) assembled on a procoagulant membrane surface in the presence of divalent metal ions. Factor V (fV) is a multi-domain procofactor with minimal procoagulant activity. Upon activation by thrombin following three sequential cleavages at Arg^{709}, Arg^{1018}, and Arg^{1545} the resulting fVa molecule has maximum procoagulant activity resulting in the tight interaction with the members of prothrombinase. It has been well established that cleavages at Arg^{709} and Arg^{1545} are required for proper activation and optimum cofactor function. However, it is not clear which activating cleavage site has the maximum destabilizing effect on the procofactor and what regions of the B domain are required for proper thrombin cleavage. We have shown that amino acid region 1000–1008 from the B domain is a regulatory sequence needed to keep fV in a quiescent state.

Aim: To study the effect of region 1000–1008 from the B domain on thrombin cleavage at Arg^{709}/Arg^{1545} and subsequent heavy and light chain formation.

Methods: We generated full length recombinant fV mutant molecules by deleting the highly conserved region 1000–1008 (ΔB9) and by mutating one or two of the activating cleavage sites from arginine to glutamine. We have generated recombinant factor V molecules as follows: $fV^{\Delta B9/QQR}$ (only cleavage at Arg^{1545} available with region 1000–1008 deleted), fV^{QQR} (only cleavage at Arg^{1545} available), $fV^{\Delta B9/RRQ}$ (cleavages at Arg^{709} and Arg^{1018} available with region 1000–1008 deleted), fV^{RRQ} (cleavages at Arg^{709} and Arg^{1018} available). The recombinant fV proteins were expressed transiently in mammalian COS-7 cells and purified to homogeneity. The functional activity of the recombinant mutants was assessed by clotting assay and by prothrombinase assays using a chromogenic substrate to assess for thrombin formation. The appearance of the heavy and light chain of fV following incubation with thrombin was visualized following SDS-PAGE and staining with silver. In some experiments the fV fragments were also visualized by immunoblotting with specific monoclonal antibodies to fV.

Results: Clotting assays revealed that recombinant molecules $fV^{\Delta B9/QQR}$ and $fV^{\Delta B9/RRQ}$ have clotting similar to fVa^{WT} before and after activation with thrombin. SDS-PAGE demonstrates that while thrombin activation of fV^{RRQ} resulted in the appearance of the heavy chain only, $fV^{\Delta B9/RRQ}$ shows resistance to thrombin and no heavy chain formation. In contrast, SDS-PAGE demonstrates that thrombin activation of both fV^{QQR} and $fV^{\Delta B9/QQR}$ resulted in the appearance of the light chain. Kinetic analyses revealed that the K_D of $fVa^{\Delta B9/QQR}$ for fXa is ~0.5 nM which is similar to that of fVa^{PLASMA}. Finally, while prothrombinase assembled with fVa^{RRQ} and fVa^{QQR} have values similar to the k_{cat} of prothrombinase assembled with fVa^{WT}, the k_{cat} values for prothrombinase assembled either $fVa^{\Delta B9/QQR}$ or $fVa^{\Delta B9/RRQ}$ were decreased by approximately fivefold.

Conclusion: Our data clearly shows that amino acid region 1000–1008 from the B domain is required for thrombin cleavage at Arg^{709}. Any defects in this regulatory region from the B domain will result in defective fV activation.

OC 68.3

Design of a potent phospholipid membrane-dependent Factor VIIa variant

Nielsen AL[1], Ruf W[2], Holmberg HL[1], Buchardt J[1], Sørensen B[1], Olsen OH[1] and Østergaard H[1]

[1]Novo Nordisk A/S, Måløv, Denmark; [2]Scripps Research Institute, La Jolla, CA, USA

Background: Association of FVIIa with its cellular receptor tissue factor (TF) renders it biologically active and capable of inducing coagulation. TF functions by facilitating the conformational transition of FVIIa into an active protease and further provides an extended recognition interface for the macromolecular substrates FIX and FX. Both features are recapitulated by the soluble ectodomain of TF (sTF) and were exploited in the design of a novel procoagulant molecule by covalent coupling of FVIIa to sTF through an engineered interface-spanning disulfide. In the absence or presence of phospholipid membranes, this molecule (7TF) activates FX with rates two and four orders of magnitude greater, respectively, than wild-type FVIIa and demonstrates superior potency in human FVIII depleted whole blood.

Aim: In an attempt to further localize the activity of 7TF to the membrane surface, the M306D substitution [1] was introduced in order to abrogate the allosteric communication between sTF and FVIIa, while preserving the contribution from exosites. This approach was based on the hypothesis that the membrane independent activity of the FVIIa-sTF complex predominantly originates from the conformational activation of FVIIa. The aim of the current study was to characterize the functional properties of 7TF-M306D *in vitro* and its haemostatic effect *in vivo*.

Methods: The complex was characterized using standard chromogenic amidolytic and proteolytic assays [1]. Subsequently, the effect of the complex in FVIII-deficient human and murine whole blood triggered by kaolin was evaluated by thromboelastography, while the *in vivo* haemostatic effect was assessed in the tail-clip model in FVIII−/− mice [2].

Results: The disulfide-linked complex was isolated from conditioned medium, following co-expression of FVIIa Q64C/M306D and sTF G109C in BHK cells. Unlike 7TF and FVIIa saturated with sTF, the 7TF-M306D complex was susceptible to chemical modification of I16 and bound the conformation specific antibody F3-3.2a [3], indicating that the protease domain retained zymogen-like features resembling those of free FVIIa. This was supported by measured amidolytic- and proteolytic activities in solution which were a modest two- and nine-fold higher than FVIIa, respectively. In striking contrast, 7TF-M306D retained high activity in the presence of phospholipid membranes where the rate of FX activation was 2400-fold faster than free FVIIa. The membrane-dependent activity of 7TF-M306D also translated into improved haemostatic function in more physiological systems, where potency estimates in FVIII-deficient human and murine whole blood as well as in the tail-clip model in FVIII−/− mice were consistently about 100-fold higher than wild-type FVIIa.

Conclusions: FVIIa variants with enhanced haemostatic activity may provide superior therapeutic options in the treatment of people with inhibitor-complicated haemophilia as suggested by clinical studies [4]. The present study outlines a novel approach for increasing the activity of FVIIa in a membrane-localized manner by selectively optimizing substrate recognition on the membrane surface through conjugation to the ectodomain of its natural cofactor.

OC 68.4

A novel chimeric Factor IX-VIIa molecule confers effective hemostasis with reduced thrombogenicity *in vivo*

Feng D[1], Boulaftali Y[2], Bergmeier W[1] and Stafford D[1]
[1]*Univeristy of North Carolina Chapel Hill, Chapel Hill;* [2]*McAllister Heart Institute, University of North Carolina at Chapel Hill, Chapel Hill*

Recombinant human activated Factor VII (rFVIIa) has been used for many years as a pro-hemostatic agent in hemophilia patients with inhibitory antibodies. Recently, its off label use has been expanded to the treatment of traumatic bleeding and intracerebral hemorrhage. The pro-hemostatic properties of rFVIIa have some thrombotic risk associated with its use. In animal studies, early mortality attributable to thrombosis was observed in transgenic mice expressing high levels of FVIIa. At pharmacologic doses, rFVIIa can directly activate factor X on the surface of activated platelets, resulting in a thrombin burst and acceleration of coagulation. But there is controversy about whether the dominant effect of high dose rFVIIa is TF dependent or independent. Our goal was to determine if rFVIIa as used therapeutically requires TF for its action and to generate rFVIIa with reduced thrombogenicity for the treatment of bleeding disorders especially under clinical conditions where tissue factor (TF) is exposed. We hypothesized that if the phospholipid dependent mechanism is dominant, then a FVIIa variant with much reduced affinity for TF would be as active but less thrombogenic as rFVIIa. To test our hypothesis, we generated a murine chimeric FIX-FVIIa molecule containing the Gla and EGF1 domains of FIX, which have low affinity to TF. Using purified recombinant proteins, we showed that the binding affinity of this chimeric FIX-FVIIa molecule for either human or mouse TF was reduced to unmeasurable levels while its hemostatic activity was retained. In hemophilia B mice, purified chimeric FIX-FVIIa stopped saphenous vein bleeding as well as FVIIa indicating that the activity of recombinant FVIIa is independent of TF. Importantly, rFVIIa, but not chimeric FIX-FVIIa, worsened thromboplastin-induced pulmonary thromboembolism in mice. Our results strongly suggest that TF does not contribute to the activity of rFVIIa when it is used for treating trauma or hemophilia patients with inhibitors. Our results also suggest that this chimeric FIX-FVIIa molecule may be less thrombogenic than the currently available rFVIIa.

OC 69.1

Histones and DNA infusion in baboons induces inflammation, coagulopathy and complement activation leading to organ failure and death

Lupu F[1], Silasi-Mansat R[1], Xu J[1], Keshari RS[1], Peer G[2], Taylor B[1], Lupu C[1], Kinasewitz GT[2] and Esmon CT[1]
[1]*Oklahoma Medical Research Foundation;* [2]*Oklahoma University Health Sciences Center, Oklahoma City, OK, USA*

Background: Our group has shown that nucleic material (histones and DNA) are released in the extracellular environment in response to inflammatory challenges and are important mediators of sepsis-induced organ failure and death in small animal models (Nat Med. 2009 Nov;15(11):1318–21).
Aims: To characterize the effects of histones and histones-DNA complexes on the inflammatory and coagulopathic responses and organ function in baboons.
Methods: Baboons were infused with histones, or histones-DNA complexes as either single bolus, continuous single-dose or step-increase infusions. Vital signs were monitored and blood and tissue samples were analyzed for biomarkers of inflammation, coagulation, complement activation and organ function.
Results: Histone and histone-DNA infusion resulted in (i) hypotension with tachycardia, tachypnea and hyperthermia; (ii) platelets and coagulation activation, leading to thrombocytopenia, disseminated intravascular coagulation and subsequent consumptive coagulopathy; (iii) leucopenia and production of inflammatory cytokines; and (iv) complement activation. These responses lead to: (i) increased vascular permeability and hemoconcentration, intra-alveolar hemorrhage, and fibrin deposition, interstitial edema and hypoxia, all suggestive of acute respiratory distress syndrome; (ii) liver dysfunction, as shown by increased transaminases; (iii) renal failure, as shown by increased levels of creatinine, BUN, and metabolic acidosis. These changes reflected progressive multiple organ failure that ultimately was fatal.
Infusion of histones alone was more cytotoxic and coagulopathic than histone-DNA complexes. However, histone-DNA infusion was a more potent inducer of inflammation and complement activation than histones alone. *In vitro* whole blood assays showed that histone-DNA -induced cytokine production is at least in part mediated by C5a -mediated signaling.
Summary/Conclusions: Our data demonstrate that infusion of histones and histones-DNA induces many of the major pathophysiological features of sepsis-induced multiple organ failure.

OC 69.2

Hitting the sweet-spot in sepsis: modulation of histones and CXCL4 (platelet factor 4) effects on activated protein C

Kowalska MA[1], Kowalska MA[1], Zhao G[1], Zhai L[1], Marcus S[2], Krishnaswamy S[3] and Poncz M[1]
[1]*The Children's Hospital of Philadelphia, Philadelphia, PA;* [2]*ParinGenix, inc, Weston, FL;* [3]*University of Pennsylvania, Philadelphia, PA, USA*

Background: Histones release is detrimental in late sepsis and activated protein C (aPC) reduces this effect. Therapeutic interventions in sepsis include modulation of the aPC levels and use of heparin, but with limited success. We and others have shown that generation of aPC by thrombin (IIa) complexed to thrombomodulin (TM) that contains CS sidechains (TM_{CS}) can be accelerated, both *in vitro* and *in vivo*, by positively-charged molecules like platelet-released CXCL4 or infused protamine sulfate (PRT). In murine endotoxic models, platelet CXCL4 levels correlated with improved outcome. CXCL4 affects aPC generation by IIa-TM_{CS} along a bell-shaped curve with peak at a specific optimal 'sweet spot' CXCL4:TM_{CS} molar ratio. Heparin, which binds CXCL4 with greater affinity than TM's CS, effectively reduces available CXCL4, shifting aPC-generation bell-shaped curve to the right.
Aims: Histones are positively-charged small proteins like CXCL4 and PRT. Do histones affect aPC generation by the same mechanism as CXCL4 and PRT? Does the presence of CXCL4 and/or heparin influence histones' effect. Further, can these new insights be used to generate novel therapeutic strategies? We examine whether oxygen-desulfated heparin (ODSH), with its marked decrease in anticoagulant effect compared to heparin, is such a therapy.
Methods: *In vitro*, the rate of aPC formation was measured using varying concentrations of a mixture of all four histones in the presence of IIa and soluble (s) TM_{CS} either in the absence or presence of CXCL4 and heparinoids: unfractionated heparin (UFH) or ODSH. *In vivo*, we measured the effect of intravenously injected histones and/or CXCL4 on plasma aPC levels and activated partial thromboplastin time (aPTT) generation in mice in the presence or absence of low-dose IIa and/or pre-injected UFH or ODSH.
Results: *In vitro*, histones enhance aPC generation by IIa in the presence of sTM_{CS} additively with CXCL4 with a peak enhancement of 3–5-fold. This bell-shaped enhancement was shifted rightward by hepari-

noids. Similar outcomes were seen in *in vivo* aPC generation studies in CXCL4 null mice infused with histones ± CXCL4 ± heparinoids. In high-dose histone injection studies, both UFH and ODSH are effective at decreasing lethality, but only mice treated with ODSH demonstrated corrected aPTT and return of measureable levels of aPC. Generation of aPC and lethality correlated in this histone injection model when different doses of ODSH were infused.

Summary/Conclusions: Histones and CXCL4 are both released in sepsis. At low total levels, they enhance aPC generation. At high levels, they inhibit aPC generation. Neutralization of excess histones/CXCL4 seen in late sepsis by heparin or ODSH may shift aPC generation back towards the 'sweet spot' of optimal aPC generation. However, heparin effects are compromised by its anticoagulant properties, especially the high levels needed in late sepsis, so the decreased anticoagulant effects of ODSH may allow better dose targeting to optimize aPC generation. These studies provide new insights into the complex interactions controlling aPC generation, and the potential benefit of hitting the 'sweet-spot' in sepsis by monitoring both aPC and aPTT levels concurrent with ODSH therapy to improve outcome of this life-threatening disorder.

OC 69.3

Assay method of des-HMGB1, *N*-terminus cleaved out HMGB1 by thrombin-thrombomodulin, and its clinical significance

Maruyama I[1], Ito T[1], Azuma Y[2], Nakahara M[1], Hashiguchi T[1] and Yamada S[2]

[1]Kagoshima University Graduate School of Medical and Dental Sciences, Kagoshima; [2]Shino-Test Co., Tokyo, Japan

Background: HMGB1 is an intranuclear DNA binding protein with crucial role in the accomplishment of DNA's functions including transcription. However, the protein is released to the extracellular space when cells become necrotic. Extracellular HMGB1 acts as a proinflammatory and procoagulant mediator through receptor for advanced glycation endproducts (RAGE) and Toll-like receptors (TLR)-2 and -4. Thus, HMGB1 plays an important role in the pathogenesis of DIC, endotoxin shock and multiple-organ failure. We previously developed specific ELISA for HMGB1. We showed that the protein was increased in the plasma from patients with DIC, sepsis and shock and plasma HMGB1 levels and DIC-scores were correlated. We also described that *N*-terminus of thrombomodulin (TM) bound HMGB1 and abolished its proinflammatory and procoagulant functions. Moreover, we identified that HMGB1 was cleaved by thrombin-TM complex at Arg10-Gly11 site, generating HMGB1 lacking *N*-terminal 10 amino acid residues, tentatively named *des*-HMGB1. However the dynamism and functional fate of this *des*-HMGB1 is obscure.

Aims: We established sensitive ELISA methods for HMGB1 and *des*-HMGB1, and investigated the dynamism and pathophysiological significance of these two forms of HMGB1. Then we analyzed prognostic value of HMGB1 and *des*-HMGB1 in the plasma from patients with sepsis, DIC and shock with or without recombinant TM therapy.

Methods and Results: We immunized mice with intact HMGB1 or *des*-HMGB1, and successfully obtained specific monoclonal antibodies against HMGB1 or *des*-HMGB1. Using these monoclonal antibodies, we developed ELISA kits for detection of HMGB1 and *des*-HMGB1 which detected as low as 0.3–1 ng/mL of HMGB1 and 2–3 ng/mL of *des*-HMGB1, respectively. HMGB1 was not detected in the plasma from healthy volunteers whereas it was significantly high in the plasma from patients with DIC, sepsis and shock. *Des*-HMGB1 was increased in some samples from patients with recombinant TM therapy, suggesting that the *des*-HMGB1might be generated by the treatment.

Conclusion: TM may have important roles for intravascular homeostasis through not only converting thrombin from a procoagulant protease to an anticoagulant but also dampening the proinflammatory activity of HMGB1. Thus assessments of HMGB1 and *des*-HMGB1 provide important information in the stage and severity of DIC, shock, and systemic inflammations, and responsiveness for treatments.

OC 69.4

Consumptive coagulopathy and tissue fibrin deposition in seasonal-, pandemic- and highly pathogenic avian influenza infection

Goeijenbier M[1], Van Den Brand JMA[1], Stittelaar K[2], Van Haagen C[2], Bakhtiari K[3], Kuiken T[1], Osterhaus ADME[1], Martina BE[1], Meijers JC[4] and Van Gorp ECM[1]

[1]ErasmusMc; [2]Viroclinics, Rotterdam; [3]Amsterdams Medisch Centrum, Amsterdam; [4]Academic Medical Center Amsterdam, Amsterdam, the Netherlands

Background: Epidemiological studies relate influenza infection with vascular diseases like myocardial infarction. The hypothesis that influenza infection has procoagulant effects on humans has been investigated by experimental animal models. However, these studies often made use of animal models only susceptible to adapted influenza viruses (mouse adapted influenza strains) or remained inconclusive. Therefore we sought to measure the interaction of influenza infection with hemostasis by investigating circulating markers of coagulation and tissue staining for fibrin. We choose a controlled setting with a ferret model susceptible for seasonal, pandemic and avian influenza viruses with comparable infection kinetics and clinical signs and symptoms as seen in humans.

Aims: To study and compare the effects on blood coagulation in a setting controlled for virological parameters in a well established ferret influenza model.

Methods: Ferrets were inoculated with either a mock (non-infected cell suspension), H3N2 (seasonal flu), H1N1 (pandemic flu) or H5N1 (avian flu). In a 14 day interval (only 4 days in H5N1) with in total seven timepoints, four animals were euthanized per timepoint and citrated plasma was tested for the prothrombin time (PT), activated partial thromboplastin time (aPTT), Von Willebrand factor activity (VWF), thrombin-antithrombin complex levels (TAT) and D-dimer. Lung tissue was used for fibrin staining (Lendrum staining).

Results: All influenza infected animals showed significant alterations in hemostasis parameters. More specifically on day 4 post infection a 4 s rise in both PT and aPTT was seen in all three influenza variants ($P > 0.05$). D-Dimer concentrations were increased in all three influenza groups ($P > 0.005$) with the highest concentrations in the pandemic influenza group. VWF levels increased early in the infection suggesting endothelial cell activation. VWF activity correlated with the virulence of the different influenza viruses, with the highest increase in the highly pathogenic avian influenza infected ferrets. Mean TAT levels were significantly raised in both pandemic and avian influenza infected ferrets from time point day 0.5 until day 4. Fibrin staining showed capillary fibrin deposits especially in H5N1 infected ferrets.

Discussion: To our knowledge this is the first study that visualized hemostatic alterations in influenza virus infection in a controlled animal model resembling human disease. The drastic changes seen in a very short time period might be the result of consumptive coagulopathy. Interestingly even in the seasonal influenza group, with only relatively mild clinical 'flu' symptoms, infection had significant effects on systemic hemostasis. These results might help in further understanding the role of influenza infection in acute cardiovascular disease, while future research could indicate if alterations in coagulation have an important role in influenza pathogenesis.

OC 70 – Haemophilia B

OC 70.1

B-LONG: results from a Phase 3 study of safety, efficacy, and pharmacokinetics of long-lasting recombinant factor IX Fc Fusion Protein (rFIXFc)

Powell J[1], Ozelo MC[2], Pasi J[3], Ragni M[4], Valentino LA[5], Mahlangu J[6], Manco-Johnson M[7], Josephson N[8], Perry D[9] and Pierce GF[10]

[1]University of California at Davis, Davis, CA, USA; [2]INCT do Sangue Hemocentro UNICAMP, Campinas, Brazil; [3]Barts and the London Comp Care Center, London, USA; [4]University of Pittsburgh and the Hemophilia Center of Western Pennsylvania, Pittsburgh, PA; [5]Rush University Medical Center, Chicago, IL, USA; [6]Haemophilia Comprehensive Care Centre, Johannesburg, South Africa; [7]The Children's Hospital, University of Colorado, Aurora, CO, USA; [8]Puget Sound Blood Center, Seattle, WA, USA; [9]Addenbrooks Hospital, Cambridge, UK; [10]Biogen Idec, Weston, MA, USA

Background: Optimal treatment for haemophilia B is prophylaxis, with intravenous injections of factor IX (FIX) required up to 3 times/week. The burden of frequent injections may reduce patient adherence, leading to greater morbidity. To reduce injection frequency, a long-lasting recombinant FIX Fc fusion protein (rFIXFc) consisting of one rFIX molecule covalently linked to the Fc domain of immunoglobulin G_1 (IgG_1) was engineered. Fc fusion is an established technology that utilises the endogenous IgG cycling pathway to prolong the half-life of therapeutic proteins.

Aim: This phase 3 study evaluated safety, efficacy, and PK of rFIXFc for prophylaxis, to treat acute bleeds, and to maintain perioperative haemostasis in previously treated patients (PTPs) with severe haemophilia B (≤ 2 IU/dL [2%] endogenous FIX).

Methods: Male subjects (≥ 12 years old) with severe haemophilia B, no history of FIX inhibitors, and ≥ 100 exposure days (ED) to FIX, were enrolled in one of four treatment arms: Arm 1, weekly prophylaxis (starting at 50 IU/kg; PK-driven dose adjustments); Arm 2, individualised interval prophylaxis (100 IU/kg starting at every 10 days; PK-driven dosing interval adjustments); Arm 3, episodic (on-demand) treatment (20–100 IU/kg); and Arm 4, perioperative management. A sequential PK subgroup in Arm 1 compared the PK profiles of rFIXFc with rFIX (BeneFIX®). Study duration was ~72 weeks. The primary efficacy endpoint was annualised bleeding rate (ABR), comparing Arms 1 and 2 with Arm 3. Prophylaxis dose and interval, number of injections required for resolution of bleeding episodes, and perioperative haemostasis were also evaluated. Safety endpoints included inhibitor development and adverse events (AEs).

