Methods: During the last 6 years, in our Dental Department, we performed 154 surgeries on 49 patients (41M, 8F; median age 48 years, range 11–82) affected by HBD: 15 severe, 7 moderate, 10 mild HA; 2 severe, 2 mild HB; 6 type 1, 1 type 2A, 3 type 2B, 3 type 3 VWD. TheHemophiliaCenterprovided personalized therapeutic schemes, on the basis of coagulopathy type/severity and type of surgery. Factor VIII concentrates were administered in severe, moderate and few cases of mild HA; FIX concentrates in severe and mild HB; desmopressin in mild HA, VWD type 1 and type 2A; FVIII/VWF concentrates in VWD type 1, in case of low response or contraindication to Desmopressin, type 2B and type 3. One hundred and twenty one dental and roots extractions, 10 third molar surgical extractions, 1 excisional biopsy, 2 cysts enucleation, 18 scaling and roots planing, 1 gingival graft, 1 hypertrophic gingival tissue removal were performed under local and loco-regional anesthesia. Local hemostasis was ensured applying gelatine packing, fibrin glue, absorbable suture, 15-min compression with tranexamic acid saturated gauze. In the post-operative period patients were treated with antibiotics and continued the self-infusion of concentrates/desmopressin for an average period of 5 days (3–7). Tranexamic acid mouthwashes (three times a day for 3 days) were prescribed; acetaminophen was used as the only pain-relief treatment.
We didn't observe any hemorrhagic or infectious complications. All patients completed the post-surgery home-treatment.
Conclusions: A tailored prophylactic treatment ensures a good hemostasis in HBD patients undergoing dental procedures. Multidisciplinary approach allow to manage coagulopathic patients without bleeding complications; home-treatment reduces management cost.

PO 113

Rituximab plus prednisolone for managing hemophilia A with FVIII-inhibitor

Ding K, Wu J and Zhang L
Anhui Provincial Hospital, Hefei, China

Backgrand: The Hemophilia A patients with FVIII inhibitor often experienced recurrent episodes of deadly bleeding and treating them is difficult.
Aim: to explore the treatment for the Hemophilia A patients with inhibitor with Immunosuppressive therapy.
Methods: Case: An 23-year-old Chinese male was diagnosed with severe hemophilia A with high title anti-FVIII inhibitor. He had Hematuria and soft tissue hemorrhage in his left psoas. A blood examination showed neutrophilia with a white blood cell count of 11,200/μL (77.1% neutrophils), an activated partial thromboplastin time of 126.90 s, coagulation factor VIII (FVIII) < 1.0%, and anti-FVIII inhibitor, 5 BU/mL. Anti-FVIII inhibitor title, FVIII level and the percent of CD20+ cells were detected after rituximab used.
Results: The bleeding episodes were controlled with intravenous high-dose FVIII followed by fresh frozen plasma and PCC. In addition, oral prednisolone (30 mg/day) plus four low-dose of rituximab (100 mg/week × 4) effectively suppressed anti-FVIII inhibitor levels while simultaneously reducing the CD20+ cells count (0%). No other drug side effect occurs.
Conclusion: This report describes the effectiveness of a combination of prednisolone and rituximab followed by immune tolerance therapy in managing hemophilia A with high title anti-FVIII inhibitor.

PO 114

Evaluation of quality of life in adult patients with hemophilia in Northwest of Iran

Dolatkhah R[1], Fakhari A[2], Zakaria Pezeshki M[3], Shabanlouei R[4], Gholchin M[4] and Tavassoli N[4]
[1]Hematology and Oncology Research Center, Tabriz University of Medical Sciences; [2]Associated Professor of Psychiatry, Clinical Psychiatry Research Center; [3]M.D.Associate Professor, Program for Estimation of Pretest Probability; [4]Hematology and Oncology Research Center, Tabriz University of Medical Sciences, Tabriz, Iran

Background and Aims: Several studies have been published addressing quality of life (QoL) issues in people with hemophilia, and nowadays several hemophilia Health Related QoL (HRQOL) measures are available. The purpose of HRQoL evaluation is to go beyond the presence and severity of symptoms of disease or side effects of treatment, examining how patient perceive and experience these manifestations in their daily lives.'A36 Hemofilia-QoL' is a disease specific questionnaire for the assessment of the HRQoL in adults living with hemophilia. This questionnaire is a self-report measure that comprises 36 items, and is quick and simple to administer. Higher Score is better QoL in these patients.
Aims: The main aim of this study is evaluation of Quality of Life in adult patients with hemophilia in northwest of Iran, Tabriz Hemophilia Treatment Center.
Methods: A total of 100 Adults with Hemophilia were recruited assessed in Hemophilia Treatment Center of Tabriz. Inclusion criteria were age over 17 years, mild to severe hemophilia A or B (HA and HB), and informed consent from the participants. All statistical analyses were performed using the SPSS statistical package (version 13.0).
Results: The Mean age of the hemophilia patients was 32.16 years (range 17–70, SD 11.68). Eighty tree patients were HA, and 17 cases were HB, and the average of the Qol were 71.70 and 72.75 respectively. There was statistical difference in patients whit different severity of diseases, as severe hemophiliacs had less score: Mild = 104.53, Moderate = 68.56, and Severe = 64.31.The QoL was very poor in urban area in contrast to patients who lived in the city (54.45 vs. 74.21, respectively).Single patients have a better QoL than married patients (76.56 vs. 68.50, respectively).
Conclusion: Using items from A36Hemofilia QoL instruments proved to be a useful approaches to the assessment of Physical Health and Health Related criteria in patients with Hemophilia.