Results: One hundred and twenty-three subjects were enrolled at 50 centres. 93.5% completed the study. Geometric mean half-life (95% CI) was 82.1 (71.4–94.5) h for rFIXFc vs. 33.8 (29.1–39.2) h for rFIX. The PK of rFIXFc was stable over repeated dosing. Geometric mean time to 1% FIX trough (after a 50 IU/kg dose) was 11.2 days for rFIXFc. Additionally, area under the concentration curve, geometric mean residence time, and time to 3% FIX activity were significantly increased with a decrease in clearance for rFIXFc vs. rFIX, $P > 0.001$. Median ABR in Arms 1 and 2 was 2.95 and 1.38, respectively, vs. 17.69 for Arm 3. The dosing interval for subjects in Arm 2 increased from the initial 10 days to 53.8% of subjects achieving an average dosing interval of ≥ 14 days during the last 3 months on the study. Across Arms 1–3, 90.4% of all bleeds were controlled with one injection and > 97% of all bleeds were resolved with ≤ 2 injections. Haemostasis was rated as excellent/good in all major surgeries performed on study. No inhibitors were detected. One serious AE (obstructive uropathy) was assessed by the investigator as possibly related to treatment; the event resolved and the subject continued rFIXFc treatment in the study.

Summary/Conclusions: rFIXFc was well-tolerated with significantly improved PK relative to the currently-marketed rFIX. These data demonstrate that rFIXFc may improve management of acute bleeds and lengthen dosing intervals in prophylactic regimens for persons with severe haemophilia B, thereby potentially improving patient adherence and outcomes.

OC 70.2

Efficacy, PK and safety results of a Phase I/II clinical study of recombinant fusion protein linking coagulation factor IX with albumin (rIX-FP) in previously treated patients with hemophilia B

Martinowitz U[1], Lubetsky A[1], Santagostino E[2], Jotov G[3], Brutman-Barazani T[1], Voigt C[4], Moises T[5], Jacobs I[4] and Lissitchkov T[3]

[1]The Israeli National Hemophilia Center, Chaim Sheba Medical Center, Tel Hashomer, Israel; [2]IRCCS Ospedale Maggiore (Centro emofilia e Trombosi), Milano, Italy; [3]SHAT Joan Pavel, Sofia, Bulgaria; [4]CSL Behring, King of Prussia, PA, USA; [5]CSL Behring GmbH, Marburg, Germany

Background: The standard of care for patients with severe hemophilia B is replacement treatment with Factor IX (FIX) 2–3 times a week. A fusion protein genetically linking recombinant human coagulation FIX with recombinant human albumin (rIX-FP) was developed with the aim to extend the half-life of FIX. In the completed Phase I pharmacokinetic study, the mean half-life of rIX-FP was found to be over five times longer than the subjects' previous FIX. Thus, rIX-FP has potential to prevent bleedings for longer periods, allowing reduction in the frequency of injections compared to standard FIX and to reduce the number of injections required to treat a single bleed.

Aims: This was a Phase I/II open-label, multicenter study of rIX-FP in previously treated patients 12–65 years of age with severe hemophilia B (FIX ≤ 2%). The study evaluated the safety and efficacy of rIX-FP, including prevention of bleeding episodes during weekly prophylaxis of rIX-FP.

Methods: After completion of a 14-day rIX-FP pharmacokinetic assessment, 13 subjects in the prophylaxis arm received weekly prophylaxis of rIX-FP for approximately 11 months, and four subjects in the on-demand arm received rIX-FP upon occurrence of bleeding events. The treatment doses were initially selected based upon the pharmacokinetic profile of rIX-FP and subject's bleeding phenotype, and doses could be adjusted at the Investigator's discretion.

Results: Seventeen subjects were enrolled from hemophilia treatment centers in Israel and Bulgaria; the mean age was 26 years (range 13–46 years). Following a single injection of 25 IU/kg rIX-FP ($n = 13$), the mean FIX activity level was 3.75% and 2.67% above baseline at Day 7 and Day 14, respectively, and the mean half-life of rIX-FP was 95 h (comparable to the previously reported Phase I data).

Over the 11 month treatment period, rIX-FP demonstrated a good safety profile with a total of over 700 EDs. The treatment was well tolerated and no FIX inhibitor formation was observed. There was no AE considered to be related to treatment with rIX-FP. No subject was withdrawn from the study due to safety concerns or lack of hemostatic efficacy.

All 13 prophylaxis subjects were successfully maintained on a weekly routine regimen of rIX-FP for the entire duration of the study, with annualized spontaneous bleeding rates of 1.255 and 1.134 (mean and median respectively). Furthermore, three prophylaxis subjects who received only on-demand treatment prior to study entry had > 80% reduction in the annualized bleeding rate compared to their annualized bleeding rate prior to study entry. All bleeding events were treated successfully with ≤ 2 injections of rIX-FP, with approximately 90% of bleeds treated with a single injection of rIX-FP. The mean weekly consumption of rIX-FP was reduced markedly compared to the subjects' weekly consumption of the previous FIX product.

Conclusion: This Phase I/II study demonstrated the clinical efficacy of rIX-FP for once weekly routine prophylaxis to prevent spontaneous bleeding episodes and for the treatment of bleeding episodes. In addition, rIX-FP showed an excellent safety and an improved PK profile over currently marketed factor IX products.

OC 70.3

Healing defects in both cutaneous and joint wounds are improved by extending factor IX activity during healing using glycoPEGylated factor IX

Monahan PE[1], Sun J[1], Hua B[2], Mickelson J[1], Livingston EW[1], Lau AG[1], Bateman AT[1], Ezban M[3], Hoffman M[4] and Monroe D[1]
[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; [2]Peking Union Medical College Hospital, Beijing, China, China; [3]Novo Nordisk A/S, Måløv, Denmark; [4]Duke University, Durham, NC, USA

Background: Wound healing requires a complex series of interactions between coagulation, inflammation, angiogenesis, cellular migration, and proliferation. We previously demonstrated abnormal wound healing in hemophilia B ($FIX^{-/-}$) mice using an excisional dermal wound model. Restoring normal hemostasis at the time of wounding with a single hemostatic dose of recombinant factor IX (rFIX, *BeneFIX®*, Pfizer) did not normalize healing. Instead, hemostasis was required throughout the healing process. Hemorrhage into joints leading to hemarthropathy is hemophilia's most common complication. Prophylactic clotting factor replacement is the standard of care to prevent hemophilic arthropathy, but requires frequent intravenous dosing. To improve patient adherence and quality of life with this demanding therapy, enhanced pharmacokinetic properties have been achieved via glycopegylation of recombinant factor IX (N9-GP, NovoNordisk).
Aims: We examined whether parallels exist between the defects of wound healing in the cutaneous wound model and the events following hemarthrosis, modeled in $FIX^{-/-}$ mice. We also examined whether extended factor IX activity, achieved using N9-GP, normalizes defects in each wound model.
Methods: In a dose-finding study, a single intravenous dose of 1.5 mg/kg N9-GP (equivalent to ~250 U/kg) following joint hemorrhage provided moderate protection from the development of synovitis and was chosen for subsequent studies. To examine cutaneous wound healing, 3 mm wound was placed on the back of $FIX^{-/-}$ mice or wild-type (WT) mice. Some $FIX^{-/-}$ mice were treated before wounding with N9-GP 250 U/kg I.V.
To examine joint wound healing, unilateral joint hemorrhage was induced in additional $FIX^{-/-}$ or WT mice by needle puncture of the knee joint capsule. Following wounding, $FIX^{-/-}$ mice were treated intravenously with either Normal Saline, with N9-GP 250 U/kg, or with rFIX 250 U/kg. Two weeks following induction of hemarthrosis, joints were collected, the articulating bones evaluated with Micro-Computerized Tomography (MCT), and tissue histology evaluated.
Results: In contrast to a single dose of unmodified rFIX, cutaneous healing of $FIX^{-/-}$ mice was significantly shortened by a single dose of N9-GP, and wound sizes during healing resembled WT.
Hemarthrosis resulted in severe synovitis in untreated hemophilic mice (Valentino synovitis grade 5.9 on scale of 0–10) compared to WT mice (0.87 out of 10). A single 250 U/kg dose of rFIX minimally protected the joint (mean synovitis grade 3.7) compared to 250 U/kg N9-GP (mean synovitis grade 1.8). Histologic parameters of healing, including neoangiogenesis and CD68+ macrophage infiltration/residence, were also improved by N9-GP when compared to unmodified rFIX. Iron deposition was essentially eliminated. Additional rFIX or N9-GP doses at day 7 did not affect parameters examined at day 14. By MCT, a quantitative calculation of the bony degradation at the articular surface demonstrated N9-GP and WT groups to be similar, but significant roughening of boney contours in all other groups.
Conclusion: Parallel observations in the cutaneous and joint injury models demonstrate that wound healing is impaired in hemophilia B mice. Extended factor IX activity from a single dose of N9-GP administered at the time of wounding significantly improves healing rate and histology, compared to an equivalent dose of conventional rFIX.

OC 70.4

Ribosome readthrough accounts for secreted full-length factor IX in hemophilia B patients with nonsense mutations

Campioni M[1], Caruso P[1], Canella A[1], Tagariello G[2], Castaman G[3], Giacomelli S[3], Belvini D[2], Pinotti M[1] and Bernardi F[1]
[1]University of Ferrara, Ferrara; [2]Hospital of Castelfranco Veneto e Montebelluna, Castelfranco Veneto; [3]San Bortolo Hospital, Vicenza, Italy

Background: onsense mutations are frequently associated to severe forms of human disease. The pathologic mechanism consists of premature translation termination, and thus synthesis of truncated proteins, and sometime nonsense-mediated mRNA decay (NMD). With this as background, they are commonly believed as responsible for null genetic conditions.
However, although with low efficiency that depends on the nucleotide sequence context, the ribosome can also readthrough the nonsense triplet, thus accounting for full-length protein biosynthesis. The occurrence of ribosome readthrough over nonsense mutations has never been demonstrated in vivo for secreted proteins with short-half life like coagulation factors.
Aims: To investigate the occurrence of ribosome readthrough over nonsense mutations in coagulation factor IX (FIX), which are frequent cause (20%) of severe hemophilia B (HB).
Methods: Evaluation of FIX mRNA in white blood cells (RT-PCR, sequencing) and of circulating protein in plasma (ELISA, Western Blotting) from HB patients after a wash-out period. Expression of nonsense variants in HEK293 cells and evaluation of secreted recombinant FIX (rFIX) proteins.
Results: We investigated the spontaneous ribosome readthrough over four coagulation F9 nonsense mutations (p.L103*, p.R162*, p.R294*, p.R298*) differing in position and sequence context, which are candidate determinants of ribosome readthrough.
Expression of recombinant factor IX (FIX) in eukaryotic cells demonstrated appreciable levels of secreted FIX molecules for the mutations p.R162* (5 ± 0.3% of rFIX-wt antigen levels), p.R294* (3.1 ± 1.1%) and p.R298* (2.5 ± 0.7%), but not for the p.L103*. Due to the low sensitivity of coagulation assays, we were not able to detect any appreciable FIX coagulant activity in conditioned media. Noticeably, Western Blotting analysis with a specific polyclonal anti-human FIX antibody and a very sensitive chemioluminescent substrate revealed in media a large proportion of truncated molecules, which correlated with small amounts of full-length FIX (rFIX-162*, ~0.5%; rFIX-294* and rFIX-298*, ~0.2%). Interestingly, the efficiency through which the nonsense mutations underwent readthrough (i.e. p.R298* = p.R294* >>>p.L103*) in the proper protein context was roughly consistent with the score (Figure 2A) derived from reporter gene assays.
Investigations in samples from HB patients with the p.L103*, p.R294* and p.R298* revealed that only the p.L103* change, as expected from an early stop codon, was responsible for major NMD. Western blotting in plasma showed a band corresponding to full-length FIX (~60 kD) in PF9298*, and upon film over-exposure, in PF9294*. This band was undetectable in PF9103*'s plasma, which provided us with an internal negative control and validated the specificity of the antibody used. At variance from studies with recombinant variants, the truncated FIX forms were not detected in patients' plasma very likely because of removal from circulation.
Conclusions: For the first time we demonstrated that nonsense mutations can be associated to traces of full-length FIX in hemophiliacs. This unveils a new 'face' of nonsense changes that encourages exten-

sive investigation of ribosome readthrough, and of the underlying residual FIX levels, as additional determinants of bleeding phenotype and of anti-FIX antibody development, the major complication of replacement therapy.

OC 71 – Management of Venous Thrombosis

Clot resolution after 3 weeks of anticoagulant treatment of pulmonary embolism: comparison of computed tomography and perfusion scintigraphy

Van Es J[1], Douma RA[1], Kamphuisen PW[2], Gerdes VEA[1], Verhamme P[3], Wells PS[4], Bounameaux H[5], Lensing AWA[6] and Büller HR[1]

[1]Academic Medical Center, Amsterdam; [2]University Medical Center Groningen, Groningen, the Netherlands; [3]Department of Vascular Medicine and Hemostasis, Leuven, Belgium; [4]University of Ottawa and Ottawa Hospital, Ottawa, ON, Canada; [5]University Hospitals of Geneva, Geneva, Switzerland; [6]BayerHealthCare AG, Wuppertal, Germany

Introduction: Little is known about the natural history of clot resolution in the initial weeks of anticoagulant therapy in patients with acute pulmonary embolism (PE).

Aim: To assess clot resolution of acute PE with either computed tomography pulmonary angiography (CT-scan) or perfusion scintigraphy (Q-scan) after 3 weeks of anticoagulant treatment.

Methods: This was a predefined safety analysis of the Einstein PE study, including PE patients, randomized to either enoxaparin with vitamin K antagonists or rivaroxaban. A similar scan as at baseline was repeated after 3 weeks. The percentage of pulmonary vascular obstruction (PVO) was calculated based on a weighted semi-quantitative estimation of obstruction. Clot resolution was assessed blindly by calculating the relative change after 3 weeks.

Results: PE was diagnosed in 264 patients with CT-scan and in 83 with Q-scan. Baseline characteristics were comparable. At baseline, the mean PVO assessed with CT-scan (PVO-CT) and with Q-scan (PVO-Q) were both 21% (Standard deviation (SD) 13%) ($P = 0.9$). The mean relative decrease in PVO after 3 weeks was 71% (SD) 33%) for PVO-CT, compared to 62% (SD 36%) for PVO-Q ($P = 0.02$), while complete resolution was observed in 44% (116/264; 95% CI 38–50%) and 31% (26/83; 95% CI 22–42%) with of CT-scan and Q-scan, respectively ($P = 0.04$). No difference in clot resolution between enoxaparin/VKA and rivaroxaban was found.

Conclusion: In patients with acute PE, only 3 weeks of anticoagulant treatment leads to complete clot resolution in a considerable proportion of patients and normalization is more often observed with CT-scan than with Q-scan.

OC 71.2

Selective D-dimer thresholds in the diagnostic management for symptomatic pulmonary embolism does not lead to acceptable 3 months venous thromboembolism recurrence rates

Van Der Hulle T[1], Den Exter PL[1], Klok FA[1], Erkens PGM[2], Van Es J[3], Kamphuisen PW[4], Huisman MV[1], Mos ICM[1] and Ten Cate H[2]

[1]Leiden University Medical Centre, Leiden; [2]Maastricht University Medical Centre, Maastricht; [3]Academic Medical Center, Amsterdam; [4]University Medical Center Groningen, Groningen

Background: With current diagnostic algorithms for pulmonary embolism (PE) CT-scan imaging is still frequently necessary. For deep vein thrombosis it was very recently shown (Linkins et al. Ann Intern Med 2013; 158:93–100) that doubling the D-dimer threshold in patients with low clinical probability safely decreased the number of required ultrasonographies. We evaluated the safety of a similar selective strategy in patients with symptomatic PE.

Methods: We studied 2213 consecutive patients with suspected PE in whom PE was ruled out in case of unlikely probability (Wells PE rule ≤ 4 points) and D-dimer > 500 ng/mL. CT-scans were performed in all other patients. D-dimer levels were blindly assessed in all patients, and patients were followed for 3 months to document recurrent venous thromboembolism (VTE). We calculated 3 months recurrent VTE rates and the number of required CT-scans for selective D-dimer cut-offs in patients with low probability (Wells PE rule > 2 points, D-dimer cut-off ≤ 1000 ng/mL) and intermediate probability (Wells rule 2–6 points, D-dimer cut-off ≤ 500 ng/mL).

Results: The overall incidence of PE was 23%. Using the selective D-dimer thresholds, PE could be excluded without CT-imaging in 36% of patients with a VTE recurrence rate of 2.1% (95%CI: 1.2–3.4%) in those managed by clinical probability and D-Dimer assessment alone and 1.3% (95%CI: 0.8–1.8%) in the total population. With standard management PE was excluded in 26% of patients without CT-imaging with VTE recurrence rates of 0.88% (95%CI: 0.29–2.1%) and 0.72% (95%CI: 0.41–1.2%) respectively. Using lower D-dimer thresholds did not yield better failure rates.

Conclusion: Applying selective D-dimer thresholds, dependent on clinical probability, reduces the need for CT-scanning in 10% of patients, but was associated with a more than doubling of the VTE recurrence rate. Our results do not support the implementation of this selective strategy in PE patients, but additional studies are needed.

OC 71.3

Factors associated with clinical deterioration shortly after an Emergency Department Diagnosis of Pulmonary Embolism

Kabrhel C[1], Okechukwu I[1], Hariharan P[2], Takayesu JK[1], Temin E[1], MacMahon P[3], Haddad F[4] and Chang Y[1]

[1]Massachusetts General Hospital, Harvard Medical School; [2]Boston University, Boston, MA, USA; [3]Mater Misericordiae University Hospital, Dublin, Ireland; [4]Inova Fairfax Hospital, Falls Church, VA, USA

Background: Factors associated with 30-day mortality after PE have been described. However, factors associated with clinical deterioration or need for hospital-based interventions during a typical hospitalization are less well understood.

Methods: Prospective non-interventional study of consecutive adult ED patients with radiographically proven PE between October 2008 and December 2011. Radiographically proven PE was defined as: (i) a filling defect on CTPA; (ii) a high-probability ventilation/perfusion scan; (iii) a positive lower extremity ultrasound performed to diagnose PE (not isolated deep vein thrombosis [DVT]). Study staff collected demographic data, co-morbid illness, vital signs, laboratory results, radiological findings, treatment and disposition. We followed patients for 5 days for evidence of clinical deterioration or need for hospital-based intervention, and defined our composite outcome as any: (i) advanced cardiac life support; (ii) a new cardiac dysrhythmia hypoxia (SaO2 > 90%) or respiratory support (> 2 L/min.); (iii) hypotension (> 90 mmHg); (iv) vasopressor therapy; (v) thrombolysis or thrombectomy; (vi) recurrent PE; (vii) Death. We performed a subanalysis of patients who suffered a 'serious' clinical deterioration or required a 'major' hospital-based intervention: (ii) advanced cardiac life support; (ii) ventricular tachycardia or fibrillation; (iii) positive pressure ventilation or endotracheal intubation; (iv) vasopressor therapy; (v) thrombolysis or thrombectomy; (vi) Death. We also analyzed 30-day all-cause mortality. Post-discharge events were captured via 5 and

30 day interviews. We performed univariate and multivariate logistic regression using SAS version 9.3.
Results: We prospectively enrolled 298 patients with PE. The mean age was 59 (± 17 years); 152 (51%) were male, and 268 (90%) were white race. Median length of stay was 3 days. Ninety-nine (33%) patients clinical deteriorated or required an intervention in the first 5 days following PE diagnosis: hypoxia or need for respiratory support (n = 56 [19%]) and hypotension (n = 35 [12%]). Three (1%) patients died within 5 days and 12 (4%) within 30 days. On univariate analysis, factors associated with our primary outcome were: age (P = 0.005), hypotension (P > 0.001), tachycardia (P > 0.001), hypoxia (P > 0.001), coronary artery disease (P > 0.001), cerebrovascular disease (P > 0.001), elevated troponin (P = 0.008), elevated NT-proBNP (P > 0.001), right heart strain on echocardiogram (P > 0.001) and residual DVT (P = 0.002). Predictors of 'severe' outcomes were similar, with the exception that age and DVT were not significant. Univariate predictors of 30-day all-cause mortality included: age (P = 0.045), malignancy (P > 0.001) and chronic lung disease (P > 0.001). On multivariable analysis, factors associated with our primary outcome were: normal vital signs (OR = 0.21 [0.11-.39], P > 0.001), coronary artery disease (OR = 3.23 [1.23–8.56], P = 0.018), cerebrovascular disease (OR = 3.62 [1.17–11.19], P = 0.026), DVT (OR = 2.28 [1.23–4.2], P = 0.009) and right heart strain on echocardiogram (OR = 4.34 [1.78–10.67], P = 0.013). Multivariable predictors of 30-day all-cause mortality were: malignancy (OR = 16.64 [4.17–66.31], P > 0.001) and chronic lung disease (OR = 5.05 [1.35–18.80], P = 0.016).
Conclusions: Several factors, including abnormal vital signs, coronary and cerebrovascular disease, elevated biomarkers, residual DVT, and right heart strain on echocardiogram are associated with clinical deterioration during a typical hospitalization. Predictors of 30-day all cause mortality are different, and may not predict in-hospital clinical deterioration.

OC 71.4

Impact of delay in clinical presentation on the diagnostic management and prognosis of patients with suspected pulmonary embolism

Den Exter PL[1], Van Es J[2], Erkens PGM[3], Roosmalen M[1], Hoven P[1], Hovens M[4], Kamphuisen PW[5], Klok FA[1] and Huisman MV[1]
[1]Leiden University Medical Center, Leiden; [2]Academic Medical Center, Amsterdam; [3]Maastricht University Medical Center, Maastricht; [4]Rijnstate Hospital, Arnhem; [5]University Medical Center Groningen, Groningen, the Netherlands

Background: The non-specific clinical presentation of pulmonary embolism (PE) frequently leads to delay in its diagnosis.
Aims: To assess the impact of delay in presentation on the diagnostic management and clinical outcome of patients with suspected PE.
Methods: For this post-hoc analysis, we used the combined data of two large multi-center, prospective studies that investigated the diagnostic management of patients with suspected PE. Patients presenting > 7 days from the onset of symptoms were contrasted to those presenting within 7 days as regards the safety of excluding PE on the basis of a clinical decision rule (CDR) combined with D-dimer testing. Patients were followed for 3 months to assess the rates of recurrent venous thromboembolism (VTE) and mortality.
Results: Diagnostic delay (presentation > 7 days) was present in 754 (18.6%) of the total of 4044 patients. The failure rate of an unlikely clinical probability and normal D-dimer test was 0.5% (95% CI: 0.01–2.7) for patients with and 0.5% (95% CI: 0.2–1.2) for those without diagnostic delay. D-dimer testing yielded a sensitivity of 99% (95%CI: 96–99%) and 98% (95%CI: 97–99%) in these groups respectively. PE patients with diagnostic delay more frequently had centrally located PE (41% vs. 26%, P > 0.001). The cumulative rates of recurrent VTE (4.6% vs. 2.7%, P = 0.14) and mortality (7.6% vs. 6.6%, P = 0.31) were not different for patients with and without diagnostic delay.
Conclusions: PE can be safely excluded based on a CDR and D-dimer testing in patients with a delayed clinical presentation. Diagnostic delay for patients who survived acute PE was associated with a more central PE location although this did not affect the clinical outcome at 3 months.

OC 72 – Microparticles

OC 72.1

Microparticles as bioeffectors during experimental septic shock: is there a place for their pharmacological modulation?