PO 115

A possibility of relation between weather to joint bleedings in haemophic patients

Fuj Tii[1], Saito S[1] and Fuj Tii[2]
[1]Hiroshima University Hospital; [2]Hiroshima University, Hiroshima, Japan

Background: It has been known well that weather has some relevance to joint pain in persons with rheumatism, metal plates by the treatment of bone fractures and some trouble in their joints. Haemophilic patients also have arthritis as well as them and some complain that there are more joint bleeds in bad weather than those in fine weather.

Aims: To clarify whether there is the relation between weather to joint bleedings or not in haemophic patients.
Methods: Hand-held patient diaries have been collected from the patients who have home infusion treatment in Hiroshima University Hospital once a year. The days and parts of joint bleedings in respective patients were identified on their patient diaries. And then, we investigated the weather, minimum temperatures and atmospheric pressures at patients' residential area on the day and the day before of respective bleedings on the basis of database from Hiroshima Local Meteorological Observatory.
Results: The data from 23 haemphilic patients in our hospital was collected and investigated. The total number of joint bleeding episodes amounted to 2391 in the total 71 years' data. There was no difference of bleeding counts among the seasons. The mean temperature difference when bleedings episodes occurred was 1.61 degree C and the mean atmospheric pressure difference was 2.83 hectpascal on the day when bleeding episodes occured. Nine of 11 patients who experienced more bleeding episodes at the change of weather than at invariable weather had bleedings when the weather became worse. All of them except for one case had some severe target joints. On the other hand, a half of 12 patients who had no relation to the change of weather on bleedings had bleedings when the weather became worse.
Summary/Conclusions: It could not be clarified statistically whether there is the relation between weather to joint bleedings or not in haemophic patients. As the reason, so many factors concern to joint bleedings as exercises, unusual motions, existence of target joints or prophylaxis and so on. However, the bleeding episodes may more frequently occur when the weather became worse. It is possible that change of weather could concern to irritation or occult pain of target joints at least.

PO 116

A prospective post-authorization safety surveillance study in 384 hemophilia A patients with antihemophilic factor (recombinant) plasma/albumin free method demonstrates safety and efficacy in Japan

Fukutake K[1], Hanabusa H[2], Taki M[3], Matsushita T[4], Shima M[5], Shirahata A[6] and Advate[7]

[1]Tokyo Medical UniVersity; [2]Ogikubo Hospital, Tokyo; [3]St. Marianna University School of Medicine Yokohama City Seibu Hospital, Yokohama; [4]Nagoya University Hospital, Nagoya; [5]Nara Medical University, Kashihara; [6]Kitakyushu Yahata Higashi Hospital, Kitakyushyu, Japan; [7]Baxter, Tokyo, Japan

Background: Post authorization surveillance studies are essential for the evaluation of safety in the real life clinical practice settings. Japanese Post-Authorization Safety Surveillance Study (J-PASS) of ADVATE [Antihemophilic Factor (Recombinant) Plasma/Albumin Free Method rAHF-PFM] was initiated in February 2007 under Japanese ordinance Good Post-Marketing Study Practice (GPSP).
Aims: To investigate safety, i.e. adverse events, namely inhibitor development, and efficacy in hemophilia A patients who are using rAHF-PFM in routine clinical practices, which are including on-demand and prophylaxis treatments.
Methods: The prospective, multicenter, open-label, observational surveillance was conducted at 101 sites during the period from February 2007 to June 2012 to investigate hemophilia A in patients who were prescribed rAHF-PFM under treatment regimen for 2 years, with more than three exposure days experience of previous FVIII products (EDs), and regardless of presence or absence of inhibitors, using electrical data capture system (EDC).
Results: Of 384 subjects receiving the rAHF-PFM more than once, 341 (89%) completed 2 years of observation and 43 subjects were withdrawn: lost to follow-up (15), move to other hospitals (7), unable to complete during the study period (7), subject request (6), adverse events (3) or unsatisfied therapeutic response (1), and others (6). The severity of hemophilia were as follows: < 1%:288 (75%), 1–2%: 45 (12%), > 2–5%:28(7%) and > 5%:21(6%). The mean age at the time of enrollment was 25 years (range:0–81). EDs at study entry were as follows: ≤ 50EDs (n = 42), 51–150EDs (n = 16), to ≥ 151EDs (n = 326). As the worst record on efficacy evaluation during study period, Excellent/good rating was 92.7% for prophylaxis and 95.3% for on-demand therapy. Thirty-six subjects had inhibitor history, and 6 among them had positive titer at entry. Of the 30 subjects with a prior history of inhibitor at entry, no one developed recurrent inhibitors. One of the 6 subjects with inhibitor at entry dropped out, because of an increase in inhibitor titer from 5BU/ml to 33BU/ml after ITI. Three of 39 subjects with ≤ 50EDs and no inhibitor history at entry developed low titer inhibitor (7.69%, 95%CI:1.62, 20.87). No *de novo* inhibitor developed in 309 subjects with ≥ 51ED (0%, 95%CI:0, 0.96). No inhibitor was detected in subjects who switched from pd-FVIII or 2nd generation rFVIII to rAHF-PFM. Of 236 subjects who started or were on prophylaxis at entry, 210 continued on the prophylaxis regimen and their median annual bleeding rate (ABR) was 3.96 times/y. The prophylaxis regimens were 3 times per week (50%), two times per week (30%), one time per week (12%) and other. Of 148 who started on-demand therapy at entry, 32 moved to prophylaxis. Their median ABR was improved from 23.52 to 1.98.
Conclusions: This result further supports the safety profile of rAHF-PFM with both prophylaxis and on demand therapy in a large Japanese Hemophilia A population.

PO 117

Treatment of hemophiliacs with inhibitors Experiences of mascara-ALGERIA-N.GAID MEHALHAL, F .ARBAOUI, H.CHALABI, N .YAKHOU. E.P.H YESSAD KHALED. MASCARA.- ALGERIA-

Gaid Mehalhal N

EPH Yessaad Khaled, Mascara, Algeria

The appearance of alloantibody inhibitor or anti FVIII or FIX side effect is the largest and most formidable replacement therapy concentrates.
The incidence of inhibitors is higher in severe HA, 20% and 30%, it is only 4% and 5% in HB.
Paptients and Methods: We report in this observation a series of 37 hemophiliacs with 33 HA (89%) and 4 HB (10%) including 3 from the same sibling.
The median age was 21 years (range 2–40 years).
Hemophilia is severe in 19 cases (51%), moderate in 11 cases (29%), Minor in seven patients (18%).
Between 2005 and 2012, and 19 severe hemophiliacs 5 of them have developed inhibitors with a hemophiliac B.
The median age at the time of the discovery of the ACC is 8 years (range 2–14 years old).
The diagnosis was read 4 times a periodic review and once to the inefficiency of replacement therapy.
The treatment was administered the FVII available in our center since 2007.
A hemophiliac A 10 year old received prophylaxis for 2 years. due to an injection of Novoseven. due to 90 μg/kg per week and self-treatment.
Control of the ACC as was done in about every 6 months depending on the availability of reagents. We found a rate stabilization ACC or a regression to an advanced 0.6 UB.
Conclusion: The occurrence of inhibitors in hemophiliacs is the most serious complications making replacement therapy ineffective and support difficult due to irregular and insufficient amounts of specific treatments in our country and irregular systematic research specific treatments in our country.

PO 118

Retrospective study of sporadic haemophilia in the region of Murcia, Spain

García-Candel F[1], Tizzano E[2], Majado MJ[1], Cabañas V[1], García-Candel A[1], Moreno M[1] and Moraleda JM[1]
[1]*Hospital Clínico Universitario Virgen de la Arrixaca, El Palmar (Murcia);* [2]*Hospital Sant Pau, Barcelona, Spain*

Background: Classically, the incidence of sporadic haemophilia is about a third of total cases, but in more recent publications there is an incidence of 30–50% depending on several series, predominantly in severe haemophilia.
Aims: Our goal was to study the distribution of sporadic haemophilia in our population and the gene mutation type.
Methods: In our region there are 80 hemophiliac patients, 65 HA and 15 HB, distributed in 53 unrelated families. We have studied the family pedigree of 46 families in the years 2007–2011. We study the genetic mutation causing hemophilia by long range polymerase chain reaction (PCR).
Results: We obtained 24 sporadic families (52.2%). In this group the incidence of severe haemophilia (A or B) was 79.1% (severe haemophilia A 54.2% and severe haemophilia B 25%. The type of gene mutation found were: Intron 22 inversion (5 families), point mutations (14 families), splicing mutations (2 families), large deletions (1 family), partial deletions (1 family), duplication (1 family). Five familes had mutations not described in the Haemophilia A Data Base (HAMSTeRS). Eight families had mutations with high risk of developing inhibitors.
Conclusions: The sporadic haemophilia is a signifiant group in the hemophilic population. In our series, the incidence is similar to the recently data published with the special importance of new mutations not previously described and the mutations with high risk of inhibitor development.