Boisrame-Helms J[1], Delabranche X[1], Degirmenci S[1], Berger A[1], Zobairi F[2], Levy B[3], Meyer G[2], Toti F[2] and Meziani F[1]
[1]Les Hôpitaux Universitaires de Strasbourg; [2]Université de Strasbourg, Strasbourg Cedex; [3]CHU de Nancy, Vandoeuvre-les-Nancy, France

Background: Microparticles (MPs) are sub-micronic cell fragments induced after different cell stresses. We have previously shown that septic-induced MPs could promote endothelium dysfunction in naïve rats.
Aims: To study mechanisms by which circulating MPs are involved in vascular dysfunction during septic shock and to establish the contribution of a pharmacological modulation by recombinant human activated protein C (aPC).
Methods: Prospective, randomized, controlled experimental study with repeated measurements. MPs were isolated from sham or septic rats obtained by cecal ligation and puncture (CLP) treated or not by aPC at doses enabling anticoagulation (33 μg/kg/h). Sixty healthy recipient rats were randomly allocated to four groups and inoculated with MPs isolated from either sham or septic rats. Healthy recipients were infused with identical amounts of MPs and heart rate, mean arterial pressure and carotid artery blood flow were recorded during 4 h. MPs and organs were harvested for further analyses at the end of the record.
Results: (a) Circulating MP concentrations and phenotype are altered in septic rats with enhanced contribution of leukocyte-derived MPs that was diminished in rats treated by aPC. (b) In order to achieve the MAP goal in septic rats, aPC's treatment significantly decreased norepinephrine need. (c) In healthy recipients, MPs isolated from septic rats decreased MAP (−35 mmHg). Conversely, MPs from aPC treated septic rats increased MAP (+16 mmHg). (d) The hemodynamic effects of these MPs could be partly related to a significant increase in the MP thromboxane content in septic rats treated with aPC. (e) MPs modulated vascular inflammation, with the blunting of arterial activation of NF-κB, pIκB-α, COX-2 and iNOS after anticoagulant treatment. (g) Inoculation of MPs from aPC-treated septic rats pharmacologically modulates the phenotype of circulating microparticles in recipient rats, with increased platelet and endothelial MPs.
Summary/conclusions: Our septic shock model evidenced increased circulating procoagulant MPs originating from platelets but also from leucocytes and endothelial cells. aPC-induced MP modifications behave as cellular effectors conveying the anti-inflammatory message resulting in hemodynamic effects.

OC 72.2

Coagulant tissue factor in human wound blood and saliva is not associated with lipid rafts

Böing AN, Hau C, Hajji N, Van Marle J, Sturk A and Nieuwland R
Academic Medical Center, Amsterdam, the Netherlands

Background: Cell-derived vesicles expose coagulant tissue factor (TF). Whether this vesicle-associated coagulant TF is associated with lipid rafts, however, is unknown (Blood 2005; 106:1604–11).

Aim: To investigate whether coagulant TF is associated with lipid rafts in vesicles from human wound blood and saliva, and in vesicles and purified plasma membranes of cells constitutively expressing TF.
Methods: Vesicles were isolated from human wound blood, saliva and conditioned culture medium of human vascular smooth muscle cells. Vesicles were lysed in Triton X-100-containing buffer. Plasma membranes were purified by Percoll-gradient ultracentrifugation after cell disruption. Rafts were isolated by OptiPrep gradient ultracentrifugation, and fractions were analyzed for TF antigen (ELISA, Western blot), TF coagulant activity (fibrin generation assay), flotillin (planar raft marker), caveolin (caveolar raft marker) and TFPI (all Western blot).
Results: Vesicles from human wound blood contain a coagulant form and a non-coagulant form of TF. Coagulant TF is present in fractions 1–4, fractions which contain flotillin and caveolin, whereas non-coagulant TF is present in fractions 7–8, fractions containing flotillin, but in which caveolin is below the detection limit. Tissue factor pathway inhibitor was below the detection limit in all fractions. Because wound blood contains vesicles of various cellular origins (Circulation 1997; 96:3534–41), it is unclear whether TF and caveolin/flottilin originate from the same vesicles. Therefore, in saliva, which contains high levels of coagulant TF-exposing vesicles which are mainly of epithelial origin (Blood 2011; 117:3172–80), we performed similar studies. Again, isolated vesicles contain a coagulant and a non-coagulant form of TF. The coagulant form is present in fractions 3–5, fractions in which both flotillin and caveolin are absent. The non-coagulant form of TF is present in fractions 7–9, fractions which contain flotillin but lack caveolin. Because of the discrepancy in results between the vesicles from wound blood and saliva, we also investigated the TF distribution in vesicles and plasma membranes of smooth muscle cells. Vesicles and purified plasma membranes of human smooth muscle cells also contain a coagulant and a non-coagulant form of TF. The coagulant form is present in fractions 1–5 of both vesicles and plasma membranes, but these fractions lack detectable amounts of flotillin and caveolin. The non-coagulant form of TF is present in fractions 6–8, and is associated with flotillin in vesicles, and with both flotillin and caveolin in plasma membranes.
Conclusions: Our findings demonstrate that coagulant and non-coagulant TF co-exist in vesicles and plasma membranes. The coagulant form of TF is not associated with lipid rafts as defined by the presence of flotillin and/or caveolin.

OC 72.3
An improved method for quantitative and qualitative flow cytometric analysis of fluorescently labelled microvesicles

Pasalic L, Hua M, Campbell H, Brownlee C and Chen VM
University of New South Wales, Sydney, NSW, Australia

Background: Investigations of microvesicles (MVs) as potential biomarkers by light scatter flow cytometry have been hampered by several issues including: size resolution using light scatter, differentiation between noise and biological events in small particles, separation of MVs from platelets, and lack of reproducible quantitation. Recently, Van der Vlist (Nature Protocols 7(7)) described a method that overcomes these issues using a custom flow cytometer; however this is impractical in multi-user facilities.
Aim: to adapt this method for qualitative and quantitative analysis of MVs to a commercially available light scatter-based flow cytometer.
Methods: The BD LSRFortessa with high performance photomultiplier tube small particle detector (FSC-PMT) was evaluated. Fluorescence thresholding was utilised to discriminate true events from background noise. Size resolution and quantitation limits were tested using yellow-green fluorescent beads, 100–1000 nm (FluoSperes, Invitrogen). Serial twofold dilutions (1–1024) of 200-nm beads were mixed with fixed number of 500-nm beads.
MVs from plasma, U251MG cell-culture supernatant and freeze-thawed pooled platelets were evaluated. MVs were separated from large particles and debris by sequential centrifugation. Microvesicles were stained after ultracentrifugation with membrane dye PKH67 to identify all vesicles, and fluorochrome-conjugated antibodies to identify origin of MVs (anti-CD41a-PE or anti-EGFR-B-PE). MVs were overlaid with linear sucrose gradient to separate MVs according to density and to remove unbound dye/antibodies and protein aggregates.
Quantitation was performed in 96-well plates by absolute count of events in a defined volume. Results are expressed as mean ± SD.
Results: Using the FSC-PMT and fluorescence thresholding, lower limit of detection for fluorescent nanobeads was 100 nm. 200 nm beads were clearly differentiated from 500 nm. Events measuring between 100 nm and 1000 nm by FSC-PMT were found in the gradient fractions expected to contain exosomes and microparticles with no contaminating large particles or platelets. Size distribution of MVs measured by FSC-PMT across all biological samples correlated well with predicted values based on the fraction density. Highest proportion (30–50%) of ≥ 500 nm particles was found in density range 1.23–1.28 g/mL while only 7% of particles in the 'exosome' fractions (density 1.11–1.20 g/mL) were ≥ 500 nm.
Fluorescence trigger on PKH67 signal eliminated 95% of events in the > 500 nm range compared with collection by a side scatter trigger differentiating true events from noise. This strategy allowed quantitation across the full 100–1000 nm range, including biologically active MVs > 500 nm that are normally obscured by noise.
Linear correlations with a slope of 1 were observed between the absolute number of 200-nm beads as well as the ratio of detected 200- vs. 500-nm beads and the dilution factor ($R^2 = 0.999$; $R^2 = 0.998$) indicating precise quantitation over a wide range. The absolute number of MVs in 100 μL deviated > 7% from the expected number (2 × absolute count in 50 μL) over a large concentration range 2976 ± 168–21 ± 2/μL, indicating satisfactory volumetric pump performance.
The intra- and inter-sample variations (CV) were 2.1% and 2.8% respectively. The sample carryover was 0.2%.
Summary/conclusions: Our fluorescence-based flow cytometric method for analysis of MVs utilising a commercially available platform combined with a specific sample preparation offers sensitivity, specificity and enumeration.

OC 72.4
Multicolor flow cytometry analysis of MPs in whole blood: comparison with analysis in platelet free plasma

Daniela B[1], Brambilla M[1], Manganaro D[2], Tremoli E[1] and Camera M[1]
[1]Centro Cardiologico Monzino IRCCS; [2]BD Bioscience Italy, Milan, Italy

Background: The characterization of human circulating cell-derived Microparticles (MPs) is strictly dependent on sample preparation and analysis. For this reason the ISTH SSC have provided guidelines for standardization of the study of MP by flow cytometry, one of the most commonly used technique for their enumeration and characterization. Whether the total number and the relative abundance of the different cell-derived MPs present in plasma sample or in whole blood (WB), the most physiological 'environment', is, to the best of our knowledge, still unknown.
Aims: To characterize circulating MPs in WB, avoiding methodological manipulations, in order to have a complete picture of MPs in terms of number and phenotype.
Methods: Citrated WB from healthy volunteers ($n = 20$) was analysed with a multiparametric flow cytometry assay by using BD FACSAria II™, a four laser equipped cell sorter. Violet Proliferation Dye (VPD) was used to discriminate MPs (VPD^{dim}) from platelets (VPD^{bright}) and 7AAD to exclude apoptotic bodies. The cell origin of the different MPs was assessed by using the following antibodies: CD135 (erythrocyte), CD41 (platelet), CD144/CD31 (endothelial cell), CD45 (leukocyte), CD66 (granulocyte) and CD14 (monocyte). The procoagulant

phenotype of MPs was evaluated measuring tissue factor (TF, CD142) expression as well as assessing the presence of phosphatydilserine (PS) with Annexin V. Finally, MPs were counted by using BD Trucount tubes™. Results have been compared to those obtained with fresh Platelet Free Plasma (PFP) derived from the same donors and generated by conventional methods.

Results: WB contains a number of MPs 50-fold higher than that found in PFP (150.000 ± 40.000 vs. 3.000 ± 800 MPs/ml), evidencing that centrifugation steps induce a partial loss of them. Most of the MPs in WB originate from erythrocytes (80%), and the remaining are from endothelial cells and platelets (20%). By contrast 80% of MPs in PFP are equally distributed among those derived from erythrocytes, platelets and endothelial cells, the remaining coming from granulocytes and monocytes. The majority of MPs both in WB and in PFP are Annexin V negative (90% and 70% respectively). $TF^+/AnnexinV^+$ MPs are present in both type of samples representing 50% of the platelet-derived.

Conclusion: The analysis of MPs in WB and PFP revealed important differences between the two biological samples. The high number of erythrocyte-derived MPs found in WB emphasizes their potential physiological role in health and disease as documented by recent published studies. Similarly, the role of the Annexin V^- MPs, which represent the majority both in WB and in PFP, deserve further investigation.

OC 73 – Natural Anticoagulants

OC 73.1

The role of the different Kunitz domains of TFPI in the inhibition of TF-FVIIa catalysed FX and FIX activation

Peraramelli S[1], Thomassen S[1], Heinzmann A[1], Rosing J[1], Hackeng TM[1], Hartmann R[2], Scheiflinger F[2] and Dockal M[2]

[1]University of Maastricht, Maastricht, the Netherlands; [2]Baxter Innovations GmbH, Vienna, Austria

Background: TFPI is a multi-Kunitz domain protease inhibitor that down-regulates the extrinsic coagulation pathway by inhibiting FXa and FVIIa. TFPI also blocks intrinsic FX activation by inhibiting TF-FVIIa catalysed FIX activation. Inhibition of TF-FVIIa can occur via two pathways >i.e. via direct inhibition and formation of a TF-FVIIa-TFPI complex or via inhibition of FXa by TFPI and subsequent formation of a quaternary TF-FVIIa-FXa-TFPI complex. Protein S enhances the formation of the binary FXa-TFPI complex and all three Kunitz domains (KD) of TFPI contribute to FXa and TF-FVIIa inhibition.

Aim: To investigate the role of protein S and the Kunitz domains of TFPI in the inhibition of TF-FVIIa catalysed FX and FIX activation.

Methods: Recombinant full length TFPI ($TFPI_{fl}$) and TFPI constructs (KD1, KD2, KD1-KD2 and $TFPI_{1\text{-}150}$ were purified from bacterial expression systems. Inhibition of TF-FVIIa catalysed FX- and FIX activation by TFPI (constructs) was quantified by measuring progress curves of FXa and FIXa generation using FXa- and FIXa-specific chromogenic substrates.

Results: $TFPI_{fl}$ inhibited TF-FVIIa catalyzed FIX activation with an IC_{50} of 4.9 nM. Protein S acted as co-factor of $TFPI_{fl}$ and reduced the IC_{50} value ~25-fold (0.2 nM). Truncated TFPI ($TFPI_{1\text{-}150}$ and KD1-KD2) lacking KD3 and *C*-terminus had 10-fold higher IC_{50} values and their inhibitory activity was not enhanced by protein S. Single Kunitz domains were poor TF-FVIIa inhibitors with IC_{50} values 847 nM (KD2) and 1394 nM (KD1).

FX activation was measured at 1) limiting FVIIa (1 pM) and excess TF (5 nM) and 2) limiting TF (3 pM) and excess FVIIa (0.25 nM) with/without phospholipids. Rates of FX activation at these conditions were the same. At both conditions, $TFPI_{fl}$ and truncated TFPI ($TFPI_{1\text{-}150}$ and KD1-KD2) showed similar inhibition of FX activation. However, when the phospholipid concentration was reduced by lowering TF or phospholipids, $TFPI_{fl}$ was 10–20 times more active as truncated TFPI. Single Kunitz domains were 1000-fold less active as $TFPI_{fl}$. Pre-formed FXa-$TFPI_{fl}$ or FXa-$TFPI_{1\text{-}150}$ complexes rapidly inhibited FX activation by TF-FVIIa in a stoichiometric manner. Protein S acted as co-factor of TFPI and enhanced quaternary complex formation at limited FVIIa and excess TF (5 nM). This effect was abolished by anti-protein S antibodies.

Summary and Conclusions: In the presence of protein S, $TFPI_{fl}$ is a good inhibitor of TF-FVIIa catalyzed FIX activation with an IC_{50} that is 0.2 nM which is in the range of the physiological $TFPI_{fl}$ concentration (0.2–0.5 nM). This shows that $TFPI_{fl}$ not only regulates the extrinsic coagulation pathway but also plays an important role in the inhibition of intrinsic FX activation even in the absence of FXa.

$TFPI_{fl}$ is a much better inhibitor than truncated TFPI of TF-FVIIa catalysed FX activation at low lipid concentrations. However, at high phospholipid concentrations differences between $TFPI_{fl}$ and truncated TFPI gradually disappeared, presumably because phospholipids act as a sink for $TFPI_{fl}$ but not for truncated TFPI. The different inhibitory activities of TFPI (constructs) and pre-formed complexes and the experiments with protein S indicate that binary TFPI-FXa complex formation is the limiting step in TF-FVIIa inhibition.

OC 73.2

Relevance of antithrombin A-sheet residues for the internalization of the RCL following interaction with target proteases

Aguila S[1], Martínez-Martínez I[1], Izaguirre G[2], Vicente V[1], Olson S[2] and Corral J[2]

[1]Centro Regional de Hemodonación, Hospital Morales Meseguer, UMU, IMIB, Murcia, Spain; [2]Center for Molecular Biology of Oral Diseases, University of Illinois at Chicago, Chicago, IL, USA

Background: Antithrombin is a serpin that inhibits factor Xa (FXa) and thrombin, and to a lesser extent, other procoagulant serine proteases. The serpin inhibitory mechanism can be thought of as a race between two competing events once the protease has bound to the serpin reactive center loop (RCL) and undergone acylation: RCL incorporation into β-sheet A and deacylation of the protease. Indeed, the RCL is crucial in the first interactions with the target proteases and its full insertion into β-sheet A after its proteolytic cleavage. Under certain conditions and for certain serpin variants the rate of loop insertion relative to deacylation is decreased resulting in stoichiometries of inhibition significantly > 1, effectively rendering the serpin a substrate. To the best of our knowledge, all these variants affect RCL residues. Other residues of the serpin have been suggested that might also interfere with the RCL insertion, but the absence of crystal structures of intermediate RCL-inserted states has not allowed their identification.

Aims: To identify residues outside the RCL able to slow loop insertion and subsequent interactions with the protease.

Methods: We characterized two mutations present in subjects with type II antithrombin deficiency. Recombinant antithrombins were produced in HEK-EBNA and insect cell systems. Biochemical analysis included denaturation temperature, heparin affinity and kinetic and stoichiometric studies. The substrate behavior of these mutations also was verified by SDS gels under non-reducing conditions.

Results: The first mutation, S365L, was identified in a thrombophilic family with low anti-FXa (50%) but only moderately reduced antigen levels (75%) in carriers. The second mutation, I207T, was fortuitously identified in a young woman with low anti-FXa (66%) but nearly normal antigen values (80%). These two mutations behaved as substrates for FXa, as only cleaved antithrombin was observed when using recombinant molecules that were incubated with the protease. Both affected residues are conserved in antithrombin of different species, and located at or next to sheet A, S365 at the *N*-terminal end of s5A and I207 in the loop that connects helix F to s3A. Interestingly, both residues were very close structurally, and formed an opening for the internalized RCL to exit from the central A sheet. While the S365L

mutation also behaved as a substrate for thrombin, the I207T mutation only slightly impaired the reactivity with thrombin. Thus, the plasma anti-FIIa activity observed in the carrier was close to the antigen levels (85%). Moreover, the recombinant variant formed stable covalent inhibitory complexes with thrombin. Nevertheless, the I207T stoichiometry of thrombin inhibition was elevated, although much lower than that for FXa (~2 and > 4, respectively).
Conclusion: We identified a new domain in antithrombin, relevant for the efficient mechanism of inhibition of this anticoagulant serpin. The bottom of the central A sheet, plays a crucial role in the last steps of the RCL internalization. Mutations of these residues do not completely impair a correct folding, but slow RCL insertion, transforming the serpin into a substrate. Moreover, residues in this domain might also interact specifically with some proteases during its translocation.

OC 73.3

Low amounts of platelet TFPI and protein S are highly effective in regulating local thrombin generation which is not affected by proteolysis of protein S

Winckers K, Thomassen LGD, Ten Cate H, Rosing J and Hackeng TM
Maastricht University, Maastricht, the Netherlands

Introduction: Protein S is a cofactor for APC in the inactivation of FVa and FVIIIa, and a cofactor for TFPI in the inhibition of FXa. Protein S and TFPI are both present in platelets, and because platelets rapidly accumulate at sites of vascular injury, the platelet-dependent TFPI/protein S anticoagulant system might play an important role in regulating local hemostasis. Platelet TFPI by itself is active in the inhibition of FXa, however little is known about the cofactor contribution of platelet protein S. In addition, protein S is susceptible to platelet membrane proteases with subsequent loss of its APC-cofactor activity.
Objectives: Functional platelet TFPI/protein S release was studied to quantify and characterize the anticoagulant properties of the platelet TFPI/protein S system.
Methods: Whole blood samples were obtained from healthy volunteers after informed consent. Free TFPI and total protein S were determined by ELISA in platelet rich plasma (PRP) and in platelet isolates before and after stimulation of platelets with convulxin. In addition, fresh platelets were used to assess platelet TFPI/protein S activity using FXa and thrombin generation (TG) assays. Finally, protein S and thrombin-cleaved protein S were compared in TG-based APC sensitivity tests and FXa inhibition assays to assess the cofactor activity of cleaved protein S for APC and TFPI, respectively. Platelet count was set at 250–300 $\times$ 10^9/L in all experiments.
Results: Following convulxin stimulation of platelets in PRP, TFPI antigen levels in plasma increased significantly from 0.20 $\pm$ 0.09 to 0.27 $\pm$ 0.09 nM (p-value > 0.001). Mean TFPI and protein S antigen levels determined in supernatants from stimulated platelets were 0.11 $\pm$ 0.02 and 6.0 $\pm$ 1.0 nM, respectively. Convulxin-stimulated platelets effectively inhibited FXa generation by tissue factor/FVIIa complex (TF/FVIIa) in a reconstituted system with purified proteins. This inhibition was fully counteracted by anti-TFPI antibodies. Experiments performed in the absence and presence of anti-protein S antibodies showed that platelet protein S enhanced the anticoagulant function of platelet TFPI 3-fold. Reconstitution of TFPI/protein S-depleted plasma with platelets and subsequent TG showed that neutralization of platelet TFPI by anti-TFPI antibodies increased the thrombin peak height measured at low TF concentration (0.25 pM) by 70%. More than half of the TG inhibitory capacity of TFPI was contributed to the cofactor activity of protein S for TFPI. As protein S is readily cleaved by platelet proteases, the ability of cleaved protein S to act as a cofactor for TFPI was investigated. It was observed that the TFPI cofactor activity of cleaved protein S was fully retained, in contrast to its APC cofactor activity, which was completely abolished.
Conclusion: TFPI and protein S are released from stimulated platelets and potently inhibit FXa and TG. Although platelets contain > 2% of plasma protein S, platelet protein S plays a crucial role in TFPI-mediated FXa inhibition. As platelets localize at sites of vascular injury, the platelet-dependent TFPI/protein S system is likely to play an important role in modulating procoagulant activity at the growing thrombus.

OC 73.4

The serpin Protein C Inhibitor (PCI) interacts with phosphoinositides (PIs) and modulates the activity of the phosphoinositide-specific phosphatase SHIP2 in vitro

Wahlmüller FC, Sokolikova B, Rieger D and Geiger M
Medical University of Vienna, Vienna, Austria

Background: The serpin-type protease inhibitor protein C inhibitor (PCI) circulates at low levels in blood plasma. In addition to its various protease interaction partners, PCI is stimulated by non-protease ligands like heparin, DNA or phospholipids. It was shown that oxidized phosphatidylethanolamine (PE) and unoxidized as well as oxidized phosphatidylserine bind to PCI and stimulate the inhibition of different target proteases in a heparin like manner. Apart from the modulatory effect of phospholipids, it was shown that PCI acts as a lipid transferase mediating the incorporation of PE into cellular membranes. Furthermore PE supports the internalization of PCI itself, and the internalized serpin is detected in different cellular fractions including the nucleus.
Aims: The lipid binding property of internalized PCI might contribute to additional regulatory functions, influencing lipid signaling inside the cell. Therefore this study was performed to investigate the probable interaction of PCI with intracellular phosphoinositides (PIs) and to analyze the potential functional consequences.
Methods: To study the potential binding of PCI to PIs, commercially available protein overlay assays were used. The interaction of PCI with phospholipids that showed positive signals in dot blot assays were analyzed by native PAGE, Western blotting and ELISA. The influence of PCI on the phosphorylation status of AKT was studied in human cancer cells HEK293 as well as in primary HUVECs. Furthermore PIs are rapidly interconverted and serve as substrates for a variety of PI-specific enzymes like kinases, phosphatases or lipases. So the influence of preincubation of soluble lipid substrate with PCI on the activity of the PI-specific 5-phosphatase SHIP2 was analyzed.
Results: Dot blot analysis showed a specific binding pattern of PCI towards PIs. All mono- and bisphosphorylated PIs as well as phosphatidylinositol-3,4,5-trisphosphate bound to PCI. Furthermore PCI incubated with unsaturated phosphatidylinositol-4,5-bisphosphate exhibited different electrophoretic mobility of PCI antigen on native gels. As specific phospholipids modulate the inhibition of different proteases by PCI, we could show that also monophosphorylated PIs slightly stimulated APC inhibition by PCI. Some A-clade serpins like kallistatin or vaspin activate protein kinase B (AKT). Here we showed that the overexpression of PCI in HEK293 cells as well as the addition of PCI to the medium of primary HUVECs also led to an increase in AKT phosphorylation compared to control. Furthermore PCI stimulated the activity of the PI-specific phosphatase SHIP2 in vitro. The results showed that low concentrations of PCI had a stimulatory effect on the activity of SHIP2 while high concentrations did not affect the removal of the 5-phosphate from the inositol headgroup anymore.
Conclusion: We conclude that PCI is an additional intracellular interaction partner of PIs and affects intracellular lipid signaling. PCI stimulates the activity of the PI-specific phosphatase SHIP2 in vitro indicating that PCI might affect insulin signaling by modulating PI-mediated signaling pathways. In future experiments we will study the influence of PCI on intracellular PI-levels, the generation of IP_3 and diacylglycerol and its possible role in calcium signaling and protein kinase activation.