PO 119

Physiotherapy is an important element of the modern haemophilia treatment

Halimeh S, Rott H, Kappert G, Kindermann C and Rosenthal M
GZRR, Duisburg, Germany

Introduction: Patients with haemophilia suffer from joint bleedings which can leed to athropathia.
The administration of factor concentrate is primary to prevent of these bleedings.
Thus we like to investigate if there is an additional benefit by subsidiary measures. We offered these patients physiotherapy in our centre and investigated them systematically.
Methods: Forty-four patients (age 4–62 years) were interviewed to quality of life and their pain sensation before and after 1 year of physiotherapy. We used also the substitution calendar as a data source. Twenty-nine patients (66%) were treated prophylactically and 15 patients (34%) were treated on demand.
For the data analysis we used SPSS (version 21.0). With algebraic sign test by the scaled sizes and CHI2-test by the dichotomous sizes.
Under physiotherapy the well being has increased. Pain could be diminished 2.6 scale points in the mean. Analgesics use was reduced 1 scale point in the mean. The number of bleedings decreased and additional concentrate administration could be reduced. During the physiotherapy all kind of injuries were less frequent as before.
Conclusions: An individualized physiotherapy can raise the quality of life of a patient with haemophilia through increase of the physical function, prevention of bleedings and injuries and also pain reduction. Besides this costs can be reduced as there is less coverage of factor concentrate.
These results can only be achieved if the physiotherapy is adjusted on the status of the individual joint.

PO 120

Assessment of QoL in Korean hemophiliacs: the impact of health- related factors, social state and a treatment factor on QoL of Korean hemophiliacs

Han JW[1], Jeon SE[2], Ho Jin S[2], Sun Ah L[3] and Chur woo Y[4]
[1]*Yonsei University Health System, Seoul;* [2]*Pusan National University Hospital, Pusan;* [3]*Daegu Fatima Hospital, Daegu;* [4]*Eulji university Hospital, Daejeon, South-Korea*

Background: Health-related factors, treatment factors and social state of hemophilia patients may have impact on their QoL. However, the impact of these factors, especially social state and treatment factors, may be different among countries with different social, cultural backgrounds and treatment approach. Therefore, identification of those factors in each country is vital to establishing potential strategies to intervene in hemophilia patients.
Aims: The impact of health-related factors, a treatment factor and social state on QoL of Korean hemophilia patients were evaluated.
Methods: Data were collected by questionnaires and reviews of the medical records of Korean hemophilia patients over 17 years of age. QoL was evaluated with the standardized questionnaires of SF36. The disease- and health-related factors such as the severity and type of disease, presence of inhibitor, HCV and HIV infection history, disability, and analgesic use history were obtained from medical records. Arthropathy was evaluated by a patient's perception of involved major joints, both knee, ankle and elbow joints. Sociodemographic data such as marital state, occupational state and education years were obtained by questionnaires. Self-injection ability, as a treatment factor, was evaluated by self-injection diaries and questionnaires. Age-adjusted partial correlation analysis and multiple regression analysis were conducted to elucidate the impact of theses observed data on QoL of the patients.
Results: Similar to results of other studies, the severity of hemophilia, inhibitor presence and other disease- and health-related factors were correlated only with several physical health scales of SF36. Marital state, the only social state, correlated with QoL of hemophilia patients in Korea, also had impact only on the physical health scale. However, self-injection score, the only treatment factor surveyed in the study, was significantly associated not only with physical health but also with mental health scales of Korean hemophilia patients.
Summary/Conclusion: Health-related factors and social state had impact only on the physical health of Korean hemophilia patients. A treatment factor, self-injection ability, had impact on both the physical and mental health of these patients.

PO 121

Participation for innovation: survey of motivation for clinical studies evaluating new treatments for haemophilia

Henrard S[1], Speybroeck N[2] and Hermans C[3]
[1]*Université catholique de Louvain;* [2]*Institute of Health and Society [IRSS], Université catholique de Louvain;* [3]*Hemostasis and Thrombosis Unit, Division of Hematology, Cliniques Universitaires, Brussels, Belgium*

Background: Over the last 50 years, clinical research into new treatments has contributed to transform the care of individuals with haemophilia. This has been largely possible through the commitment of people with haemophilia to take an active part in clinical research. While much has been achieved, much remains to be accomplished such as the development and validation of longer acting clotting factor concentrates, new bypassing agents and the validation of treatment strategies aiming at preventing or reducing the risk of inhibitor development. Although many clinical trials are currently ongoing around the world, most of them are facing difficulties in recruiting candidate

patients, mainly in developed countries. In this context, there is a major need to improve the patients' awareness of the importance of clinical research in haemophilia and highlight the opportunities of an active participation in clinical trials.

Aims: A survey was launched to evaluate the motivation of patients with haemophilia for clinical research and identify factors which might influence their willingness to participate.

Methods: A specific questionnaire was sent to 136 adults with haemophilia (≥ 18 years) regularly attending the haemophilia treatment Center of the Cliniques Universitaires Saint-Luc, Brussels, Belgium. Different aspects such as socio-demographic status, familial situation, haemophilia treatment, knowledge about principles and perceived benefits and risks of clinical studies, positive and negative factors for motivation were extensively addressed. The classification tree (CT) was used to identify predictors of willingness to participate. CT-based models are non-linear and non-parametric alternatives to linear models for regression problems.

Results: A total of 60 patients returned the completed questionnaire (n = 60/136, 44.1%). Results show that most patients have a limited knowledge about the general principles of clinical research. Among the 60 patients, 49 would agree to participate in a clinical trial but are mainly concerned by possible side effects of new treatments (n = 25/49, 51.7%) or time lost from school or work (n = 26/49, 53.1%). Moreover, few patients are ready to take part in phase 1 trial fearing unknown reactions or side-effects (n = 10/49, 20.4%). Predictors of willingness to participate in a clinical study were evaluated using CT and three groups were created. Group 1 is compounded by patients who report no knowledge of clinical research modalities (Rate of willingness to participate: 28.6%, n = 2/7). The 2 other groups are compounded by patients who report a good knowledge of clinical research modalities and who are not interested in having more information (Group 2, Rate of willingness to participate: 0.0%, n = 0/2) or in contrary who want more information (Group 3, Rate of willingness to participate: 92.2%, n = 47/51).

Summary/Conclusions: In conclusion, the rate of willingness to participate in clinical studies is significantly lower in patients who report no knowledge of clinical studies modalities and in patients who are not interested in having more information on it. This survey highlights the importance to raise awareness and provide better knowledge about the modalities, risks and benefits of clinical research in order to increase the number of potential participants in clinical trials in haemophilia and probably other rare diseases.

PO 122

Do inhibitors, treatment regimen and bleed frequency impact parent-directed haemophilia treatment centre and provider utilisation: An analysis of parents of children with haemophilia in the HERO study

Iorio A[1], Nugent D[2], Stain AM[3], Gregory M[4], Pericleous L[5] and Cooper D[6]

[1]McMaster University, Hamilton, Canada; [2]Children's Hospital of Orange County, Orange, USA; [3]Kiddies Health Care Inc, Toronto, Canada; [4]UK Haemophilia Society, London, UK; [5]Novo Nordisk A/S, Bagsværd, Denmark; [6]Novo Nordisk Inc., Princeton, USA

Background: Congenital haemophilia is primarily treated through comprehensive care at a haemophilia treatment centre (HTC) by a variety of healthcare professionals. Annual or semiannual comprehensive care visits support home treatment in most developed countries. However, little is known about the relationship amongst the presence of inhibitors, on-demand vs. prophylactic treatment or bleed frequency, and HTC utilisation of the comprehensive team members involved in care.

Aims: To describe the relationship between resource utilisation, inhibitor status, treatment regimen and bleed frequency as reported by parents of children with haemophilia (children) in the Haemophilia Experiences, Results and Opportunities (HERO) Study.

Methods: A post-hoc descriptive analysis of data from parents of children < 18 years in eight countries with home treatment (Argentina, Canada, Germany, France, Italy, Spain, UK and United States). Annual bleed frequency was categorised for analysis (0, 1–5, 6–10, 10–20, > 20 bleeds).

Results: Of 453 parents, most reported their oldest children < 18 years had no inhibitors (411), and most children were treated with prophylaxis (without inhibitors: 80 on-demand, 311 prophylaxis; with inhibitors: 7 on-demand, 24 prophylaxis). The distribution of children among each annual bleed frequency category (0/1–5/6–10/10–20/> 20) was 65/197/78/27/24. Mean/median ages (years) were similar across treatment regimens among children without inhibitors (on-demand 9.5/9, prophylaxis 9.7/9) and among children with inhibitors (on-demand 11.7/11, prophylaxis 11.3/13). Median age was higher with increased annual bleed rates (9/9/10/11/12). Most parents responding were female (without inhibitors81%, with inhibitors 71%). Rates of full-time, part-time or self-employment were similar in parents of children without inhibitors (on-demand 33%, prophylaxis 36%), in parents of children with inhibitors (on-demand 29%, prophylaxis 32%) and with increasing bleed frequency (38%/36%/32%/32%/30%). Activity risk was similar across children with and without inhibitors, irrespective of treatment or annual bleed frequency. Mean/median annual bleeding frequency was higher in children without inhibitors on on-demand (7.5/3 vs. 5.2/3) and in children with inhibitors on prophylaxis (12.1/8) and on-demand (9.2/6). Mean/median annual HTC visits were higher in children on prophylaxis (without inhibitors 5.5/2, without inhibitors 7.3/4) than on-demand (without inhibitors 4.8/3, with inhibitors 4.8/3). Median visits were higher with increased bleed frequency (2/2/3/3/5). The healthcare professionals reported as involved in haemophilia management were largely similar across groups, including by annual bleed frequency. Nurses were more frequently involved in the care of children with inhibitors on prophylaxis (71%) than on-demand (57%), whereas social workers were less frequently involved (8% vs. 29%). Physiotherapist involvement was more frequently reported for children without inhibitors on prophylaxis (34%) than on-demand (23%).

Conclusions: Parents responding to the HERO survey provided interesting insights into differences between care of children and adult with haemophlia. While children with higher bleed frequencies were older, parental employment rates were similar irrespective of bleed frequency, the presence of inhibitors and treatment regimen. HTC utilisation was higher in children on prophylaxis vs. on-demand, suggesting perhaps closer monitoring; utilisation also increased in children with higher bleed frequency. Involvement of physiotherapy and social workers in comprehensive care was less than expected.