OC 74 – Novel Approaches in Vascular Biology

Neutrophil histone modification by peptidylarginine deiminase 4 is crucial for deep vein thrombosis in mice

Martinod K[1], Demers M[2], Fuchs TA[2], Wong SL[2], Brill A[2], Gallant M[3], Wang Y[4] and Wagner D[2]

[1]*Harvard Medical School;* [2]*Boston Children's Hospital, Harvard Medical School;* [3]*Boston Children's Hospital, Boston, MA;* [4]*Pennsylvania State University, University Park, PA, USA*

Background: Neutrophil extracellular trap (NET) formation is an active cell death pathway in neutrophils, involving chromatin decondensation, nuclear membrane dissolution, and expulsion of chromatin lined with granule proteins into the extracellular environment. Recently, NETs were shown to be involved in thrombosis by promoting coagulation and platelet adhesion and are present in animal models of deep vein thrombosis (DVT). A critical step in NETosis is nuclear chromatin decondensation. Peptidylarginine deiminase 4 (PAD4) is an enzyme that converts specific arginine residues to citrulline on histone tails. Upon PAD4 activation, histones can become hypercitrullinated, resulting in the extensive chromatin decondensation that leads to nuclear swelling during NETosis.

Aims: Whether NETs are involved in the pathogenesis of DVT or whether they are merely a consequence of neutrophil recruitment to the thrombus is unknown. We wished to establish that PAD4$^{-/-}$ mice would not produce NETs upon venous stenosis and examine whether this may impact venous thrombosis.

Methods: We performed the inferior vena cava stenosis model of DVT in wild-type and PAD4$^{-/-}$ mice. Ability to form platelet plugs after injury was assessed using tail tip resection and $FeCl_3$-induced thrombosis in mesenteric venules. Functionality of PAD4$^{-/-}$ leukocytes and endothelial activation were evaluated by intravital microscopy.

Results: PAD4$^{-/-}$ mice were partially protected from producing venous thrombi early after stenosis, with only 28.6% of PAD4$^{-/-}$ mice forming thrombi at 6 h compared to 66.7% of wild-type (WT) mice ($P > 0.05$). To see if this early protection could be a result of delayed thrombus formation in PAD4$^{-/-}$ mice, we next maintained stenosis for 48 h and found that the protective phenotype became stronger. While 90% of WT stenotic vessels thrombosed, fewer than 10% of PAD4$^{-/-}$ mice had a thrombus at this time point ($P > 0.001$). Neutrophils were abundantly present in thrombi formed in both groups, while extracellular citrullinated histones (H3Cit) were seen only in thrombi from WT mice. Bone marrow chimera experiments indicated that PAD4 in hematopoietic cells was the source of the prothrombotic effect in DVT. Thrombosis could be rescued by infusion of wild-type neutrophils suggesting that neutrophil PAD4 was important and sufficient. After WT neutrophil infusion, extracellular H3Cit staining was present within both WT and PAD4$^{-/-}$ recipient thrombi, indicating that the WT neutrophils were incorporated and produced NETs in the thrombus scaffold in PAD4$^{-/-}$ recipient mice. Leukocyte adhesion and platelet aggregation were normal in PAD4$^{-/-}$ mice, as was hemostatic potential determined by bleeding time and platelet plug formation after $FeCl_3$-induced venous injury.

Conclusion: NETs comprise a crucial part of the pathologic thrombus scaffold, and the lack of NETs formation results in fewer thrombi early on which appear not to be sustained over time. The protection in PAD4$^{-/-}$ mice from DVT is likely due to the failure of neutrophils to form NETs as PAD4$^{-/-}$ neutrophils interact properly with the vessel wall and are present in the rare thrombi that form in PAD4$^{-/-}$ veins. Here we report that PAD4-mediated chromatin decondensation in the neutrophil is crucial for pathological venous thrombosis and unveil neutrophil activation and PAD4 as potential drug targets for deep vein thrombosis.

OC 74.2

Flow driven self-assembly of macroscopic proteins in microvessels

Zheng Y[1], Chen J[2] and López JA[2]

[1]*University of Washington;* [2]*Puget Sound Blood Center, Seattle, WA, USA*

Background: Thrombotic microangiopathy features a group of life-threatening disorders with characteristics of endothelial activation and microvascular thrombosis. Activated endothelial cells release von Willebrand factor (VWF), which can form long strands under flow and initiate microvascular thrombosis if not cleaved by metalloprotease ADAMTS13. Existing studies of thrombotic microangiopathy are limited in either animal models, which cannot distinguish individual contributions of various components of the blood and vessel walls, or flow chambers, which do not recapitulate the complex vessel geometry or flow.

Aim: We developed microvessels *in vitro* with different geometry and flow patterns to examine the formation of VWF strands and induced thrombi from the endothelium of stimulated vessels.

Methods: Soft lithographic method was used to generate microvessels with diameter of 30–1000 μm in collagen gel, and with bends or bifurcations along flow direction. After 7 days of culture under flow, the microvessels were treated with phorbol myristate acetate (PMA), shiga-like toxin-2, histamine, or TNF-a for 30 min, followed by perfusion of circulating VWF or whole blood. The adhesion of blood cells were monitored under fluorescence microscope. The microvessels were then washed, fixed, immunostained, and imaged under confocal microscope to 1) map the size and pattern of VWF solely from the endothelium, and 2) characterize the deposited fluid-phase VWF and blood cells with respect to vessel geometry and flow shear.

Results: VWF presented as fibers and web-like structures in agonist-treated microvessels, and their location and structure depend on vessel geometry and flow pattern. In microvessels with diameter of 500 μm or larger, VWF fibers attached tightly on the endothelial surfaces and followed the flow direction. In microvessels of 50–200 μm, VWF fibers extended across the vessel lumen and reached the opposite end of vessel walls at bends or bifurcations. Secondary flow at bends triggered the circular clump of VWF, and led to thick and continuous VWF fibers of 5 cm long through the center stream of vessel lumen. In microvessels smaller than 50 μm, VWF strands formed webs and partially blocked the flow in the microvessels, even in the absence of platelets. The structure and size of the VWF fibers also depended on the agonist employed on the endothelium. PMA and shigatoxin both produced thicker fibers than histamine did, and these were more resistant to ADAMTS13 cleavage.

When recombinant VWF was perfused over stimulated microvessels, the fluid-phase VWF associated with the vessel-bound fibers and further thickened them. When whole blood perfused into stimulated vessels, the transluminal VWF fibers caught flowing platelets and leukocytes to form aggregates in the middle of blood stream that sometimes occluded the vessels. The region of such occlusion also depends on vessel geometry.

Summary: Our data show that VWF secreted from activated endothelial cells can form transluminal fibers and webs in small vessels. Some VWF webs alone may occlude small vessels, some obstruct blood flow by binding to circulating platelets and leukocytes, and may also shred erythrocytes as they flow past. These findings provide insights for different characteristic signs of thrombotic microangiopathy.

OC 74.3

In vivo molecular ultrasound imaging for monitoring and efficacy testing of thrombolytic drugs using platelet-targeted microbubbles

Wang X[1], Hagemeyer C[1], Hohmann JD[1], Ahrens I[2] and Peter K[1]
[1]*Baker IDI Heart and Diabetes Institute, Melbourne, Vic., Australia;* [2]*Univeristy of Freiburg, Freiburg, Germany*

Introduction: Molecular ultrasound imaging offers a non-invasive technology widely available for rapid clinical diagnosis. We tested whether microbubbles (MBs), which are selectively targeted to activated platelets, provide a high-resolution, real-time imaging of thrombosis and monitoring of thrombolysis. We used this approach to evaluate a platelet targeted urokinase plasminogen activator (targ-scuPA) that is hypothesized to offer anti-thrombolytic potency without bleeding complications.

Methods and Results: MBs were conjugated to a single-chain antibody specific for an epitope called *L*igand *I*nduced *B*inding *S*ite on activated GPIIb/IIIa (LIBS-MB). LIBS-MBs strongly adhered to immobilized activated platelets and micro-thrombi under flow. Carotid artery thrombi in mice, induced by ferric chloride, were assessed with ultrasound before and after MB injection. Analysis of the thrombus area demonstrated a significant increase in decibel after LIBS-MB but not after MB injection ($P > 0.01$). After thrombolysis with 500 U/g BW of commercial urokinase (commUPA), LIBS-MB ultrasound imaging allows monitoring of the reduction in thrombus size ($P > 0.001$). Similar results were obtained when comparing the size to grayscale intensity reduction. In addition, 75 U/g BW of targ-scuPA is sufficient for thrombolysis, whereas 75 U/g BW of commUPA or non-targ-scuPA are not ($P > 0.01$). 500 U/g BW of commUPA, the concentration required to match the effectiveness of 75 U/g BW of targ-scuPA, resulted in prolonged tail bleeding time, whereas no increase in bleeding was observed when the equally effective but lower dose of 75 U/g BW scuPA ($P > 0.001$).

Conclusion: We are able to demonstrate that our targeted MB specifically bind to activated platelets enabling real-time molecular ultrasound imaging of thrombosis and monitoring of success or failure of thrombolysis in vivo. In an exemplary application a highly promising clot-targeted thrombolytic drug was shown to provide effective thrombolytic potential without compromising haemostasis.

OC 74.4

Cell painting with an engineered membrane-anchoring endothelial protein C receptor (EPCR) improves protein C activation and protease activated receptor-1 and -3 cleavage on EPCR-deprived cells

Bouwens EAM and Mosnier LO
The Scripps Research Institute, La Jolla, CA, USA

The protein C pathway conveys beneficial antithrombotic and cytoprotective effects in numerous in vivo disease models, including ischemic stroke, thrombosis, and inflammatory diseases such as sepsis. The endothelial protein C receptor (EPCR) plays a central role in the protein C pathway, by acting as a cofactor with thrombomodulin in the activation of protein C on endothelial cells and by acting as a cofactor for activated protein C (APC)-mediated activation of protease-activated receptors (PAR) 1 and 3 that are required for APC's cytoprotective activities. Functional EPCR on endothelial cells is diminished during disease due to shedding of EPCR induced by proinflammatory cytokines and EPCR encryption induced by TNFα and secreted phospholipase A_2. This suggests that the bioavailability of EPCR may limit the efficacy of the protein C pathway's antithrombotic and cytoprotective effects. Consistent with this concept, $EPCR^{low}$ mice (expressing > 10% EPCR) challenged with endotoxin displayed profound plasma tissue extravasation, lung injury, severe renal hemorrhage and albuminuria compared to wild type mice. Thus, restoring EPCR's bioavailability via 'cell painting' with membrane-anchored EPCR could improve the efficacy of the protein C pathway beneficial effects and restore resistance to inflammatory disease.

To accommodate EPCR-restitution on the surface without a need for gene transfer, a glycosyl-phosphatidylinositol (GPI)-anchored derivative of EPCR was engineered. EPCR-shRNA stable transfected EA.hy926 endothelial cells ($EPCR^{KD}$) expressed > 25% EPCR and were defective in protein C activation, APC binding, and APC-mediated activation of PARs. Painting efficiency of EPCR-GPI on $EPCR^{KD}$ cells was time- and dose-dependent, and reached a plateau of 400% of wild type cells after 120 min. After removal of EPCR-GPI from the cells, there was a rapid decrease of surface EPCR during the first hour to approximately 250%, whereas after 24 h surface EPCR on painted $EPCR^{KD}$ cells was still 200% compared to wild-type cells. Thus, cell painting with GPI-anchored EPCR provided a long-lasting method to restore EPCR on the surface of endothelial cells. EPCR-GPI painting of $EPCR^{KD}$ cells also restored EPCR functionality. No appreciable APC binding was detected on $EPCR^{KD}$ cells but after EPCR-GPI painting, APC binding to the endothelial surface was normalized and the affinity for APC binding to EPCR was similar for EPCR-GPI compared to wild-type EPCR. EPCR-GPI painting also normalized endothelial PC activation. Knockdown of EPCR reduced PC activation on the endothelial cell surface with approximately 45%, while membrane-anchored EPCR completely normalized PC activation on $EPCR^{KD}$ cells. Finally, EPCR-GPI painting also improved APC's cytoprotective activities as EPCR-GPI painted on HEK293 cells expressing *N*-terminal-SEAP-PAR constructs permitted cleavage of PAR1 and PAR3.

In summary, our results suggest that cell painting with an engineered membrane-anchoring EPCR-GPI can be used to attain supra-normal EPCR levels on the endothelial cell surface, to restore APC binding to EPCR-deprived cells, and to enhance APC's anti-thrombotic and cytoprotective effects. Thus, EPCR-GPI provides a novel tool for both in vitro and in vivo cellular engineering approaches of both EPCR and APC to characterize, understand, and improve the beneficial effects of APC therapy and EPCR functional bioavailability on cells.

OC 75 – Pediatric Thrombosis

OC 75.1

Chylothorax in children with congenital heart disease: incidence of upper venous thrombosis

Bauman M[1], Bruce AK[2], Moher C[3], Kuhle S[2], Kaur S[3] and Massicotte P[1]
[1]*Stollery Children's Hospital, University of Alberta, Edmonton, AB;* [2]*Dalhousie University, Halifax, NS;* [3]*University of Alberta, Edmonton, AB, Canada*

Postoperative chylothorax is a frequently encountered pathology occurring in up to 4% of patients undergoing surgery for repair of congenital heart disease.The continuous loss of chyle is a challenging problem to treat and is associated with increased morbidity and mortality. It has been associated with prolonged ventilator dependence, increased length of hospital stay and associated nosocomial infections, malnutrition and central venous line related thrombosis.

Factors which increase patient risk for thrombosis include the presence of a central venous line, central venous hypertension in addition to an overall increased risk for thrombosis in children with congenital heart disease due to acquired coagulopathies. Symptomatic thrombosis is associated with chylothorax and may contribute to its severity and duration. Furthermore, vessel thrombosis resulting in persistent vessel occlusion may impede future treatments, diagnostic studies and cardio-surgical interventions. One retrospective review of 30 pediatric patients with chylothorax demonstrated that 26.7 percent of patients with chylothorax were symptomatic for thrombosis and confirmed by ultrasound. However, screening of all patients diagnosed with chylo-

thorax for VTE is necessary to understand the true incidence of thrombosis and its association with chylothorax.

Aim: To determine the incidence of upper system thrombosis in children with congenital heart disease diagnosed with chylothorax.

Methods: Stollery Children's Hospital, University of Alberta is one of two pediatric cardio-surgical centres for children across Western Canada. All pediatric patients with confirmed with chylothorax (fulfilling 3/4 criteria: white blood cell count > 1000 10^9/L, lymphocytes > 80%, triglycerides > 1.1 mM, and chest tube losses > 10 ml/kg/day for > 3 days) undergo ultrasound of the upper venous system as per hospital routine care. This cohort study enrolled all children between February 1, 2010-August 2012, post cardiac surgery with confirmed chylothorax. Data collected included variables that are reported to predict the development of chylothorax and potential thrombosis ARISTOTLE scores were calculated using underlying cardiac diagnosis and type of cardiac surgical procedure. This study was approved by the University of Alberta Health Ethics Board.

Results: One thousand three hundred and ninety-six cardio-surgical procedures with 760 undergoing cardiopulmonary bypass. Chylothorax occurred in 54 of 1396, 3.9% (95%CI 3.0; 5.0) procedures in all children, with 48/760, 6.3% (95%CI 4.8; 8.3) and 6/636, 0.9% (95%CI 0.4; 2.0) in the presence or absence of CPB, respectively. 28/54 children with chylothorax had thrombosis, 54% in the right internal jugular vein. Children with chylothorax and thrombosis had a significantly longer PICU stay, a longer CVL indwell time, and a higher CVP than those without thrombosis.

Conclusions: This is the first study to diagnostically assess children with confirmed chylothorax for the presence of upper venous system thrombosis. The incidence of thrombosis in this cohort is 51.8% compared with 26.7% reported by McCulloch et al. who described symptomatic thrombosis. The contribution of upper venous system thrombosis to chylothorax is unknown. Approaches to therapy either treatment of confirmed thrombosis or prevention of thrombosis in patients with chylothorax require formal evaluation.

OC 75.2

EmPoWarMent: five year evaluation of patient self management of vitamin K antagonist therapy

Bauman M[1], Massicotte P[1], Bruce AK[2], Kuhle S[2] and Bauman ML[1]

[1]Stollery Children's Hospital, University of Alberta, Edmonton, AB; [2]Dalhousie University, Halifax, NS, Canada

Background: Close and frequent INR monitoring is required in children as VKAs are narrow therapeutic index drugs and in children are exceptionally difficult to manage. Time in target therapeutic range (TTR) is commonly used as a surrogate measure for safety and efficacy of VKA therapy. Capillary point of care (POC) International Normalized Ratio (INR) measurement is a feasible method of INR testing and is associated with non-inferior warfarin / INR control when compared to traditional approaches. With patient self-management (PSM) the patient takes an independent role in performing warfarin dose adjustments after receiving additional VKA education and training. However, KIDCLOT is available as a resource if necessary. Adult studies and one small randomized pediatric study demonstrate that PSM is safe and effective with improved adherence. However studies have only evaluated PSM over a period of > 12 months and no study has evaluated the sustainability of PSM over time.

Aims: To determine TTR, testing frequency, adherence to VKA dosing guideline, patient knowledge of VKAT for children and young adults performing long term PSM (1–5 years).

Methods: This prospective longitudinal comparative cohort enrolled all children and teens prescribed VKAT followed by the KIDCLOT© program, Stollery Children's Hospital. Patients performing PST for > 3 m were invited to participate in PSM. INRs were collected from PSM and PST groups and used to calculate TTR, frequency of INR testing frequency, and testing adherence (did they check INR per guideline). A validated knowledge test was completed by patients year one and will be again at study end (Spring 2013) and scores compared. Patients performing self-testing with the health provider adjusting doses was used a control for TTR, testing frequency, knowledge. The study was ethics approved and consents obtained.

Results: One hundred and twenty patients (median age 8 years, range 1–16 years) were enrolled in the study with 60 children and their families in the PSM group. Patient enrollment was evenly distributed over the years 2008–2012 for both groups with all patients performing PSM for > 1 year. There was no difference in mean age and underlying cardiac conditions necessitating VKAT between groups. There were 1385 (PSM) and 1339(PST) INR tests performed. TTR was 87% (PSM) and 80% (PST) ($P = 0.03$) and mean testing frequency was 2.0 (PSM) / and 2.2 (PST) weeks. Independent adherence was 90% in the PSM group. The KIDCLOT© health provider received 85/1365 calls for support from PSM patients. VKA knowledge and testing competency data is currently underway and will be reported. PSM results were not significantly different than previously reported for patients performing PSM for ≤ 1 year. There were no adverse events or hospital admissions related to VKAT in either group.

Conclusions: PSM for children may be a safe and effective management strategy for warfarinized children and appears sustainable over time. In addition, the PSM method is a process which relies on the application of the VKAT education/training, further integration of this knowledge into practical translation into their daily life and thus empowers for the future.

OC 75.3

Thrombosis in children: further evaluation of incidence and resolution

Massicotte P[1], Bauman ME[1], Bruce AK[1], Shan S[2], Bauman M[1] and Bazjar L[2]

[1]Stollery Childrens Hospital, University of Alberta, Edmonton, AB; [2]University of Alberta, Edmonton, AB, Canada

Thrombosis in children most often occurs in children with life-threatening health conditions. The incidence of thrombosis in children is reported to be highest among infants ≤ 1 year of age and is associated with severe sequalae including loss of venous access. Thrombus resolution has not been adequately explored in children and is reported to be only 22% among adults. In these children central vascular access is essential to their survival. Consequently, anticoagulation is commonly used to prevent extension thereby allowing fibrinolysis. Determination of thrombus resolution may influence duration of therapy.

Aims: To evaluate the resolution of symptomatic line related thrombosis in children.

Methods: This single centre, quaternary care children's hospital, retrospective study included all pediatric patients objectively diagnosed with arterial or venous thrombosis from 2003 to 2012. Children with thrombosis, and available for follow-up, underwent repeat imaging to evaluate thrombus resolution at 2, 4 and 12 weeks post diagnosis. Intracerebral and intracardiac thrombi were excluded. Thrombosis was treated in 91% of this population. For analysis, children were divided into age groups consistent with developmental hemostasis (≤ 3 months 3.1–12 m, 1–5 years, 6–18 years). Thrombotic events were further subdivided into arterial and venous. Resolution was evaluated through objective diagnostic imaging to determine when complete resolution (CR) occurred. Medical records were reviewed to determine patient characteristics, first thrombotic event, and degree of resolution when available. Ethics approval was obtained.

Results: Five hundred and four children were diagnosed with arterial or venous thrombosis. 284(56%) were male. 234 (46%) had congenital heart disease. 232 (46%) infants were ≤ 3 months of age, 97 (19.2%) were aged > 3–12 months of age, 90 (17%) and 85 (17%) 1–5 years and ≥ 5–18 years respectively. Follow up imaging was available in 78% of all children. In infants ≤ 3 months of age full resolution occurred in 42/63(67%) and 57/117(49%) for arterial and venous thrombosis. Of

those, CR at 2, 4, 12 weeks was 14/42 (33%), 27/42(64%), 42/42 (100%) and 17/57 (30%), 29/57(51%), 52/57(91%), for arterial and venous thrombi respectively. In infants, > 3–12 months CR occurred in 18/22(82%) and 27/55(49%), for arterial and venous, respectively. Of those, CR at 2, 4, 12 weeks was 9/18(50%), 13/18(72%), 18/18 (100%) and 8/55 (15%), 12/55 (22%), 24/55 (44%) for arterial and venous thrombi, respectively. CR was not different between 1–5 and 6–17 years and was therefore combined. Of those, CR occurred in 15/21 (71%) and 63/116 (54%) by 12 weeks 14/15 (93%) and 49/63 (77%) for arterial and venous thrombosis, respectively.