PO 123

Potential relationships between negative impacts on employment or relationships with haemophilia centre/provider utilisation: An analysis of parents of children with haemophilia from the HERO study

Iorio A[1], Cassis F[2], Gregory M[3], Kalnins W[4], Wisniewski T[5] and Cooper D[5]

[1]McMaster University, Hamilton, Canada; [2]University of São Paulo Faculty of Medicine Clinics Hospital, São Paulo, Brazil; [3]UK Haemophilia Society, London, UK; [4]German Haemophilia Society, Hamburg, Germany; [5]Novo Nordisk Inc., Princeton, USA

Background: Psychosocial issues affecting children with haemophilia, their parents and unaffected siblings include negative parental experiences with employment and, for both parents and patients, difficulties with relationships with friends and siblings. The relationship amongst these issues and healthcare utilisation is not well known.

Aims: To describe the relationship of utilisation of haemophilia treatment centres (HTCs) and healthcare professionals with parent-reported negative experiences with employment and parent/children/sibling relationships in the Haemophilia Experiences, Results and Opportunities (HERO) Study.
Methods: A post-hoc descriptive analysis of data from parents of children with haemophilia < 18 years from 8 countries with home treatment (Argentina, Canada, Germany, France, Italy, Spain, UK and United States).
Results: Of 453 parents (80% female), 268 reported a negative experience with work, 175 reported a negative experience telling friends about their son's haemophilia and 38 reported a negative impact on unaffected siblings. There was no difference in employment rate amongst parents who did/did not report negative experiences with work (73%). The majority (55%) of parents who reported a negative impact described it as small. Parents who reported negative experiences telling friends were less likely to be employed (63%) than those who did not (78%) and were more likely to report a considerable or a little negative impact on siblings (28% vs. 18%). Parents with negative experiences at work reported higher mean/median HTC visits/year (6.3/3 vs. 4.1/2 without). Social workers were involved in the management of 26% of children whose parents reported a negative impact on siblings. Social workers were more frequently involved with children whose parents reported negative experiences with work (30% vs. 24%) and telling friends (33% vs. 25%). Nurse involvement was higher in those reporting negative experiences with work (71% vs. 64%) and telling friends (74% vs. 64%). The frequency of counsellor/psychologist involvement was similar amongst parents who did/did not report negative experiences with work or telling friends. More parents with negative experiences with work (22% vs. 12%) or telling friends (25% vs. 13%) reported treatment for psychological conditions for themselves, their partners or their sons in the previous 5 years. Psychological support was more frequent for their sons (work: 24% vs. 14%; friends: 25% vs. 17%) and for the parent or partner (work: 31% vs. 24%; friends: 33% vs. 24%). Ratings of helpfulness of support were similar across those with/without negative experiences.
Conclusions: For parents, there was no difference in the employment rate of those with or without negative impact on work, and the majority who reported a negative impact described it as small. Those with negative experiences telling friends were more likely to report negative impacts on unaffected siblings. HTC visits were higher when parents had negative experiences with work. Social workers were slightly more frequently involved in management of children whose parents reported negative experiences with work or telling friends. Slightly more parents with negative experiences reported treatment for psychological conditions, including support for their son or themselves/partners. Further studies might assess negative experiences and their temporal relationships with HTC visits and feedback.

PO 124

Potential relationships between negative impacts on employment or relationships and haemophilia treatment centre/provider utilisation: an analysis of adults with haemophilia from the HERO study

Iorio A[1], Cassis F[2], Gregory M[3], Kalnins W[4], Wisniewski T[5] and Cooper D[5]
[1]*McMaster University, Hamilton, Canada;* [2]*University of São Paulo Faculty of Medicine Clinics Hospital, São Paulo, Brazil;* [3]*UK Haemophilia Society, London, UK;* [4]*German Haemophilia Society, Hamburg, Germany;* [5]*Novo Nordisk Inc., Princeton, USA*

Background: Psychosocial issues facing people with haemophilia include dealing with negative experiences with employment, relationships and intimacy, and with other adults. The relationship amongst these issues to healthcare utilisation is not well known.
Aims: To describe the relationship of haemophilia treatment centres (HTCs) and healthcare professional utilisation with negative experiences with employment, relationships and intimacy amongst adults with haemophilia in the Haemophilia Experiences, Results and Opportunities (HERO) Study.
Methods: A post-hoc descriptive analysis of data from adults ≥ 18 years from 8 countries with home treatment (Argentina, Canada, Germany, France, Italy, Spain, UK and United States).
Results: Of 515 adults, 393 a reported negative impact on work, 158 reported a negative impact on relationships and 123 reported a negative experience telling friends about their haemophilia. Of the 265 adults in long-term relationships, 135 reported impacts on intimacy. Mean/median ages were similar amongst adults with and without negative experiences. Adults who reported negative impacts on work were less likely to be employed (59% vs. 80%); of the 393 adults reporting a negative impact, the impact was reported as very large (25%), moderate (34%) and small (41%). More adults reporting negative impact on work (32% vs. 25%) sought HTC advice on employment. Adults reported HTC advice on employment as helpful (mean/median 4 on a 1-to-5-point scale), although this was lower for those reporting a negative impact on work (mean 3.8 vs. 4.6 without). Adults with negative experiences with relationships and telling friends were more likely to have sought advice on employment. Adults reporting negative impacts on relationships were likely to have also had negative impacts on intimacy (30% vs. 12%) and telling friends (39% vs. 27%). Adults reporting negative experiences telling friends were likely to report negative impacts on relationships (33% vs. 22%) and intimacy (32% vs. 18%). Adults reported HTC advice on intimacy as helpful (mean/median 3.9/4). Adults reporting impacts on intimacy were more likely to have had discussions on intimacy with the HTC (37% vs. 20%), but were less likely to report this discussion as very helpful (28% vs. 48%). Median number of HTC visits per year was 2, regardless of negative experiences. Nurses were more frequently involved in haemophilia management for adults with negative experiences with work (56% vs. 41%), relationships (55% vs. 52%), telling friends (61% vs. 50%) and intimacy (70% vs. 44%); social worker involvement was more frequently reported by those with negative experiences (work, 24% vs. 8%; relationships, 23% vs. 19%; telling friends, 33% vs. 16%; intimacy, 29% vs. 11%). Counsellor/psychologist involvement was infrequently reported (15%), including in those with negative experiences. Slightly more adults with negative impacts on relationships (34% vs. 22%) and negative experiences telling friends (32% vs. 24%) reported being treated for psychological conditions.
Conclusions: Most adults found advice from HTCs helpful, and those with negative experiences were more likely to have seen an HTC nurse, social worker or counsellor/psychologist. More specific studies assessing the temporal relationship with HTC visits/advice and negative experiences may guide better resource utilisation.

PO 125

Relationship of quality of life, pain and self-reported arthritis with activity, bleed rate and haemophilia treatment centre/provider utilisation: results from the HERO study

Iorio A[1], Forsyth A[2], Guelcher C[3], Buzzi A[4], Wisniewski T[5] and Cooper D[5]
[1]*McMaster University, Hamilton, Canada;* [2]*Rush University Medical Center, Chicago;* [3]*Children's National Medical Center, Washington, DC, USA;* [4]*Fondazione Paracelso Onlus, Milan, Italy;* [5]*Novo Nordisk Inc., Princeton, USA*

Background: Haemophilic arthropathy results in varying degrees of pain and disability. The Haemophilia Results, Experiences and Opportunities (HERO) study examined health-related and psychosocial issues impacting adults with haemophilia (adults) and associated effects on quality of life (QoL).

Aims: To examine potential relationships amongst QoL measures, pain interference and self-reported arthritis and age, employment, activity, bleed frequency, and haemophilia treatment centre (HTC) and healthcare professional utilisation.
Methods: Adults ≥ 18 years completed a 5-point Likert scale on pain interference over the prior 4 weeks, a health-related visual analog scale (VAS, 0–100, coded as an 11-point categorical response) and a standard QoL assessment (EQ-5D-3L mobility, usual activities, self-care and pain/discomfort). Data from 8 countries with home treatment (Argentina, Germany, France, Italy, Spain, UK and United States) are presented.
Results: Overall, 515 adults (236 with self-reported arthritis) responded. Adults with self-reported arthritis were older (median 41 vs. 35 years); median age increased with progressive disability and worsening pain. The percentages reporting full-time, part-time or self-employment declined with increasing disability (EQ-5D self-care none/moderate/unable: 73%/53%/36%) and pain interference (none or a little/moderate/a lot or extreme: 73%/67%/40%); among adults with arthritis, the percentage employed was lower (57% vs. 69% unemployed). The percentage self -reporting arthritis incompletely correlated with 'moderate' functional disability on EQ5D (self-care 61%, usual activities 70%, mobility 63%, pain/discomfort 49%) and pain interference (a lot/extreme 66%). The percentage reporting 'good' EQ-5D VAS scores of 80–90–100 declined with increasing pain/disability as indicated by the EQ-5D mobility (none/moderate/unable: 56%/17%/50%), usual activities (39%/8%/0%), self-care (52%/10%/7%) and pain/discomfort (none/moderate/extreme: 63%/26%/14%), pain interference (54%/19%/10%) and presence of arthritis (no/yes: 43%/22%). Median annual bleed rates increased with increasing pain/disability on EQ-5D mobility (2/7/203), usual activities (5/13/7), self-care (3/8/38) and pain/discomfort (2/6/18), pain interference (3/6/10) and self-reported arthritis (3/10). Adults with disability/pain on EQ-5D reported a higher mean but only slightly higher median HTC visits per year; there was little difference even in mean visits across pain interference categories and between those with and without arthritis. The percentage of adults reporting a lot/extreme pain interference was generally higher in those with more disability as reported by all 4 EQ-5D domains, and in those with arthritis. Adults reporting difficulties with self-care and pain/discomfort, pain interference or arthritis were more likely to report nurse involvement (self-care: 45%/60%/79%; pain/discomfort: 49%/51%/67%; pain interference: 48%/52%/61%; arthritis: 45%/61%) as well as social worker involvement (self-care: 16%/23%/50%; pain/discomfort: 14%/20%/32%; pain interference: 14%/25%/28%; arthritis: 14%/27%) in their haemophilia management. In contrast, physiotherapist utilisation was only moderate and did not change much with disability (self-care 32%/44%/43%), pain (pain/discomfort 39%/35%/44%) or arthritis (34%/41%).
Conclusions: Increased disability and pain were associated with increased age, lower employment, more bleeds and slightly more HTC visits. Whereas nurse and social worker involvement in haemophilia management increased with disability/pain and the presence of arthritis, physiotherapist utilisation was moderate and fairly similar regardless of the extent of disability/pain or presence of arthritis. Additional physiotherapy involvement or follow-up might be helpful in those with haemophilic arthropathy; this could be evaluated in a prospective study.