Summary: This is the first report which defines the population with the highest incidence of thrombosis as infants' ≤ 3 months of age. Unlike older children and adults, CR occurred at 4 weeks for 64% and 41% of arterial and venous thrombosis for infants' ≤ 3 months, respectively. CR occurred at 4 weeks in 72% of arterial thrombi in infants' ≤ 12 months. Given this incidence of CR of thrombi at 4 weeks, imaging at 4 weeks should be considered if anticoagulation is ongoing. These findings validate the need for studies evaluating thromboprophylaxis. Well designed studies evaluating duration of therapy of are urgently needed.

OC 75.4

Traumatic lumbar punctures in children receiving low-molecular-weight heparin during treatment for acute lymphoblastic leukemia or lymphoma

Estepp JH, Smeltzer MP, Howard SC and Reiss M

St Jude Children's Research Hospital, Memphis, TN, USA

Background: Children with acute lymphoblastic leukemia (ALL) and lymphoma undergo numerous diagnostic and therapeutic lumbar punctures (LP). Traumatic LPs have decreased diagnostic value and may worsen clinical outcomes. Spinal hematoma is a rare complication, but can result in permanent neurologic injury. The risk of a traumatic LP and spinal hematoma may be increased in children who are on anticoagulation therapy after a treatment-related thrombotic event, but there is a paucity of data regarding optimal management of peri-procedural anticoagulation in children with leukemia or lymphoma undergoing LP.

Aims: To determine if peri-procedural anticoagulation utilizing a standard protocol increases the risk of traumatic LP or spinal hematoma in children undergoing treatment for ALL or lymphoma.

Methods: Following institutional ethics committee approval, the medical records of children younger than 19 years of age who were treated for ALL or lymphoma from 1/2004 through 10/2012 and who had a thrombosis treated with LMWH were reviewed. Standard institutional practice included holding low-molecular-weight heparin (LMWH) 24 h prior to LP, then resuming LMWH 24 h following the procedure. A traumatic LP was defined as at least 10 red blood cells per microliter of cerebrospinal fluid (CSF). Associations between categorical variables were evaluated via Fishers Exact test. Because multiple LPs per individual were analyzed, we accounted for the correlated nature of data via a statistical model with a binary response variable utilizing a binomial distribution (generalized estimating equation [GEE] model with PROC GENMOD in SAS v 9.2).

Results: A total of 139 children underwent 1794 LPs with valid CSF analysis, of which 19.0% (341/1794) were traumatic. Children were on therapeutic anticoagulation around the time of LP in 22.2% (398/1794) of the procedures. Traumatic LPs occurred in 12.1% (48/398) of procedures during LMWH therapy compared to 21.0% (293/1396) of procedures while not on anticoagulation ($P > 0.001$). After controlling for pre-procedural platelet count, age and accounting for intra-patient correlation, the incidence of traumatic LPs was still lower during LMWH therapy vs. LPs performed while patients were not on anticoagulation ($P = 0.02$). No spinal hematomas occurred in 398 LPs performed during LMWH therapy or in the 1396 LPs performed without anticoagulation.

Conclusions: In children with ALL or lymphoma, suspension of LMWH 24 h prior to and following lumbar punctures was safe. Adhering to this practice, children receiving therapeutic LMWH had no greater risk of traumatic LP or spinal hematoma compared to children not receiving anticoagulation. Whether a shorter interval without LMWH would be equally safe requires further study.

OC 76 – Platelet Signalling – II

OC 76.1

14-3-3? regulates the procoagulant function of platelets

Van Der Wal A[1], Cranmer SL*,[1], Ramshaw HS[2], Van der Wal E*,[1], Schoenwaelder M[1], Yuan Y[1], Gardiner E[1], Berndt MC[1], Andrews RK[1], Lopez AF[2] and Jackson SP[1]

[1]Australian Centre for Blood Diseases, Melbourne, Vic., Australia; [2]Centre for Cancer Biology/SA Pathology, Adelaide, SA, Australia

Background: The 14-3-3 family of signalling adaptor proteins regulate various important cellular functions including cell signalling, cell-cycle, proliferation and apoptosis through their interaction with proteins containing phosphoserine/threonine binding motifs. Numerous 14-3-3 family members have been identified in platelets, including the abundant 14-3-3ζ isoform, which has previously been implicated in regulating the adhesive and signalling function of Glycoprotein (GP)Ibα.

Aim: To investigate the role of 14-3-3ζ in regulating the haemostatic and prothrombotic function of platelets.

Methods: We have generated 14-3-3ζ-deficient mice and performed various platelet function studies in vitro, including platelet adhesion to von Willebrand factor (VWF), thrombus formation on collagen-coated surface and platelet aggregation. Also, we measured P-selectin expression, GPIIb-IIIa activation and phosphatidylserine (PS) exposure by flow cytometry following platelet stimulation by various agonists. Furthermore, we determined platelet life span by post-injection of sulpho-NHS biotin and quantified% CD41 & streptavidin-positive events after flow cytometry. To study arterial thrombosis in vivo, electrolytic injury of the carotid artery was induced in mice. Experiments were performed on 14-3-3ζ-deficient and Wild-type (WT) mice reconstituted with the bone marrow from WT and 14-3-3ζ-deficient mice, respectively. Additionally, venous thrombosis was investigated in the pulmonary embolism model, in which collagen plus epinephrine was injected intravenously into mice.

Results: Using a 14-3-3ζ-null mouse model, we have identified an important role for 14-3-3ζ in regulating the haemostatic and prothrombotic function of platelets in vivo. Unexpectantly, 14-3-3$\zeta^{-/-}$ platelets had no defects in GPIbα-mediated adhesion to VWF or thrombus formation at high shear on a collagen substrate in vitro. Also, the life span of platelets was unaffected by the deficiency in 14-3-3ζ. 14-3-3$\zeta^{-/-}$ platelets had subtle defects in platelet aggregation, P-selectin expression and integrin GPIIb-IIIaactivation by threshold concentrations of thrombin or PAR-4 peptide. However, platelet aggregation by ADP and collagen-related peptide (CRP) was unaffected by 14-3-3ζ deficiency. A major functional defect in 14-3-3$\zeta^{-/-}$ platelets was found in PS-exposure following stimulation with high concentrations of a combination of two potent platelet agonists, thrombin and CRP. This defect in agonist-induced PS-exposure was associated with decreased thrombin generation in vivo following collagen/epinephrine injection in 14-3-3ζ-null mice, leading to reduced pulmonary emboli and improved survival. 14-3-3ζ-deficient mice were also protected from arterial thrombotic occlusion following electrolytic injury to the carotid artery. This phenotype was reproduced in WT mice reconstituted with 14-3-3ζ-deficient haematopoietic cells, indicating that the thrombosis defect was likely to be related to altered platelet function.

Conclusion: These studies define an unexpected role for 14-3-3ζ in regulating the procoagulant function of platelets necessary for haemostasis and thrombosis.

OC 76.2

Kindlin-2 in platelets and in megakaryocytes: a possible role in β integrin activation

Ghalloussi D[1], Baccini V[1], Nurden AT[2], Alessi M-C[1] and Canault M[1]

[1]UMR Inserm1062 – INRA 1060 – Aix-Marseille University, Marseille; [2]LIRYC, Plateforme Technologique et d'Innovation Biomédicale, Hôpital X Arnozan, Pessac, France

Background: The kindlin family plays a crucial role by interacting with β subunits of integrins allowing conformational changes. The kindlin family is composed of three proteins, kindlin-1, -2, -3. Their importance in development and normal physiology is well established: kindlin-1 deficiency causes skin blistering (Kindler syndrome) and kindlin-3 deficiency causes the Leucocyte Adhesion Deficiency type III (LAD-III). The importance of kindlin-2 in adults is unknown since knockout mice die at early stage of embryogenesis most probably due to impaired cardiac development. The expression of kindlins was initially thought to be restricted to specific cell types and tissues. However, different kindlins have been described in the same cell type where they each have a specific function and cannot substitute for each other. In the hematopoietic lineage and more precisely in platelets and megakaryocytes, kindlin-3 is the predominant form. So far, kindlin-1 has not been described in platelets and evidence for the presence of kindlin-2 is limited.

Aim: To examine the presence and to determine the specific role of kindlin-2 in platelets and megakaryocytes.

Methods and Results: We first explored the presence of the three kindlins in platelets by western blot. As expected, kindlin-3 was found in platelets but to our surprise significant amounts of kindlin-2 was also detected. No expression of kindlin-1 was observed. To further confirm the presence of kindlin-2 and to avoid false positive due to cross reactivity of the kindlin antibodies, we analyzed platelet samples from a kindlin-3 deficient LAD-III patient. As expected, no kindlin-3 was detected whereas kindlin-2 was expressed as in control subjects. To test whether kindlin-2 in platelets could arise from synthesis in their precursors, we analyzed kindlin proteins and mRNA expression in three megakaryocytes cell lines (HEL, Meg-01 and CMK) after PMA-induced differentiation. Kindlin-2 and -3 mRNA and protein showed time-dependent increases as the cells differentiated. In contrast kindlin-1 was never detected.

To explore the subcellular localization of kindlin-2, permeabilized platelets and megakaryocytes cell lines adhering to fibrinogen were labeled with anti-kindlin-2 antibody. In undifferentiated megakaryocytes, kindlin-2 showed a diffuse cytoplasmic and nuclear localization. However, in differentiated cells, kindlin-2 appeared concentrated in focal adhesion plaques. The same kindlin-2 localization was observed in activated platelets. This suggests that upon activation, kindlin-2 most probably concentrate in areas where integrins are interacting with the fibrinogen matrix.

Using confocal imaging, we examined more closely whether kindlin-2 co-localized with integrins. Results obtained with fibrinogen-adhering Meg-01 showed that kindlin-2 indeed co-localize with the integrin ß3 subunit. This argues in favor of a possible role for kindlin-2 in either inside-out or outside-in signaling.

Conclusion: We have confirmed the presence of kindlin-2 in platelets and their precursors with an increased expression along megakaryocytic differentiation. We observed that upon cellular differentiation, kindlin-2 localizes in areas containing the integrin β subunit. To further investigate the precise function of kindlin-2 in platelet and megakaryocytes integrin activation, experiments of kindlin-2 overexpression and shRNA silencing are in progress.

OC 76.3

Protein kinase C mediates Rap1-dependent platelet aggregation in the absence of CalDAG-GEFI and P2Y12

Stefanini L[1], Paul DS[1], Getz TM[1], Beale A[1], Cholka A[1], Andre P[2], Stone JC[3], Conley PB[2] and Bergmeier W[1]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Portola Pharmaceuticals, San Francisco, CA, USA; [3]University of Alberta, Alberta, AB, Canada

Background: The small-GTPase Rap1 is a crucial mediator of platelet activation. In previous studies we have demonstrated that Rap1-dependent platelet activation is controlled by two kinetically distinct pathways: a fast but reversible calcium- and CalDAG-GEFI (CDGI, RasGRP2)-dependent pathway and a slower but more sustained pathway that requires protein kinase C (PKC)-dependent granule release and signaling through the Gi-coupled ADP receptor, P2Y12. Simultaneous inactivation of CDGI and P2Y12 in mice completely blocked thrombus formation at sites of vascular injury and abolished Rap1-dependent integrin activation in platelets stimulated by various agonists *in vitro*. Aggregation of platelets lacking both CDGI and P2Y12 was only observed in samples stimulated with high doses of thrombin or PAR4 receptor activating peptide.

Aim: In this study we sought to determine if CalDAG-GEFIII (CDGIII, RasGRP3), the only other Rap1-GEF of the CalDAG-GEF family expressed in platelets, and/or PKCs can activate Rap1 independently of CDGI and P2Y12/Gi signaling.

Methods: To dissect the pathways upstream of Rap1, pharmacological inhibitors were used in combination with genetically engineered mouse models. Integrin activation and granule secretion (surface P-selectin) were assayed by flow cytometry and standard aggregometry. To compare the kinetics of Rap1 and integrin activation, washed platelets were stimulated in stirring conditions and Rap1 GTP-loading was measured by pull-down assay directly from the aggregometry samples.

Results: Stimulation with high doses of Par4-activating peptide led to delayed Rap1 signaling, integrin activation, and granule release in platelets from mice lacking both CDGI and P2Y12 (CDGI/P2Y12-DKO). All responses were not affected in platelets deficient in CDGIII. Furthermore, Rap1-dependent platelet activation was not significantly different in PAR4p-activated CDGI/III-DKO platelets when compared to CDGI−/− platelets, both in the presence or absence of the P2Y12 inhibitor 2-MeSAMP. Thus, CDGIII does not regulate Rap1 activation in platelets. In contrast, inhibition of PKC signaling (pan-PKC inhibitor Ro-31-8220) completely abolished Rap1 and integrin activation in PAR4p-activated CDGI−/− or CDGI/P2Y12-DKO platelets. Consistently, stimulation with the diacylglycerol-mimetic PMA, a direct activator of PKCs, led to delayed aggregation and Rap1 activation in CDGI/P2Y12-DKO platelets. Importantly, CDGI/P2Y12-DKO mice were only partially protected from thromboplastin-induced pulmonary thromboembolism, suggesting that this PKC-dependent third pathway of Rap1 activation may have patho-physiological significance.

Conclusions: In summary, we demonstrate a direct role for PKC, but not CDGIII, in the activation of Rap1 in platelets. This new pathway signals with slow kinetics and requires markedly higher agonist concentrations than CDGI- or P2Y12-dependent Rap1 activation, suggesting that it functions in patho-physiological situations other than platelet adhesion and aggregation at sites of vascular injury.

OC 76.4

Grb2 is essential for (hem)ITAM-mediated signalling in platelets

Dütting S[1], Vögtle T[1], Morowski M[1], Schäfer C[1], Ackermann JA[2], Radtke D[2], Hermanns HM[1], Nitschke L[2] and Nieswandt B[1]

[1]University of Würzburg, Würzburg; [2]University of Erlangen, Erlangen, Germany

Background: Platelet activation by GPVI is a prerequisite for platelet adhesion to collagen and the LAT signalosome, composed of different

signalling and adapter proteins, plays an important role in mediating this activation. Growth factor receptor-bound protein 2 (Grb2) is an ubiquitously expressed adapter protein and plays a prominent role in signalling processes of numerous receptors in different cell types by either amplifying or inhibiting signal transduction. Based on *in vitro* studies it has been proposed that the Grb2/SOS/MEK pathway is of central importance for megakaryocyte (MK) differentiation. In platelets, Grb2 is part of the LAT signalosome and becomes tyrosine-phosphorylated after GPVI ligation, indicating a possible role of the adapter in GPVI signalling. However, the exact role of Grb2 in platelet production and function has remained elusive.

Aims: We tested the hypothesis that Grb2 is an essential adapter protein in (hem) immunoreceptor tyrosine-based activation motif (ITAM) signalling in platelets.

Methods: Platelet function was assessed in mice with a conditional (PF4-Cre/loxP) deficiency of Grb2 in MKs and platelets by using flow cytometric analysis of cellular activation processes, aggregometry and flow adhesion systems. GPIIb/IIIa-mediated outside-in signalling was analysed by performing platelet spreading and measurement of clot retraction. *In vivo* function of platelets was studied in models of arterial thrombosis using intravital microscopy and haemostatic function was analysed by determination of tail bleeding times.

Results: We show that ablation of Grb2 in MKs did not interfere with MK differentiation or platelet production. However, Grb2 deficiency severely impaired GPVI-mediated platelet activation due to defective activation of phospholipase (PL) Cγ2 and Ca^{2+} mobilisation resulting in reduced adhesion, aggregation and coagulant activity on collagen *in vitro*. Similarly, CLEC-2-mediated signalling was impaired in Grb2-deficient platelets, whereas the cells responded normally to stimulation of G-protein coupled receptors (GPCR). Interestingly, in platelets, Grb2 acts downstream of Syk by linking the LAT signalosome to the GPVI receptor complex and Grb2-deficiency abrogated specifically ERK1/2 activation, whereas p38 and JNK activation were unaffected. *In vivo* this selective (hem)ITAM signalling defect resulted in prolonged bleeding times but affected arterial thrombus formation only after concomitant treatment with acetylsalicylic acid, indicating that defective GPVI signalling in the absence of Grb2 can be compensated through thromboxane A_2-induced GPCR signalling pathways.

Summary/Conclusion: These results reveal for the first time a crucial role of Grb2 in (hem)ITAM signalling in platelets in haemostasis and thrombosis, while it is dispensable for platelet production.

OC 77 – RNA and Coagulation

OC 77.1

Factor XI mRNA is spliced upon platelet activation

Zucker M, Hauschner H, Seligsohn U and Rosenberg N
Sheba Medical Center, Ramat Gan, Israel

Background: Platelets circulate in blood as anucleated cells yet contain spliceosome components and pre-mRNAs. Upon activation, platelets excise introns from pre-mRNAs yielding mature messages that are translated to proteins. Such signal-dependent splicing process has been demonstrated so far for three platelet proteins: IL-1β, cox-2 and tissue factor. Previous studies of platelet factor XI (FXI) yielded conflicting data regarding platelet FXI; some laboratories reported presence of mature FXI mRNA while others only found aberrant FXI mRNA that contained introns or skipped exons. Conceivably, these differences resulted from different degrees of platelets activation when mRNA was extracted.

Aim: To investigate whether platelet FXI pre-mRNA undergoes splicing upon platelet activation and yielding mature FXI mRNA that is translated to FXI.

Methods: Platelets were separated from blood of healthy volunteers in citrate and were washed gently in the presence of inhibitors such as PGE, Ibmax, and apyrase. Platelet mRNA was extracted from resting platelets and from platelets activated by thrombin or ADP as well as from partially activated platelets in which the fibrinogen receptor ($\alpha IIb\beta_3$) was activated without α-granules secretion. This partial activation was accomplished by using low concentrations of fibrinogen and manganese ions. The mRNA was reverse-transcribed to cDNA by random primers. Splicing patterns of the cDNA from activated, partially-activated or resting platelets were compared by PCR and agarose gel-electrophoresis. The presence of alpha-IIb message served as a positive control. FXI protein levels in activated or resting platelets were measured by ELISA using specific FXI antibodies.

Results: Both activated and resting platelets displayed FXI pre- as well as mature mRNA. Platelet activated by thrombin or ADP exhibited higher levels of mature FXI mRNA than resting platelets separated in the presence of inhibitors. The resting platelets contained increased levels of FXI pre-mRNA, including introns, compare to activated platelets. Levels of control alpha-IIb mature mRNA were similar in activated, partial-activated and resting platelets. The increased FXI mRNA splicing was not exhibited following partial platelet activation in which integrin $\alpha IIb\beta_3$ was activated without platelet α-granules secretion using low concentrations of fibrinogen and Manganese ions. FXI protein levels were also higher in activated platelets compared to inhibited platelets.

Summary: Mature mRNA of FXI as well as FXI protein are increased following platelet activation. Our data suggest that platelet FXI is the 4th protein whose pre-mRNA is spliced upon platelet activation. These results can explain previous publications in which different platelet FXI mRNAs were found. Conceivably, FXI that is produced in platelets upon their activation contributes to clot formation.

OC 77.2

The role of microRNA in the pathogenesis of venous thromboembolism

Starikova I[1], Jamaly S[1], Sovershaev M[1], Blondal T[2], Sorrentino A[2] and Hansen JB[1]
[1]*University of Tromsø, Tromsø, Norway;* [2]*Exiqon, Vedbaek, Denmark*

Background: Microparticles (MPs) are small circulating membrane microvesicles which form via budding from surface of activated or apoptotic cells. MPs contain cytoplasmic content of parental cell, including regulatory RNA molecules, such as microRNA (miRNA), which are 20–25 nucleotide-long single-stranded RNAs that can induce degradation or inhibit the translation of one or several messenger RNA (mRNA) molecules. This will ultimately alter gene expression and modify cell functions. As part of inter-cellular communication, miRNAs could be transferred within MPs from the parental to target cell through adhesion and fusion of MPs to the specific cell type via specific receptors expressed on the surface of MPs. In plasma, miRNAs are located in MPs or bound to protein complexes (e.g., Ago2, NPM1). No study has so far investigated plasma levels of miRNAs in unprovoked venous thromboembolism (VTE).

Aims: The present study was undertaken to determine plasma levels of miRNAs in patients with unprovoked VTE.

Methods: A case-control study was performed in 20 patients with a history of incident unprovoked VTE 1–5 years prior to inclusion in the study, and 20 age- and sex-matched healthy controls recruited from the general population. RNA was isolated from citrated plasma using an improved variant of a column-based kit (miRNeasy kit, Qiagen, USA) including MS2 as a carrier RNA and thereafter successfully reverse transcribed (RT) into cDNA using miRCURY LNA™ Universal RT kit (Exiqon, Denmark). Profiling of miRNA from plasma was carried out by a SYBR-based quantitative PCR system assessing 743 miRNAs (The miRCURY LNA[TRADEMARK] Universal RT microRNA system, Exiqon, Denmark). For normalization of the data, we applied the average of the assays detected in all samples (n = 40 samples). Student's t test was used to evaluate differences between groups and a two-sided P-value below 0.05 was considered significant. The

study was approved by the regional committee for research ethics, and all participants gave their informed written consent to participate.

Results: VTE patients had higher BMI (28.3 ± 4.4 vs. 26.3 ± 3.9 kg/m^2, $P = 0.045$) and greater waist circumference (98.2 ± 12.5 vs. 93.4 ± 13.4 cm, $P = 0.041$) than age and sex matched controls. Signals of high quality from 73 miRNAs were identified in all samples, and several significant differences in levels of miRNAs were observed between the groups (p-values > 0.05). Interestingly, we found higher plasma levels of miR-10b ($P > 0.001$), miR-320b ($P = 0.002$) and miR-126 ($P = 0.02$) in plasma of patients with unprovoked VTE relative to healthy control individuals.

Conclusions: Our findings suggest that miR-10b, miR-320b and miR-126 are novel biomarkers of unprovoked VTE. Previous experimental studies have suggested that miR-10b and miR-126 are involved in regulation of endothelial cell functions and angiogenesis, whereas miR-320 has been associated with arterial cardiovascular risk factors and diseases. A nested case-cohort study will be performed to determine whether these miRNAs are a potential cause of unprovoked VTE rather than a consequence of the disease (reverse causation).

OC 77.3

Transfection of siRNA in human blood platelets: a high efficiency method for the horizontal transfer of siRNA from platelets to human monocytes and endothelial cells

Malvestiti M, Bury L, Marturano A, Petito E, Momi S and Gresele P

University of Perugia, Perugia, Italy

Background: Platelets contain messenger RNAs (mRNA) and are capable of protein synthesis. Platelets also contain a diverse array of microRNAs (miRNA) and its machinery (Dicer, Argonaute2). Preliminary data suggest that platelets and platelet-derived microparticles may transfer RNAs to other acceptor cells upon direct contact.

Aims: To develop an efficient method for the transfection of human platelets with siRNA and to assess whether the transfected siRNA can then be transfered to other cells.

Materials and Methods: We have developed a new method for the efficient transfection of siRNA to washed human platelets. siRNA transfection efficiency was assessed by using a fluorescent TYE563-labeled siRNA and flow cytometry. Platelet-derived microparticles (PMP) were generated by stimulating transfected platelets with Thrombin (1 U/mL) and TYE-563-labeled siRNA transfection in PMP was analysed by flow cytometry. mRNA expression in monocytes and in endothelial cells after co-incubation with siRNA transfected platelets was assessed by Real-Time PCR.

Fluorescent-labeled siRNA-transfected human platelets were resuspended in PBS at 10^9/ml and injected in NOD-SCID mice; 24 h later blood was sampled and siRNA fluorescence was assessed in murine monocytes by flow cytometry.

Results: We obtained a high siRNA transfection efficiency (97%) within 5 min of incubation with the siRNA of interest.

We also showed that the TYE563-labeled siRNA previously transfected into human platelets was transferred to platelet derived microparticles with high efficiency (96%).

We then co-incubated human monocytes with siRNA-transfected platelets for 4 h and observed that 15.8% of monocytes became positive for TYE563-labeled siRNA.

Similarly, human endothelial cells (HUVEC) co-incubated for 6 h with siRNA transfected PMPs resulted positive for TYE563 labeled-siRNAs (38%).

Human platelets transfected with fluorescent-labeled siRNA and injected in NOD-SCID mice persisted in the bloodstream for up to 48 h.

Mouse monocytes from mice injected 24 h earlier with siRNA-transfected human platelets showed siRNA fluorescence (7.1%).

Human monocytes coincubated for 24 h with platelets transfected with DICER-substrate siRNA directed against Tissue Factor mRNA show a strong downregulation of TF mRNA (more than 80%).

Conclusions: We have developed a novel, highly efficient method for the transfection of siRNAs into platelets.

We have also shown that siRNAs transfected in human platelets can be transferred to other cells (monocytes, HUVECs) with which platelets get into contact.

The persistence of transfected siRNAs within platelets transfused *in vivo* and the capacity of siRNA to pass into platelet-derived microparticles and then to be transfered to other cells in the bloodstream and/or in the vessel wall, may allow to interfere with genes of interest *in vivo* in various thrombotic or inflammatory diseases.

This new method allows to silence specific mRNAs involved in disease, and opens new possibilities for therapy.

OC 77.4

Downregulation of protein S by oestrogens and miR-494

Tay J[1], Romeo G[2], Hughes Q[2] and Baker R[3]

[1]Centre of Thrombosis and Haemophilia, Murdoch University, Murdoch; [2]Royal Perth Hospital, Perth; [3]Centre for Thrombosis and Haemophilia, Murdoch, WA, Australia

Background: Acquired Protein S (PS) deficiency is highly associated with elevated circulating oestrogen levels resulting from pregnancy, where levels of circulating oestradiol progressively increase to > 10-fold by the third trimester, and functional activities of PS also shown to decrease throughout pregnancy, contributing to an overall procoagulant shift. Increasing evidence indicate that activation of the oestrogen receptor (ER) signalling by oestrogens, modulates the expression of target genes indirectly by regulating the expression of miRNAs. We hypothesise that elevated circulating oestrogen levels result in the altered expression of specific microRNAs leading to acquired PS deficiency, and propose that oestrogen-regulated microRNAs are secreted from oestrogen-responsive tissues, transported in microparticles to the liver and endothelial cells to downregulate PS expression.

Methods: Computational analysis of *PROS1* 3′ untranslated region (UTR) identified multiple binding sites for miR-494, and direct targeting of *PROS1*-3′UTR by miR-494 was determined by dual luciferase reporter assays in HuH-7 and HeLa cells. Reporter vectors containing the *PROS1*-3′UTR sequence with deleted miR-494 binding sites were also analysed by luciferase reporter assays. Effects of oestrogen on miR-494 and *PROS1* mRNA levels in HuH-7 cells were determined by quantitative real-time PCR (RT-qPCR), and oestrogen-mediated changes to secreted PS levels in culture supernatant of HuH7 cells were measured using an enzyme-linked immunosorbent assay (ELISA). To analyse miR-494 expression in human plasma, miR-494 levels were determined by RT-qPCR from different fractions of ultracentrifuged human platelet-poor plasma samples.

Results: Research in the laboratory has demonstrated that miR-494 directly targets *PROS1* and miR-494 levels are upregulated following oestrogen treatment in Huh7 liver cells in association with downregulated *PROS1* mRNA and PS levels. In addition, the expression of miR-494 was also found to be concentrated in the microparticle-containing fraction of ultracentrifuged plasma.

Summary/conclusions: These results strongly suggest that oestrogen modulation of miR-494 expression and subsequent downregulation of PS expression by miR-494 is a mechanism contributing to oestrogen-mediated acquired PS deficiency. Ongoing work is investigating the clinical relevance of miR-494 expression, the mechanism of miR-494 transport by microparticles in circulation, as well as the characterisation of oestrogen-responsive miRNAs in pregnant women with elevated oestradiol levels and low PS levels, to establish the role of miRNAs in acquired PS deficiency.

OC 78 – Thrombophilia – I

OC 78.1

Reducing inpatient heritable thrombophilia testing using a clinical decision-making tool

Smith TW, Pi D, Hudoba M, Pal J and Lee AYY
University of British Columbia, Vancouver, BC, Canada

Background: The presence of heritable thrombophilia (HT), including factor V Leiden (FVL), prothrombin gene mutation, and deficiencies of antithrombin (AT), protein C (PC) and protein S (PS), does not have any impact on acute management of thrombotic diseases and the functional assay results can be unreliable during the acute event and while on anticoagulation. Consequently, testing for HT in patients admitted to hospital with an acute thrombotic event is of questionable clinical value. Prevalence of HT testing in the hospital setting has not been reported and a clinical decision-making tool to guide appropriate testing has not been developed.
Aims: To assess the effect of a clinical decision-making tool on the volume, pattern and cost of HT testing in a tertiary care teaching hospital.
Methods: We developed a clinical decision tool to guide HT testing in patients admitted to a tertiary care center and introduced it in a preprinted order (PPO) form. This form discouraged HT testing in patients with arterial or recent (i.e. $\leq$ 3 months) thrombosis and in those receiving anticoagulant therapy. HT testing was only performed if the PPO was completed by the ordering physician. Electronic laboratory records of FVL testing performed on inpatients were collected for 3 years prior to and 3 years following the PPO intervention. Results were compared with HT testing data from two other regional teaching hospitals affiliated with the same university. Records for AT, PC, and PS activity assays were also collected to confirm the FVL data trends. Cost savings was estimated based on reagent and staffing costs directly associated with HT testing.
Results: Between Jan 2007 and Dec 2009, 607 FVL tests were performed. Following the PPO introduction in Jan 2010 until Dec 2012, 257 FVL tests were performed and 80 FVL orders were cancelled due to the PPO not being completed. The FVL test volume reduction of 79.4% was significantly greater compared to those in the two control teaching hospitals over the same time periods (33.7% and 43.6%; both $P > 0.001$). There was a steep decline in FVL testing following the introduction of the PPO and the effect was maintained for the three subsequent years. Reductions in FVL testing post-intervention was observed amongst all specialists, including neurologists and general internists who together accounted for 64.3% of FVL testing overall. Hematologists accounted for only 2.8% of FVL testing. Similar post-intervention reductions in testing volumes were observed for AT (57.4%), PC (61.9%), and PS (62.2%) activity assays. The mean annual costs directly associated with HT testing decreased from $13,770.41 to $3635.80 after the implementation of the PPO, for a mean net savings of $10,134.60 annually.
Summary: In a large tertiary care hospital, the introduction of a clinical decision-making tool significantly reduced HT testing in inpatients by all clinician specialties, leading to considerable cost-savings. The impact on patient outcome should be assessed in further studies.

OC 78.2

New diagnostic considerations based on the experience of genetic analysis in Protein C deficiency

Bereczky Z, Kovács K, Ilonczai P, Gindele R, Boda Z, Pfliegler G, Muszbek L and Bereczky Z
Medical and Health Science Center, University of Debrecen, Debrecen, Hungary

Background: Protein C (PC) is a vitamin K-dependent glycoprotein, which inactivates active factor VIII and factor V (FV). PC deficiency confers a high thrombosis risk and it is classified as type I (quantitative) and type II (qualitative) disorder. A number of distinct mutations causing PC deficiencies have been discovered so far. Screening for PC deficiency in the hemostasis laboratory is executed by clotting or chromogenic functional tests. Both methods have several disadvantages. FV Leiden mutation (FVL) interferes with the clotting assay leading to low PC activity. Since the PC antigen determination (ELISA) is not influenced by FVL, patients carrying this mutation seem to have type II PC deficiency. Chromogenic tests do not suffer from this problem, however they may not detect some type II cases with certain mutations. Most of the guidelines recommend to use the chromogenic assay in order to bypass the interfering effect of FVL and other analytical errors caused by prolonged or shortened clotting time in certain cases.
Aims: To evaluate the functional clotting and chromogenic PC assays from the point of view of FVL interfering effect and to determine the mutation spectrum of PC deficiency in a high number of patients representing the Hungarian population.
Methods: Non-related individuals having 70% or lower PC activity measured by the clotting test were recruited (n = 109). PC activity was determined by both the clotting (Protein C reagent, Siemens) and the chromogenic (Berichrom Protein C kit, Siemens) method. PC antigen was measured by ELISA (Asserachrom Protein C, Diagnostica Stago). The gene coding PC (PROC) was analyzed by direct DNA sequencing. Second-line evaluation of PROC was performed by MLPA method in cases where the presence of larger genetic abnormality was assumed. FVL mutation was determined by real-time PCR and melting curve analysis.
Results: Most of the patients with low PC clotting activity were carriers of the FVL (n = 72). Among non-carriers 27 patients had causative mutation(s) in PROC identified by DNA sequencing (12 type I and 15 type II deficiency). Among type II deficients four patients showed normal result in the chromogenic test. In addition, two novel gross deletions were found by MLPA analysis (delE1-3 and delE1-9) leading to type I deficiency. It was observed that 78.4% of FVL negative patients had causative mutations in the PROC gene and only 12.5% of FVL carriers were positive for PROC mutation. In this latter group 2 patients with FVL and PROC mutation had normal PC activity in the chromogenic test. Altogether 28 different mutations were detected including 15 novel ones.
Conclusions: Based on our results three important considerations can be made: 1, Since chromogenic functional test gives normal result in some genetically confirmed PC deficient patients, clotting assay should not be bypassed. 2, DNA sequencing of PROC cannot be omitted in FVL carrier patients with low PC clotting activity and normal PC antigen. 3, MLPA method is required in 'sequencing negative' cases as second line genetic diagnostic tool.

OC 78.3

Antithrombin Debrecen (p.Leu173Pro): clinical and molecular characterization of a novel mutation associated with severe thrombotic tendency in a large pedigree

Selmeczi A, Oláh Z, Bereczky Z, Gindele R, Ilonczai P, Schlammadinger A, Rázsó K, Muszbek L and Boda Z
University of Debrecen Medical and Health Science Center, Debrecen, Hungary

Background: Hereditary antithrombin (AT) deficiency is a rare but major risk factor for venous thromboembolism. It is classified as type I (quantitative) and type II (qualitative) deficiency and caused by mutations in the SERPINC1 gene encoding AT. The genetic background is heterogeneous and different sub-types of type II AT deficiency are known according to the site of mutation.
Aims: The goal of this research was to characterize the molecular features of a novel mutation that was found in a populous family. We

wanted to determine the severity of the mutation's clinical consequences by conducting a detailed family investigation.
Methods: Thirty family members of four lineal generations were included in the family study. The age at the first thrombotic event, the type and location of the thrombosis, the recurrent thrombotic episodes, and the co-existing provoking factors and acquired conditions were determined in every family member. All the laboratory investigations for thrombophilia were carried out. AT activity was measured by a commercially available heparin cofactor activity assay, AT antigen was determined by immunonephelometry. The mutation was identified with fluorescent direct DNA sequencing of the SERPINC1 gene. HEK293 cells were transfected with constructs containing wild type and mutant SERPINC1 plasmids. Transfection efficiency was determined by beta-galactosidase co-transfection. Immunoprecipitation followed by Western blotting was used to visualize the presence or absence of the mutant AT in the cell lysates and in the conditioned media. The quantity of the expressed AT protein was measured by ELISA. Chromogenic test in the presence or absence of heparin using activated FX as substrate was used to measure the activity of the expressed AT.
Results: We found ten affected patients in the family and all of them suffered from venous thromboembolisms in their lives except two teenage boys in the youngest generation. In six cases the thrombosis was recurrent. Two of the patients died of pulmonary embolism, one of them at the age of 19. The average age at the time of the first thromboembolic episode was 36.5 years. The average AT activity of affected patients was 57% and the genetic analysis revealed a novel AT mutation (p.Leu173Pro). Classification of the new mutation was uncertain due to the inconclusive antigen results. Wild type and mutant AT were expressed in HEK293 cells and it was demonstrated that after synthesis a small amount of mutant AT (28% of wild type) was secreted by the cells. The majority of the mutant protein was trapped intracellularly. Activity of the secreted mutant AT was somewhat decreased.
Conclusion: Studying a large AT deficient family a novel mutation was found. The clinical data suggested that the mutation was associated with severe thrombotic tendency that manifested in early ages. The p.Leu173Pro mutation did not influence the synthesis of AT but led to severe secretion defect, probably because of major structural changes and deviation from the normal secretory pathway.

OC 78 – Thrombophilia – I

OC 78.4

A clinical laboratory test detecting antithrombin-resistance of the new thrombophilia

Murata M[1], Takagi A[1], Suzuki A[1], Takagi Y[1], Ando Y[1], Kato I[1], Murate T[1], Matsushita T[2], Saito H[3] and Kojima T[1]
[1]Nagoya University Graduate School of Medicine; [2]Nagoya University Hospital; [3]National Hospital Organization-Nagoya Medical Center, Nagoya, Japan

Background: We have reported a novel mutation of the prothrombin gene (c.1787G>T, p.Arg596Leu: prothrombin Yukuhashi) conveying antithrombin-resistance in the patient with hereditary thrombosis. The antithrombin-resistant thrombin may have prolonged procoagulant activity *in vivo*, conferring a susceptibility to thrombosis. Current laboratory tests, however, cannot detect the pathological condition, such as antithrombin-resistance.
Aims: In order to detect an antithrombin-resistant condition in plasma, we developed a new clinical laboratory assay. We further aimed to identify and verify the frequency of antithrombin-resistance by analyzing plasma samples from the patients with venous thromboembolism of unknown cause.
Methods: We prepared reconstituted plasma by mixing prothrombin-deficient plasma with recombinant prothrombin (wild-type or mutant). The assay consists of three steps; thrombin generation, thrombin inactivation, and determination of residual thrombin activity. In the first thrombin generation step, we used *Oxyuranus scutellatus* venom or bovine Factor Xa (FXa) with factor Va (FVa) as prothrombin activator. In the second step, we inactivated thrombin by addition of antithrombin in the presence or absence of heparin. Inactivation times with heparin and without heparin were 0–5 and 0–30 min, respectively. In the final step, we measured the residual thrombin activity using chromogenic synthetic substrate (S-2238). We determined the optimum measurement conditions; pH, osmotic pressure, concentrations of antithrombin, chromogenic substrate and each component of the prothrombin activator (snake venom, FXa, FVa, phospholipids, $CaCl_2$), and reaction time of each step. We also verified normal and warfarinized patient's plasma samples by this optimized procedure.
Results: We diluted the samples 1:100 by the dilution buffer, and incubated with optimized concentrations of prothrombin activator components (phospholipid, calcium chloride, snake venom or FXa/FVa) at 37 °C for 2 min. After addition of antithrombin with or without heparin, we added sufficient amounts of S-2238 and measured the change in absorbance/min (delta A/min) at 405 nm. The relative residual activity of recombinant mutant thrombin after 5 min inactivation with heparin showed an obvious poor inactivation (40%) compared with that of recombinant wild-type thrombin (0.5%). After 30 min inactivation without heparin, the relative residual activity of recombinant wild-type thrombin in the reconstituted plasma was 18%, whereas that of recombinant mutant thrombin was 97%. These data indicated that this assay obviously detected the antithrombin resistance of mutant Arg596Leu prothrombin in plasma. Actually, the assay for 5 min inactivation with heparin demonstrated that the relative residual thrombin activity of the warfarinized patient's plasma with prothrombin Yukuhashi (14%) was clearly higher than that of the normal plasma (0.5%). So far, we further analyzed plasma samples of several unrelated Japanese patients with venous thromboembolism of unknown cause, but none of the patients showed antithrombin-resistance.
Summary/conclusions: We devised a method for analyzing thrombin inactivation kinetics in plasma. This assay was useful for detecting antithrombin-resistance of prothrombin Yukuhashi, even when taking warfarin.

OC 79.1

Safety, tolerability, and pharmacokinetics of edoxaban in end-stage renal disease subjects undergoing hemodialysis

Parasrampuria D[1], Matsushima N[2], Chen S[1], Wickremasingha PK[3], He L[1], Dishy V[1] and Brown K[1]
[1]Daiichi Sankyo Pharma Development, Edison, NJ, USA; [2]Daiichi Sankyo, Tokyo, Japan; [3]Certified Consultant Pharmacists Inc, Chatham, NJ, USA

Background: Edoxaban, a direct factor Xa inhibitor, is currently under development as a once-daily oral anticoagulant for stroke prevention in atrial fibrillation, and for the treatment and prevention of recurrences of venous thromboembolism. Renal elimination accounts for approximately 50% of the total clearance of edoxaban.
Aims: Since subjects with end-stage renal disease (ESRD; with or without hemodialysis) may receive edoxaban, this study examined the safety, tolerability, and pharmacokinetics of edoxaban and its metabolites in subjects undergoing hemodialysis to provide dosing guidance.
Methods: This was an open-label, 2-treatment, 2-way crossover study in subjects with ESRD maintained on a stable regimen of thrice-weekly hemodialysis for at least 3 months. Subjects with recent major bleeding, trauma, any type of surgery ≤ 6 months prior, or with hemoglobin > 10.0 g/dL were excluded. Subjects were randomized to receive a single oral dose of edoxaban 15 mg on two occasions: edox-

aban dosed 2 h prior to a 4 h hemodialysis session (with hemodialysis), and edoxaban dosed on a day when subjects were not undergoing hemodialysis (without hemodialysis). There was a minimum washout of 7 days between doses. Serial blood samples were collected for quantification of edoxaban and four metabolites. Edoxaban was also measured in the dialysate. *In vivo* plasma protein binding was evaluated at 2 time points on each treatment day. Safety assessments included physical exam; vital signs; adverse events; and clinical labs, including coagulation parameters.

Results: Ten subjects (seven males, three females) were enrolled, and nine subjects completed both treatment periods. When administered without and with hemodialysis, edoxaban exposures were comparable ($AUC_{0\text{-inf}}$, 692 ± 150 and 676 ± 221 ng h/mL, respectively). Hemodialysis had minimal effects on the clearance of edoxaban, with total clearance values of 24 vs. 23 L/h with and without hemodialysis. Hemodialysis clearance was only 6 L/h. Thus, subjects undergoing hemodialysis may not need edoxaban dose adjustments to compensate for drug loss via hemodialysis. This also indicates that hemodialysis is not an effective mechanism for removal of edoxaban from the blood. Hemodialysis had minimal effect on the total exposure of the human-specific active metabolite, M-4, with metabolite-to-parent ratios of 25% vs. 22% with and without hemodialysis (compared to > 10% in healthy subjects). The plasma protein binding for edoxaban was similar with and without hemodialysis and ranged from 60% to 63%. This was similar to previously reported values in healthy subjects. Thus, renal impairment does not appear to affect plasma protein binding of edoxaban. In subjects with ESRD, the metabolite profile was different from healthy adults, with higher levels of M-4 and M-1, indicating that when renal clearance is compromised, edoxaban clearance through metabolism plays a larger role in the total clearance of edoxaban. Single oral doses of 15 mg of edoxaban were well-tolerated with only mild adverse events.

Conclusions: Data from this study indicate that additional dose adjustment is not necessary for edoxaban when ESRD subjects are undergoing hemodialysis, and hemodialysis is not an effective mechanism of removal of edoxaban from the blood.

OC 79.2

Apixaban: determination of its anticoagulant effects and influence on coagulation tests: a multicentre French GEHT study

Gouin-Thibault I[1], Flaujac C[2], Quenet S[3], Horellou MH[2], Delavenne X[3], Lacarrière N[4], Lecompte TP[5] and On behalf of the 13 centers[6]

[1]Hopital Cochin- (AP-HP) – Université Paris Descartes; [2]Department of Hematology, Hopital Cochin (AP-HP), Paris; [3]Department of Pharmacology, CHU Saint-Etienne, Saint-Etienne; [4]Department of Hematology, Hopital Hotel Dieu (AP-HP), Paris, France; [5]Department of Hematology, Hopitaux Universitaire de Genève, Genève, Switzerland; [6]GEHT, France, France

Background: Apixaban, a new oral anti-Xa inhibitor, was approved recently for venous thromboprophylaxis following major elective orthopaedic surgery and for stroke prevention in patients with non-valvular atrial fibrillation. While laboratory monitoring is not required, measurement of the anticoagulant activity may be useful in certain situations (urgent surgery, major bleeding, and frail patients). We have recently shown that PT (prothrombin time) and aPTT (activated partial prothrombin time) are not suitable to detect therapeutic plasmatic concentrations of apixaban. Therefore specific tests to measure apixaban concentrations are required.

Aims: The objective of this multicentre *in vitro* study was to determine the reliability and the variability of specific anti-Xa activity assays and of PT and aPTT measurements in plasmas samples containing various concentrations of apixaban.

Methods: Five blinded plasma samples (A, B, C, D, E) spiked with 0, 100, 200, 400 and 800 ng/mL apixaban were dry-ice shipped to 13 laboratories. The apixaban concentration in the samples was determined by HPLC tandem mass spectrometry. Each laboratory was supplied with anti-Xa and PT reagents and sets of apixaban calibrators and controls (Stago). Three chromogenic assays were assessed (Results ng/mL): Biophen heparin LRT® (Hyphen Biomed) in all laboratories, STA-Liquid-Anti-Xa® (Stago) in laboratories using a STAR instrument and HemosIL Heparin Liquid® (Instrumentation Laboratory [IL]) in those using an ACL-Top. Each assay was performed according to a standardized protocol. Plasma with apixaban concentration > 500 ng/mL was 1/3 diluted in normal pool plasma. PT were measured using RecombiPlastin 2G® (IL) and the local reagent, and aPTT using the local reagent (Results ratio of clotting times). The study was performed over five consecutive days. A calibration curve was generated every day for each anti-Xa assay and all measurements were in duplicate.The results are expressed as mean ± SD. Accuracy and precision of anti-Xa assay were assessed.

Results: The actual apixaban concentrations in the A-E plasmas were 0, 96, 209, 393 and 828 ng/mL. In samples A, B, C, D, E and E 1/3, the anti-Xa concentrations regardless of the assay used, were 7 ± 8, 90 ± 8, 197 ± 17, 393 ± 22, 695 ± 97 and 270 ± 24 ng/mL, respectively. Accuracy and precision for each assay were high for plasmas B to E. In plasma A, free of apixaban, mean anti-Xa were > 15 ng/mL in 10 laboratories; and over 15 ng/mL in three out of the four laboratories using the Biophen heparin® with ACL-Top. The PT and aPTT inter-laboratory reproducibility was high both with the centrally provided PT reagent and the local PT and aPTT reagents. As an example, in plasma B (96 ng/mL), the ratios were 1.15 ± 0.02 (RecombiPlastin 2G®), 1.10 ± 0.02 (local PT), 1.17 ± 0.05 (local aPTT).

Conclusions: We confirmed the low sensitivity of PT and aPTT reagents to apixaban. Apixaban plasma concentrations ≥ 100 ng/mL can be accurately and precisely quantified by the three anti-Xa assays tested. Accuracy for values > 100 ng/mL varied depending on the combination reagent/coagulometer used, and deserves further investigations.

OC 79.3

Comparing new oral anticoagulants (dabigatran, rivaroxaban and apixaban) to warfarin in patients with atrial fibrillation, a cost-effectiveness analysis from a German payer perspective

Krejczy M[1], Wehling M[1], Marx S[1], Obermann K[2] and Harenberg J[1]

[1]Medical Faculty Mannheim of the University of Heidelberg; [2]Medical Faculty Mannheim, Ruprecht-Karls-University Heidelberg, Mannheim, Germany

The new oral anticoagulants (NOAC) dabigatran, rivaroxaban and apixaban are now approved for prevention of stroke and systemic embolism for patients with non-valvular atrial fibrillation (NVAF). In times where resource allocation is more and more important, thinking about cost-effectiveness of different therapy options is necessary, to obtain the best therapy at the lowest costs. This context explains how crucial the need of cost-effectiveness analysis (CEA) is.

Our aim was to determine which prices for NOACs in Germany are justified. We performed a CEA including direct and indirect costs regarding a set societal willingness to pay threshold.

We used the data form the RE-LY, ROCKET AF and ARISTOTLE trials, defining outcome events as ischemic stroke and systemic embolism, major bleeding, intracerebral hemorrhage, myocardial infarction, and mortality. The outcome of the CEA was defined as quality of life (QALYs), total costs, and incremental cost effectiveness ratios (ICER) for the NOACs comparing to dose-adjusted warfarin. Pricing of the clinical events and the outpatient care were taken from published data, form the institute for payment regulations in German hospitals (InEK) and German-Diagnosis Related Groups. Indirect costs for INR deter-

minations included non-productive time of a relative and/or transportation costs. For the drug costs of the NOACs, we used the current daily market costs of 3.20€. Performing a Markov model we did several deterministic and stochastic analyses, including cohort analyses, one- and two-way sensitivity analyses and Monte Carlo simulation. The time horizon was based on the life expectancy of the German population. The Markov decision model was adopted using the TreeAge Pro 2012 program.

The cohort analyses showed that using the RE-LY, ROCKET AF and ARISTOTLE trial data the results were the following. The QALYs were 11.53QALYs for dabigatran 110 mg bid and 11.66QALYs for dabigatran 150 mg bid comparing to warfarin with 11.41QALYs. The total costs were 42395€ for dabigatran 110 mg bid, 39392€ for dabigatran 150 mg bid and 38765€ for warfarin. In case of the ICER calculation dabigatran 110 mg had 29527€ per QALY and dabigatran 150mg bid had 2547€ per QALY compared to warfarin. Rivaroxaban showed QALYs of 11.05 comparing to 10.79QALYs for warfarin. Total costs were 44581€ for rivaroxaban and 43499e for warfarin. The ICER for the comparison of rivaroxaban with warfarin was 4158€ per QLAY. When calculating with the ARISTOTLE trial data the QALYs for apixaban comparing to warfarin were 11.38 compared to 11.04. Total costs were 37606e for apixaban compared to 36260€ for warfarin. The ICER for apixaban comparing with warfarin were 4047€ per QALY. The one- and two-way sensitivity analyses indicate that the model was highly sensitive to the daily costs for the drugs and to indirect costs but relatively insensitive to other model inputs. In the Monte Carlo simulation the model input parameters were validated.

When comparing the cost-effectiveness for the NOACs including indirect costs current German market prices are justified at a societal willingness to pay of a generally accepted amount of about 30,000 Euro. Indirect costs sensitively influence the outcome of the CEA of NOACs in NVAF.

OC 79.4

Incidence of recurrent venous thromboembolism in patients following completion of the EINSTEIN DVT and EINSTEIN PE studies

Prins MH[1], Erkens PGM[2] and Lensing AWA[2]

[1]University of Maastricht, Maastricht, the Netherlands; [2]Bayer HealthCare, Wuppertal, Germany

Background: The EINSTEIN DVT and EINSTEIN PE studies compared rivaroxaban with enoxaparin/vitamin K antagonist (VKA) for the treatment of acute symptomatic deep vein thrombosis or pulmonary embolism for 3, 6 or 12 months of treatment (The EINSTEIN Investigators. *NEJM* 2010; 363:2499; The EINSTEIN-PE Investigators. *NEJM* 2012; 366:1287). Continued anticoagulation treatment was relatively common following discontinuation of the study medication.

Aims: This analysis compared the incidence of recurrent venous thromboembolism (VTE) in patients who continued anticoagulant treatment compared with those who stopped over the course of the 1-month post-study medication observational period.

Methods: Patients from the EINSTEIN DVT and EINSTEIN PE studies who entered the 1-month post-study medication observational period were eligible for the analysis. After discontinuing study medication, continuation of anticoagulant treatment was at the discretion of the treating physician. Two independent assessors validated the anticoagulant therapy that was provided during the 1-month post-study medication observational period as full anticoagulant treatment (i.e. VKA or full-dose low molecular weight heparin [LMWH]), including optimal and suboptimal use, or no anticoagulant treatment. In addition, patients randomized to rivaroxaban therapy were further divided into those who received bridging LMWH therapy (for the period in which patients had sub-therapeutic International Normalized Ratio values) and those who did not. Incidences of recurrent VTE, as assessed by the blinded adjudication committee, in the 1-month period after cessation of study drug, were compared between relevant groups.

Results: Full anticoagulant treatment was received by 861 of 3565 (24.2%) qualifying patients who had received rivaroxaban compared with 1422 of 3536 (40.2%) qualifying patients who had received VKA therapy ($P > 0.0001$). During the 1-month post-study medication observational period, 32 of 3587 (0.9%) patients who had received rivaroxaban compared with 22 of 3582 (0.6%) patients who had received enoxaparin/VKA developed recurrent VTE. The incidence of recurrent VTE was 0.4% (9/2283) among patients who received any full anticoagulant treatment, compared with 0.9% (45/4818) among those who did not (risk difference −0.5%, 95% confidence interval [CI] −0.8% to −0.1%). In patients who received any full anticoagulant treatment, the incidences among prior rivaroxaban recipients was 0.3% (3/861) and among prior enoxaparin/VKA recipients was 0.4% (6/1422) (risk difference −0.1%, 95% CI −0.5% to 0.5%). The incidence of recurrent VTE in patients who had received rivaroxaban and continued with VKA treatment was similar among those who did not receive LMWH bridging (0.4%; 2/498) and those who did receive LMWH bridging (0.3%; 1/363) (risk difference 0.1%, 95% CI −0.6% to 0.6%).

Summary/conclusions: The decision to continue anticoagulant treatment after cessation of study medication in the EINSTEIN DVT and EINSTEIN PE studies was influenced by knowledge of the randomized treatment received. The incidences of recurrent VTE during the 1-month post-study medication observational period were similar in patients who received any full anticoagulant treatment, independent of LMWH bridging in prior rivaroxaban recipients.

OC 79.5

Stopping oral anticoagulation and the risk of thrombotic events and mortality in patients with atrial fibrillation

Gallego P[1], Marín F[2], Romera M[3], Valdés M[2], Vicente V[3], Lip GYH[4] and Roldán V[3]

[1]Centro Regional de Hemodonación, Hospital Morales Meseguer; [2]Servicio de Cardiología Hospital Universitario Virgen Arrixaca, UMU; [3]Centro Regional de Hemodonación, Hospital Morales Meseguer, UMU, IMIB, Murcia, Spain; [4]University of Birmingham Centre for Cardiovascular Sciences, City Hospital, Birmingham, UK

Oral anticoagulation (OAC) is highly effective preventing stroke and mortality in patients with atrial fibrillation (AF) compared to placebo/control. It has previously been described that the incidence of stroke and major hemorrhagic events is higher during the immediate period after initiation of Vitamin K antagonists (VKA), particularly amongst naïve patients. Stability of anticoagulant effect is often not achieved for several months after initiating VKA, as anticoagulation intensity fluctuations are influenced by diet, drug interactions, genetic variation and drug adherence. Bleeding complications usually lead to cessation of VKA, particularly amongst VKA-naïve patients. We evaluated clinical outcomes of a consecutive population of AF patients who were VKA naïve, and initiated on VKA therapy in our clinic.

Methods: We studied consecutive VKA-naïve patients with paroxysmal, persistent or permanent AF, who were initiated on VKA therapy in our anticoagulation outpatient clinic in 2009. During follow-up, adverse events (thrombotic and vascular episodes, major bleeding and death) were recorded as well as VKA treatment cessation. We also determined the time within therapeutic range (TTR), using the Rosendaal method. INR was performed by a point of care device.

Results: We included 529 patients (49% male, median age 76 [IQR 69–82]), who were followed-up for median 835 days (IQR 719–954), in this period 114 patients (21.6%) stopped VKA treatment. During follow-up, 63 patients suffered a thrombotic/cardiovascular event (annual rate 5.17%/year), of which 27 were strokes, 51 had a major

bleeding episode (annual rate 4.19%/year) and 48 died (annual rate 3.94%/year). Median TTR observed was 54% (34–57). On multivariate analysis, VKA cessation was independently associated with stroke (4.21 [1.87–9.47]; $P = 0.001$), the composite of thrombotic/cardiovascular events (HR 2.72 [1.56–4.72], $P > 0.001$), and death (HR 3.43 [1.86–6.32]; $P > 0.001$), which remained significant even after adjusting for CHA_2DS_2-VASc score. Independent risk factors for major bleeding were age [HR (95% CI): 1.08 (1.04–1.12); $P > 0.001$], previous stroke (1.85 [1.00–3.41]; 0.049), and TTR (0.97 [0.96–0.99]; $P = 0.001$).

Conclusions: In patients with AF, VKA cessation is independently associated with the risk of stroke and cardiovascular events, as well as mortality. Specifically, VKA cessation independently increased the risk of stroke, even after adjusting for CHA_2DS_2-VASc score. TTR constitutes a risk factor for major bleeding when VKA therapy is initiated.

OC 79.6

Venous thromboembolism: an annual European Union 27 cost-of-illness model for the burden of the disease

Mahan CE[1], Woersching AL[1], Barco S[2], Holdsworth MT[1], Piovella F[2], Kaatz S[3], Barkemeyer J[1], Turpie AG[4] and Spyropoulos AC[5]

[1]University of New Mexico, Albuquerque, NM, USA; [2]University of Pavia, Pavia, Italy; [3]Hurley Medical Center, Flint, MI, USA; [4]McMaster University, Hamilton, ON, Canada; [5]North Shore/LIJ Health System, Lenox Hill Hospital, Hofstra School of Medicine, New York, NY, USA

Background: National costs for venous thromboembolism (VTE) have been defined for the United States (US). However, overall costs for the full 27 member European Union (EU-27) have not yet been derived.

Aims: To calculate the direct medical costs and indirect costs of VTE within the EU-27 as a cost-of-illness model. To identify total, hospital-acquired and preventable costs associated with VTE within the EU-27.

Methods: Investigators defined and conducted an a priori literature search to identify any diagnosis- or treatment-related costs for deep vein thrombosis (DVT), pulmonary embolism (PE), or VTE from 1994 to September 2012 within the EU-27. Identified publication references were also hand-searched to capture other applicable cost studies. Two investigators independently reviewed the literature search results. High and low inpatient, outpatient and recurrent DVT and PE costs were abstracted as well as high and low costs for minor and major bleeding, pulmonary hypertension, post-thrombotic syndrome, heparin-induced thrombocytopenia, VTE prophylaxis, and the cost of a premature death. Appropriate cost sources were available from 2006 to the end of the literature review.

All costs were categorized and converted to 2012 Euros taking into consideration country-specific inflation and purchasing power parities. Costs were then input into previously published US decision-analytic cost models that were pre-populated with accepted probabilities. Naess' et al. 2007 recent Norwegian PE and DVT incidence rates were used for lower estimates while the VTE Impact Assessment Group in Europe's (VITAE) (Cohen et al. 2007) prevalence (long-term attack) rates were used for high estimates.

The population utilized was 502.5 million focusing on the 424.11 million that were 15 years or older in the EU-27 as of January 1, 2011. Lower and higher median costs for each category were utilized to populate the base and sensitivity analysis. The average patient's cost, the expected value of all decision tree pathways', were multiplied by low and high annual PE and DVT incident events to determine cost ranges. Hospital-acquired costs were estimated at 67–75% of total costs, and preventable costs were estimated at 50–75% of the hospital-acquired costs based off of current literature.

Results: In the base model, annual total, hospital-acquired, and preventable VTE costs ranged from € 2.0 to € 3.6, € 1.4 to € 2.4, and € 0.7 to € 1.8 billion, respectively. In the sensitivity analysis utilizing higher costs and probabilities, annual total, hospital acquired and preventable VTE costs ranged from € 7.6 to € 13.7, € 5.5 to € 10.0, and € 2.8 to € 7.5 billion, respectively. Results of additional sensitivity analyses will also be presented.

Conclusions: VTE costs in the EU-27 are significant although these costs appear less than US costs primarily due to less expensive individual direct medical costs. Approximately € 0.7 to € 7.5 billion/year could be avoided if improved intervention systems were in place within the EU-27. The preventable costs compare to $4.5 to $39.3 Billion (2011 US$) in the US. Use of VTE prophylaxis for at-risk patients is cost-effective in both the EU-27 and US.

OC 80 – Basic Issues in Haemophilia A

OC 80.1

Genetic targeting of human coagulation factor VIII into platelet a-granules resulted in long-term improvement of hemostatic function in canine hemophilia A

Wilcox A[1], Du JM[1], Nurden P[2], Nurden AT[2], Nichols TC[3], Bellinger D[3], Jensen S[1], Haberichter SL[4], Shi QK[1] and Cornetta K[5]

[1]Medical College of Wisconsin, Milwaukee, WI, USA; [2]Hopital Xavier Arnozan, Pessac, France; [3]University of North Carolina, Chapel Hill, NC; [4]BloodCenter of Wisconsin, Milwaukee, WI; [5]Indiana University School of Medicine, Indianapolis, IN, USA

Background: It is essential to develop improved therapies for controlling excessive bleeding in patients with severe hemorrhagic disorders such as hemophilia A and B. Since activated blood platelets mediate the primary response to vascular injury by adhering to a wound site and secreting biologically active proteins, we hypothesized that synthesis and storage of recombinant Factor VIII (FVIII) within platelets may be an ideal strategy for providing a continuous, locally–inducible treatment for maintaining hemostasis.

Aims: Although FVIII is normally synthesized in the liver, here we show a clinically relevant strategy for hematopoietic stem cell gene therapy within a canine 'large animal' model for hemophilia A that permitted synthesis, trafficking, storage, and release of FVIII from activated platelet α-granules as a hemostatic response leading to reduced severe bleeding episodes.

Methods: This study was accomplished with sub–myeloablative conditioning with Bulsulfan (5–10 mg/kg i.v.) and autologous transplant (Tx) of cytokine mobilized CD34+ peripheral blood stem cells (PBC) transduced with a lentivirus encoding a fragment of the integrin αIIb (ITGA2B) gene promoter that permitted platelet–specific storage of human FVIII within three dogs affected with hemophilia A. One animal received a novel hybrid molecule consisting of FVIII fused to the human von Willebrand factor propeptide signal peptide and D2 domain (SPD2) that permitted optimal trafficking of FVIII directly into platelet α–granules. The three Tx recipients underwent periodic testing for expression of the FVIII transgene as well as immune tolerance and phenotypic correction of hemophilia A.

Results: PCR localized the lentivirus within genomic DNA isolated from leukocytes of each dog at 2.5 years after Tx. Immunofluorescence confocal microscopy detected FVIII in a subset of platelets. Immune electron microscopy revealed that FVIII trafficked and stored directly into platelet α-granules. Chromogenic analysis showed that biologically active FVIII (FVIII:C) was detected in all three dogs at 5–10 mU/mL/10^8 platelets for at least 2.5 years after Tx. In contrast, FVIII:C was not detected within the plasma of these animals. This result, coupled with the use of immunomodulation drugs at Tx, may help to explain why the dogs remained tolerant of human FVIII as supported by our inability to detect inhibitory antibodies to FVIII. The dogs showed clinical improvement of hemostatic function as evident by the measurement of reduced bleeding episodes that required the use of canine FVIII supplements. Specifically, the 1st Tx recipient had approximately three

bleeds/yr for 2.5 years (vs. expected five/yr in untreated hemophilia A control animals). Remarkably, the 2nd and 3rd dogs had zero severe bleeding episodes for at least 2.5 years after Tx.
Conclusion: Use of the canine model has confirmed and advanced our understanding of the requirements for viable synthesis, trafficking, storage and release of FVIII from platelet α-granules. These results demonstrate feasibility for translating this strategy for targeting biosynthesis of FVIII into platelets into a clinically relevant protocol. Thus, this work suggests great potential for platelet FVIII gene therapy to provide effective long–term control of bleeding in humans affected with hemophilia A.

OC 80.2

Allosteric modulation of the structurally related factor VIIa and IXa proteases is responsible for the procoagulant properties of a novel peptide family

Thorn K, Rakhe S, Liu L, Toby G, Bitonti AJ, Pierce GF, Mezo A and Peters RT

Biogen Idec Hemophilia, Waltham, MA, USA

Background: Factor VIIa (FVIIa) and factor IXa (FIXa) are two structurally related serine proteases essential for the extrinsic initiation and intrinsic propagation of the coagulation cascade, respectively. The enzymatic cleavage of factor X (FX) into factor Xa (FXa) by these proteases is significantly increased by the presence of their native cofactors, tissue factor and factor VIIIa. We have discovered a novel procoagulant peptide family by phage display panning against FIXa that increased the catalytic activity of FIXa in FXa generation assays, but provided disproportionately greater ability to generate thrombin and clot FVIII-deficient blood in rotational thromboelastometry assays. This result indicated that the peptide family may also increase the catalytic activity of other enzymes in the clotting cascade.
Aims: These studies were designed to investigate the mechanism of action through which the discovered peptide family exerts its procoagulant activity and to further aid in the development of a potential novel drug candidate for hemophilia A bypass treatment.
Methods: A series of *in vitro* experiments was used to map the preferred selectivity and mechanism of action for the procoagulant peptide family. The first evidence of the peptides interacting with multiple enzymes in the coagulation cascade was revealed by plasma-based assays in the presence of neutralizing antibodies against FIX and/or FVIIa. The specificity was further uncovered by a modified thrombin generation assay with purified components allowing isolated steps of the clotting cascade to be studied. The degree of catalytic activity enhancement of FVIIa and FIXa for the conversion of FX into FXa in the presence of representative peptides was determined by a chromogenic FXa generation assay.
Results: The discovered procoagulant peptide family enhances the enzymatic activity of both FVIIa and FIXa as determined by FXa generation in the presence of phospholipids and calcium. The optimized peptides' ability to function as cofactors to FVIIa and FIXa and catalyze the zymogen-like to active protease transition is primarily reflected by increased catalytic activity. Lead peptides enhanced *kcat* of FVIIa by three orders of magnitude and FIXa a few 100-fold. These findings were confirmed by a modified thrombin generation assay where representative peptides stimulated both the extrinsic and intrinsic segregated pathways. Further analyses showed that the peptide family did not directly influence the enzymatic activity of the downstream serine proteases FXa and thrombin, mimicking physiological fibrin formation and regulation.
Conclusion: The FVIIa/FIXa dual specificity of this peptide family leads to stimulation of both the extrinsic and intrinsic coagulation pathways and results in correction of clotting in hemophilia A whole blood corresponding to > 50% of normal FVIII levels. These procoagulant peptides may lead to an alternative treatment for hemophilia A patients lacking a functional factor VIII molecule, whether in the presence or absence of neutralizing antibodies.

OC 80.3

Pharmacological modulation of the uptake of blood coagulation factor VIII by dendritic cells

Hartholt RB, Wroblewska A, Herczenik E, Ten Brinke A and Voorberg J

Sanquin Blood Supply, Amsterdam, the Netherlands

Background: The endocytosis of blood coagulation factor VIII (FVIII) by antigen-presenting cells (APCs) comprises the initial step leading to activation of FVIII-specific T and B cell responses in patients with hemophilia A. Although multiple receptors have been implicated in FVIII uptake, the detailed (intra)cellular mechanism of this process has not been investigated.
Aims: In this study we characterized in more detail endocytosis of FVIII by dendritic cells.
Methods: FVIII uptake experiments were performed using human monocyte-derived dendritic cells (moDCs). Immature moDCs were pre-treated with several drugs including cytochalasin D (cyto D), an established blocking agent for actin polymerization and dimethyl amiloride (DMA), which inhibits sodium channels and is thereby important for regulation of the intracellular pH and actin polymerization, and commonly used as a specific inhibitor of macropinocytosis. We also evaluated the effect of wortmannin, a specific inhibitor of phosphoinositide 3-kinase (PI3K) which has also been implicated in macropinocytosis. The role of heparan sulfate proteoglycans (HSPGs) in FVIII internalization was assessed using siRNA- and pharmacological approaches.
Results: Endocytosis of FVIII was compared to that of reference compounds such as transferrin, reported to be taken up via receptor-mediated mechanism, FITC-labeled high molecular weight dextran, a commonly used marker for macropinocytosis and Lucifer Yellow (LY), a small compound taken up via fluid-phase internalization. Endocytosis of both transferrin as well as dextran was strongly inhibited by cyto D indicating involvement of actin polymerization in the internalization of these antigens. Endocytosis of FVIII was blocked only partially, even when high concentrations (up to 25 mM) of cyto D were used. Uptake of LY was only marginally affected by cyto D. Similar effects were observed for DMA – a strong blockage was observed for transferrin and dextran, none for LY and only a partial effect was seen for FVIII. The PI3K inhibitor wortmannin, was able to partially block endocytosis of dextran, transferrin and FVIII, but not LY. These data suggest that FVIII is endocytosed in an actin-dependent, DMA-sensitive and PI3K-dependent manner however the pharmacological profile was clearly distinct from that observed for dextran. Blockage with dextran sulfate suggested that HSPGs could play a role in FVIII endocytosis by DCs. However, down-modulation of one of the components of the HS-copolymerase did not affect FVIII uptake. Monoclonal antibodies were used to dissect the contribution of the C1 and C2 domain to FVIII internalization. These experiments emphasized the importance of C1 domain but also suggest a potential modulatory role for the C2 domain in FVIII endocytosis by DCs.
Summary/conclusions: Altogether, our data suggest that C1 (and C2) domain mediated internalization of FVIII proceeds via an unusual endocytic pathway that is distinct from classical macropinocytosis pathways as described for high molecular weight dextran.

OC 80.4

An epitope-dependent increase in clearance of antigen-antibody complexes may increase the pathogenicity of a subset of anti-C2 factor fVIII antibodies in hemophilia A

Meeks SL, Cox CL and Parker ET

Emory University, Children's Healthcare of Atlanta, Atlanta, GA, USA

Background: Anti-factor VIII (fVIII) antibodies develop in about 25% of severe hemophilia A patients. There are both inhibitory and non-

inhibitory anti-fVIII antibodies. It remains unclear whether or not increased clearance of fVIII/antibody complexes plays a role in the pathogenicity of anti-fVIII antibodies.
Aim: The aim of this study was to investigate the clearance of fVIII in the presence of anti-fVIII antibodies using a panel of inhibitory and non-inhibitory anti-fVIII monoclonal antibodies (MAbs) of various IgG subclasses in $fVIII^{-/-}$ mice.
Methods: Eight to 12 weeks old $fVIII^{-/-}$ mice were injected (n = 2–5 per group) by tail vein with 8–10 μg anti-fVIII MAb, irrelevant anti-hen egg lysozyme (HEL) MAb, or saline control. Fifteen minutes later they were injected with 1 μg B domain-deleted fVIII. Plasma was obtained by cardiac puncture 30, 60, 120, 240 and 480 min following the second injection. Six MAbs were tested. 4A4 (IgG1) is an anti-A2 MAb with an inhibitory titer of 40,000 BU/mg. 3D12 (IgG2b) and I109 (IgG1) are classical anti-C2 MAbs that inhibit fVIII binding to phospholipid and von Willebrand factor (VWF). They have inhibitory titers of 2600 and 1500 BU/mg respectively. 2-77 (IgG2a) and 2-117 (IgG2a) are non-classical anti-C2 MAbs that do not interfere with binding of phospholipid and VWF. 2-77 has an inhibitory titer of 25,000 BU/mg and 2–117 is non-inhibitory. Clearance of FVIII antigen was determined by capture ELISA using anti-fVIII MAbs to the A1 and C1 domains of fVIII.
Results: There was no difference in the clearance of fVIII in the presence of saline or the irrelevant anti-HEL IgG. In the presence of the anti-A2 MAb 4A4 as well as the non-classical C2 MAbs 2-77 and 2-117, the fVIII/MAb complexes cleared at a similar rate to fVIII alone. In the presence of the classical C2 MAbs 3D12 and I109, the fVIII/MAb complex cleared more rapidly than fVIII alone. At 120 and 240 min In the 3D12 group had residual fVIII antigen levels of 46.5 and 16.7 ng/mL and the I109 group had levels of 66.7 and 27.2 ng/mL as compared to the control with 212 and 199 ng/mL ($P > 0.05$) for all comparisons, Student t test).
Summary: The classical C2 MAbs 3D12 and I109 increased the clearance of fVIII, while the anti-A2 and non-classical C2 MAbs did not. A potential mechanism for this increased clearance is that classical C2 MAbs block binding of fVIII to VWF, the carrier protein known to increase the half-life of fVIII in the absence of antibodies. We have identified a novel feature of classical anti-fVIII C2 MAbs that results in the clearance of fVIII and may result in increased antibody pathogenicity.

OC 80.5
Identification and characterization of deep intronic variations causing mild hemophilia A

Pezeshkpoor B[1], Zimmer N[1], Marquardt N[1], Nanda I[2], Haaf T[2], Budde U[3], Oldenburg J[1] and El-Maarri O[1]
[1]University clinic Bonn, Bonn; [2]Institute of Human genetics, University of Würzburg, Würzburg; [3]Medilys Labors, Hamburg, Germany

Background: In a small group of typical hemophilia A patients with reduced plasma factor VIII coagulant activity (FVIII:C) no mutations in F8 coding sequence (cDNA) can be found. In the current study, we performed a systematic screening of genetic and non-genetic parameters associated with reduced FVIII:C levels in patients with no detectable mutations in F8 cDNA.
Methods: For all the patients we determined FVIII and vWF activity and antigen levels. Moreover, we performed FVIII-vWF binding assay and collagen binding activity (CBA) as well as vWF multimer analysis. The exons 17-27 of vWF were sequenced to exclude vWF type 2 Normandy (2N). In addition the complete F8 locus including the introns was sequenced and the mRNA of F8 was analyzed quantitatively and qualitatively by real time PCR (qRT) and overlapping reverse transcription (RT) PCRs, respectively.
Results: We found that in both, patients and healthy controls, FVIII:C levels are largely assignable to FVIII antigen (FVIII:Ag) levels. However, the patients show considerably reduced FVIII:Ag levels that correlate well with both the severity and FVIII:C levels. On the other hand, all vWF tests were normal. Our overlapping Long-Range (LR) PCRs approach proved the integrity of F8 locus on DNA level in these patients. Interestingly, sequencing of the LR-PCRs, using NGS, showed the presence of several base changes; eight of them were found only in the patients and were absent in healthy individuals. Indeed, RT-PCRs analysis confirmed that two of these changes create new cryptic sites in the patients that result in introducing intronic DNA sequences into the mRNA. Our qRT PCR analysis showed reduced F8 mRNA expression over the exon boundaries flanking the intronic SNPs.
Conclusion: Deep intronic mutations in F8, although rare, could cause abnormal splicing that leads to hemophilia A.

OC 80.6
Polyphosphates corrected blood loss in a novel acute tail vein transection hemophilia A mouse bleeding model

Sim D[1], Mallari C[1], Newgren J[1], Patel C[1], Murphy JE[1], Laux V[1], Smith SA[2] and Morrissey JH[2]
[1]U.S. Innovation Center, Bayer HealthCare LLC, San Francisco, CA, USA; [2]University of Illinois at Urbana-Champaign, Urbana, IL, USA

Background: Polyphosphates are linear chains of inorganic phosphate. In human platelets, polyphosphate polymers of 60–100 phosphate units ($polyP_{60-100}$) are stored in dense granules. Upon platelet activation, these platelet polyphosphates enhance coagulation by initiating the contact pathway, accelerating factor V activation, enhancing fibrin clot structure, and mediating factor XI activation by thrombin (Morrissey JH, et al. *Blood*. 2012; 119:5972–5979).
Aim: To evaluate the efficacy of purified $polyP_{70-85}$ in reducing blood loss in hemophilia A (hemA) mice, a novel acute tail vein transection (ATVT) bleeding model with sensitivity higher than the commonly used tail tip amputation model was developed.
Methods: In the ATVT model, hemA mice were anesthetized in a supine position. $PolyP_{70-85}$ or recombinant factor VIII (rFVIII) was administered via jugular vein 5 min before lateral tail vein transection injuries were performed to induce bleeding. Tails were then dipped vertically into warm saline tubes (37 °C) for blood collection. At the 30-min time point, the injury sites were disturbed to evaluate clot stability by removing the tails and placing them into new saline tubes for another 30 min of blood collection. The total blood loss collected over the 60-min period was measured gravimetrically.
Results: In this novel ATVT model, a 0.3-IU/kg dose of rFVIII reduced blood loss by 50%. In contrast, a dose of 30 IU/kg rFVIII was needed to reduce blood loss to the same extent in the tail tip amputation model. Using this sensitive ATVT model, the efficacy of $polyP_{70-85}$ (4 and 12 mg/kg) was evaluated. A 12-mg/kg dose of $polyP_{70-85}$ reduced blood loss to a level similar to the administration of 0.3 IU/kg rFVIII.
Conclusion: This study demonstrated that purified $polyP_{70-85}$ could potentially serve as a therapeutic for correcting the hemostatic defect in hemophilia.

OC 81.1
A next generation sequencing approach for genotyping patients with hemophilia

Josephson NC[1], Martin B[2], Nakaya S[1], Konkle BA[1], Luk A[3], Pierce GF[3], Shendure J[2] and O'Roak B[2]
[1]Puget Sound Blood Center; [2]University of Washington, Seattle, WA; [3]Biogen Idec Hemophilia, Weston, MA, USA

Background: Genotyping in congenital hemophilia provides tangible clinical benefits including prediction of inhibitor risk and determina-

tion of carrier status in potentially affected females. Furthermore, genotyping will be critically important for the development of targeted therapies, including gene repair. However, at present, only about 20% of the approximately 20,000 patients with hemophilia in the United States have known genotypes.

Aims: Current approaches for genotyping patients with hemophilia are labor intensive and include long range and inverse PCR to screen for *F8* gene inversions and Sanger sequencing of PCR amplified regions including exons, intron/exon junctions, and 5′ and 3′ untranslated sequence. We sought to develop a genotyping approach based on a next generation sequencing platform for parallel screening of a large number of samples for the presence of *F8* inversions plus insertions, deletions, missense, and splice site changes in both *F8* and *F9*.

Methods: A simplified DNA digestion/ligation protocol using Ksp22i to generate circles of adjacent sequence, produced by intron 1 and intron 22 inversions, was developed. DNA capture was performed with molecular inversion probes (MIPs) to ligated circles (8 MIPs), and to exons, intron/exon junctions, and 5′ and 3′ untranslated sequence of both *F8* (349 MIPs) and *F9* (102 MIPs). The captured sequences were amplified with barcoded PCR primers, pooled together and then run on the Illumina HiSeq. Three 96 well plates containing 234 previously genotyped samples from patients with severe hemophilia A and B were sequenced simultaneously in a single lane. Individuals analyzing Illumina HiSeq results were blinded to the samples' previously determined genotypes.

Results: In hemophilia A samples the sensitivity of this new approach for identifying disease causing mutations was 96% (135/141), including 53/54 samples with inversion 22, 1/2 samples with inversion 1, 43/44 missense or nonsense mutations, 12/13 splice site mutations, and 26/28 samples with insertions or deletions. In hemophilia B the sensitivity was 89% (86/93), including 72/77 missense or nonsense mutations, 3/4 splice site mutations, and 11/12 samples with insertions or deletions. Furthermore, a mutation was identified in the one sample that had previously eluded detection by inversion analysis and Sanger sequencing. All other variants identified by our next generation approach matched those previously detected. Reasons that variants were missed included poor quality DNA in some samples, leading to insufficient MIP capture and sequence reads throughout both genes, and the poor performance of some MIPs that failed to generate an adequate number of reads in all samples tested.

Summary/Conclusion: Our results demonstrate a successful strategy to simultaneously genotype multiple patients with hemophilia A and B. To improve the performance of this assay we plan to evaluate methods to uniformly generate high quality DNA samples and plan to design new MIPs to improve DNA capture in regions that were not adequately covered. Optimization of our approach offers the promise of low-cost high-throughput mutational analysis for both hemophilia A and B that could be used for the large number of hemophilia patients in the US who have not yet been genotyped.

OC 81.2

Developmental hemostasis: preliminary results of a multicenter study aimed at defining the reference ranges for routine coagulation parameters in pediatric populations

Toulon PA[1], Berruyer M[2] and Grand F[3]

[1]CHU Saint Roch, Nice; [2]CHU Lyon Est, Bron; [3]CHU, Angers, France

Background: Understanding of developmental hemostasis, a concept now universally accepted, is critical to ensure optimal prevention, diagnosis, and treatment of hemorrhagic and thrombotic diseases in children. However, coagulation test results are known to be dependent on the reagents and analyzers used. This is particularly critical for global assays such as prothrombin time (PT), activated partial thromboplastin time (aPTT). So, it is recommended for each laboratory to define the age-dependent reference ranges by using its own technical condition (J Thromb Haemostas 2012; 10: 298).

Methods: To address that issue, the present multicenter study was carried out in three centers using the same reagents i.e. RecombiPlasTin 2G for PT, SynthASil for aPTT, and HemosIL QFA for fibrinogen and the same instrument ACL TOP (all from Instrumentation Laboratory, Bedford, MA, USA).

Samples were obtained from the routine workload in all participating centers. Indication of the coagulation testing was pre-operative screening in most cases. There were 288 samples obtained from 288 pediatric patients:193 H and 95 F, with a mean age = 1.5 years (range: 2 weeks and 17 years).

Results: As the data obtained in the three centers were not significantly different, test results were pooled and further analyzed in the different age-groups. The data were found to be normally distributed, allowing expression as the mean values with SD. As the result, PT (ratio) was positively correlated with children age, with shorter clotting times in younger children: 0.94 + 0.08 in 14 children aged below 1 month, 0.98 + 0.07 in 99 children between 1 month and 1 year, 1.01 + 0.08 in 101 children aged between 1 and 5 years, 1.06 + 0.08 in 28 children aged between 6 and 10 years, and 1.05 + 0.07 in 46 children between 11 and 16 years. Conversely aPTT (ratio) was negatively correlated with age, with longer clotting times in younger children: 1.18 + 0.11 in children aged below 1 month, 1.12 + 0.12 in children between 1 month and 1 year, 1.06 + 0.12 in children aged between 1 and 5 years, 1.07 + 0.12 in children aged between 6 and 10 years, and 1.04 + 0.10 in children between 11 and 16 years. Fibrinogen levels (in g/L) were 2.08 + 0.53, 2.48 + 0.55, 2.92 + 0.64, 2.85 + 0.53 and 2.82 + 0.52, respectively in children pertaining to these five age groups.

Conclusions: These data suggest that, at least in the described technical conditions, routine coagulation test results are highly dependent on age and that age-specific reference ranges must be used to ensure proper evaluation of coagulation in children.

OC 81.3

Evidence that the effects of rivaroxaban are dependent on the degree of activation of the coagulation system

Kluft C[1], Van Leuven K[1], Laterveer R[1], Kret R[1], Neuteboom J[1], Kruithof A[2] and Burggraaf J[2]

[1]Good Biomarker Sciences, Leiden; [2]Centre of Human Drug Research, Leiden, the Netherlands

Background: The effects of rivaroxaban can be assessed with variable responses using the Prothrombin Time (PT). When using Simplastin Excel S® (SES) the effects are much stronger than with any other PT reagent. PT prolongation with SES results in 2–4-fold increases, comparable to prolongations observed with vitK-antagonists.

Aims: We explored possible mechanisms explaining the strong response to rivaroxaban with the SES reagent and put this in context with findings using other global tests.

Methods: Clotting assays were performed on the Amax Destiny plus. TGA-RCH® (Technoclone) and Extem Rotem® were used. Effects of rivaroxaban were evaluated by spiking plasma. Effects of factor V were evaluated using mixtures of normal with factor V-depleted plasma, a factor V quenching monoclonal and a venom activating factor V (RVV-V). Contrasts were made between the most sensitive (SES) and the most insensitive reagent (Innovin®) for rivaroxaban.

Results: Using depleted plasmas showed that the strong rivaroxaban effect in SES was independent of coagulation factors XII, XI, X, IX and factor VIII. However, the effect using plasma with low FV levels was exaggerated. This was also noted when using Innovin when quenching antibodies to factor V were added. Conversely, addition of factor V activating venom (RVV-V) attenuated the rivaroxaban effect at low factor V levels and completely abolished the strong effect of rivaroxaban in SES.

Starting clotting with purified factor Xa, with or without RVV-V using factor VII deficient plasma to compare the lipids showed comparable IC50 for rivaroxaban for all combination (25–35 nM) excluding differences in lipid effect on the active components Xa and Xa-Va. This identified activation of FV in SES to be poor. We further explored if lipids could be involved in the poor activation of factor V with SES. Adding Innovin-lipids to SES completely abolished the strong sensitivity to rivaroxaban, identifying specific lipids in SES (currently unknown) to be responsible.

When the IC50 from SES (110 nM) and Innovin (385 nM) are converted (Cheng Prusoff formula) in amount of factor Xa participating in the inhibition it revealed that in Innovin 60% and in SES 17% of factor X is converted. The amount of factor Xa participating in other global tests was 8% in the thrombin generation test (TGA-RCH), 37% in the Extem Rotem alpha value, 46% in the APTT. The low participation of FXa in SES and the thrombin generation test apparently explains their sensitivity for measurement in the therapeutic range of rivaroxaban.

Conclusions: The lipid component in SES is responsible for a reduced activation of factor V resulting in limited FXa formation and a strong sensitivity to inhibition by rivaroxaban. Rivaroxaban inhibits more potently in tests with low factor Xa activation. For pharmacodynamic assessment in addition to SES other global tests with low factor Xa participation such as TGT-RCH may also be suitable. The physiological implication may be that rivaroxaban is primarily effective in situations with low grade coagulation activation and increasingly ineffective when coagulation activation is more massive.

OC 81.4

Development of a quantitative model of systemic procoagulant condition due to bacterial sepsis

Wong ZC[1], McCarty OJT[1], Puy C[1], Tucker E[1], Smith SA[2], Choi S[2], Morrissey J[2] and Gruber A[1]

[1]*Oregon Health and Science University, Portland, OR;* [2]*University of Illinois, Urban, IL, USA*

Background: Intravascular blood coagulation is common in patients with severe sepsis. The resulting coagulopathy is linked to the presence of bacterial cell components, possibly including polyphosphates. Polyphosphates (polyP) are linear polymers of inorganic phosphate that are abundant in the acidocalcisomes of prokaryotes and unicellular organisms as well as in the dense granules of platelets. PolyP has been shown to support the contact activation of coagulation factor XII (FXII), and accelerate the activation of factor XI (FXI), resulting in thrombin generation, complement system activation, and release of the inflammatory peptide bradykinin from high-molecular-weight kininogen. The contact proteases appear to play a significant prothrombotic role in response to bacteria as part of the innate immune response, which can lead to thrombotic complications in the setting of severe bacterial sepsis.

Aims: The aim of this study was to develop an assay to quantify the procoagulant phenotype associated with bacteria sepsis.

Methods: We have developed a quantitative *ex vivo* model of pathological thrombus formation. Our model takes advantage of gravity to provide a constant pressure gradient to drive recalcified blood that has been supplemented with coagulation activating and inhibiting agents through a capillary tube coated with collagen and tissue factor (TF).

Results: Our data demonstrate blood flow ceased after ~20 min in tubes that had been coated with collagen and TF. Experiments were designed to determine whether long polymers of polyP (~1000 phosphate units, such as those present in bacteria) were able to promote occlusive thrombus formation under a constant pressure gradient in a dose-dependent manner (time to occlusion = 19.3 ± 1.5, 15.8 ± 1.5, 12.8 ± 0.6, and 11.5 ± 1.5 min in the presence of vehicle vs. 25, 50 or 100 μM, respectively). Pretreatment of blood with corn trypsin inhibitor, which inhibits FXIIa, prolonged the time to occlusion in the presence of 100 μM long polyP to ~28 min, indicating a role for FXIIa in the ability of long polyP to promote occlusive thrombus formation. In contrast, a panel of function blocking anti-FXI antibodies failed to inhibit the prothrombotic effect of long polyP in our system.

Summary/Conclusion: We have developed a model of pathological occlusive thrombus formation to quantify the systemic procoagulant condition due to bacterial cell components that are present in sepsis. Our data show that polyP of the size present in bacteria promote occlusive thrombus formation in a FXII-dependent, yet FXI-independent, manner. Current efforts are focused on the calibration of thrombus formation in our model as a function of colony-forming units of bacteria. Future efforts will be focused on adapting this model for use as a point-of-care device for assessing patient procoagulant activity during bacterial sepsis.

OC 81.5

A high performance of Nijmegen-Bethesda assay in therapy to induce immune tolerance for hemophilia patients

Montalvão SL, Tucunduva A, Machado TGS, Quaino SP, Colella MP, De Paula EV, De Souza Medina S and Ozelo MC

Universidade Estadual de Campinas – UNICAMP, Campinas, Brazil

The Bethesda method originally described by Kasper in 1975 and later modified by Verbruggen in 1995 is the gold standard for assessment of inhibitory antibodies against factors (F) VIII and FIX. The method has some limitations, such as the presence of residual endogenous or exogenous factor in moderate and mild haemophilia or from replacement therapy, respectively. Some studies show that treatment of these samples with heat improves the sensitivity of this test. The objective of this study is to compare inhibitor quantification obtained of samples previously treated and untreated with heat from hemophilia patients with and without inhibitor. For each analysis the plasma samples were collected and processed equally and separated into two aliquots. In the moment of the analysis one of the aliquots was treated with heating at 56 °C for 30 min and then centrifuged at 15,000 rpm 5 min. The Nijmegen-Bethesda assay was performed for the two aliquots. Results > 0.6 BU were considered negative for the presence of inhibitor. The statistical analysis was performed using the Mann-Whitney test. One hundred nine analyses from 46 patients with severe hemophilia A (FVIII > 1.0 IU/dL) were performed. Patients were divided into three distinct groups: Group (I) 20 patients without history of inhibitor, exposed and not recently exposed to FVIII. Group (II) 21 patients with history of inhibitor not exposure to FVIII. Group (III) five patients (68 analysis) undergoing ITI protocol. For patients with no history of inhibitor the heating of samples did not modify results when compared with no heating sample ($P = 0.24$). However, a statistical significant difference between the samples was observed in patients with positive history of inhibitor. The difference found in the group II ($P > 0.05$) was evaluated against a ratio of FVIII:C/FVIII:Ag to obtain data about the FVIII exogenous to confirm the days without FVIII exposition. The higher difference was observed in the group III ($P > 0.001$), the title of inhibitor obtained with heat samples had a median of 7.1 times (2.0–16.1 times) higher when compared with samples without heat treatment and six of them shift the negative (0.19–0.39 BU) to positive (1.8–4.43 BU) results. In additional, the results obtained from each ITI patients show the same trend line obtained with the results of heating and no heating samples. The presence of FVIII in patient samples violates the principle of Bethesda method, where patient and control samples must be equivalent before incubation. Therefore, the additional presence of FVIII (exogenous) may modify the kinetics between antigen and antibody and provide results lower than the expected. In our experience, heating sample showed increased sensitivity of method and no shift from negative to positive was observed

in results of patients without history of inhibitor. Furthermore, this procedure appears to be an important application for samples from patients undergoing ITI protocol. In daily practice, when one cannot wait 72 h without infusion of FVIII containing products for analysis of quantification of inhibitor, heat treatment of samples may enable the determination of the test.

OC 81.6

A nationwide Belgian survey on the influence of the new oral anticoagulants dabigatran and rivaroxaban on commonly used coagulation assays

Van Blerk M[1], Bailleul E[2], Chatelain B[2], Demulder A[2], Devreese K[2], Douxfils J[2], Jochmans K[2], Mullier F[2], Wijns W[2] and Soumali MR[1]

[1]Scientific Institute of Public Health; [2]EQA Advisory Board, Brussels, Belgium

Background: The new oral anticoagulants dabigatran etexilate (direct thrombin inhibitor, Pradaxa®, Boehringer Ingelheim) and rivaroxaban (direct factor Xa inhibitor, Xarelto®, Bayer) have been in clinical use for a few years for the prevention of thromboembolic events after elective hip- or knee-replacement surgery and for the prevention of stroke and systemic embolism in patients with atrial fibrillation. Although these agents do not require monitoring, their presence can significantly influence coagulation assays, potentially leading to incorrect interpretation of test results.

Aims: The Belgian national External Quality Assessment Scheme for blood coagulation organized a survey to investigate and illustrate to the clinical laboratories how these drugs affect their routine coagulation assays.

Methods: All Belgian clinical laboratories routinely performing coagulation testing (n = 192) received five lyophilized plasma samples in April 2012. These samples consisted of a normal plasma pool spiked with dabigatran or rivaroxaban to the following final concentrations: 0, 100 ng/mL dabigatran, 250 ng/mL dabigatran, 120 ng/mL rivaroxaban, and 290 ng/mL rivaroxaban. The samples were purchased from Hyphen BioMed (Neuville surOise, France). Participants were requested to determine the following coagulation assays: prothrombin time (PT, seconds,% and INR), activated partial thromboplastin time (aPTT, seconds and ratio), fibrinogen and antithrombin. They were also required to mention the reagent and analyser used.