PO 126

Does higher risk activity change bleed frequency and haemophilia treatment center/provider utilisation in children with haemophilia: an analysis from the HERO study

Iorio A[1], Forsyth A[2], Querol F[3], Stain AM[4], Pericleous L[5] and Cooper D[6]
[1]McMaster University, Hamilton, Canada; [2]Rush University Medical Center, Chicago, USA; [3]University Hospital La Fe, Valencia, Spain; [4]Kiddies Health Care Inc, Toronto, Canada; [5]Novo Nordisk A/S, Bagsværd, Denmark; [6]Novo Nordisk Inc., Princeton, USA

Background: Low- to moderate-risk physical activity is recommended in people with haemophilia; however, relationships amongst activity risk level, treatment regimen, presence of inhibitors, and haemophilia treatment center (HTC) and healthcare professional utilisation have not been investigated.
Aims: To examine associations between activity risk level and HTC and healthcare professional utilisation in children with haemophilia (children), either with (WI) or without (WOI) inhibitors, taking treatment (on-demand vs. prophylactic) regimen into account.
Methods: A post-hoc descriptive analysis of data from parents participating in the Hemophilia Experience, Results and Opportunities (HERO) Study from 8 countries with home treatment responding about their oldest affected children < 18 years old.
Results: Overall, 453 parents responded; mothers accounted for 81% of parents of children WOI and 71% of parents of WI. Most (n = 391) children described had no inhibitors. Overall, 311 children WOI and 24 WI were on prophylaxis. For children WOI, most reported participating in medium-risk activities for both on-demand (lower/medium/higher: 26%/44%/30%) and prophylaxis (21%/45%/34%). Amongst the smaller number of children WI, activity was mostly reported as lower or medium-risk (on-demand: 57%/29%/14%; prophylaxis: 42%/46%/13%). Median ages (years) of children WOI and WI were 10 and 12 years, respectively. Median age generally increased with increasing activity risk amongst children, both WOI (on-demand: 2/12/11; prophylaxis: 4/11/9) and WI (on-demand: 12/10/17; prophylaxis: 13/11/13). The median number of bleeds/year was similar amongst children WOI with increasing activity risk levels (on-demand: 2/5/3; prophylaxis: 3/3/3); in WI, median annual bleed frequency decreased with increasing activity in those receiving on-demand (15/7/2) but increased in WI on prophylaxis (1/10/12). Median HTC visits/year were generally lower with higher-risk activity amongst children WOI (on-demand: 3/3/2; prophylaxis: 4/2/2) but varied for WI (on-demand: 3/5/2; prophylaxis: 6/4/4). Amongst children WOI, nurse involvement in haemophilia management increased with higher activity risk in those on prophylaxis (65%/78%) but decreased in those on on-demand (81%/67%); the same was seen for social work involvement (prophylaxis: 24%/41%; on-demand: 38%/25%). Physiotherapy involvement increased with increasing activity risk in children WOI on prophylaxis (30%/30%/42%) but not in those on on-demand (24%/23%/21%); physiotherapist visit frequency was similar. Median perceived disease control (0 = not at all to 10 = well controlled) was similar across activity risk levels for children both WOI (on-demand: 8/9/8; prophylaxis: 9/9/9) and WI (on-demand: 6/10/7; prophylaxis: 8/8/8).
Conclusions: More common use of prophylaxis treatment in the children with or without inhibitors in HERO allows for broader assessment of relationship of activity risk level to bleed frequency and HTC and healthcare professional utilisation at the expense of describing the on-demand population. As expected, increasing activity risk was reported with older children. In children WOI, bleed frequency was generally unchanged and HTC visits generally reduced with higher-risk activities; data were more variable in the small group with inhibitors. Irrespective of treatment regimen and presence of inhibitors, parents perceived good disease control regardless of activity risk.

Prospective studies are needed to better understand the relationships between activity, bleeding and HTC monitoring, and the potential impact of prophylaxis compliance on bleed frequency.

PO 127

Do bleed rates and haemophilia treatment centre/provider utilisation vary with physical activity risk in adults with haemophilia: An analysis from the HERO study

Iorio A[1], Forsyth A[2], Querol F[3], Stain AM[4], Pericleous L[5] and Cooper D[6]

[1]McMaster University, Hamilton, ON, Canada; [2]Rush University Medical Center, Chicago, IL, USA; [3]University Hospital La Fe, Valencia, Spain; [4]Kiddies Health Care Inc, Toronto, ON, Canada; [5]Novo Nordisk A/S, Bagsværd, Denmark; [6]Novo Nordisk Inc., Princeton, NJ, USA

Background: Lower- to moderate-risk physical activity is recommended in adults with haemophilia; however, relationships amongst activity risk level (accounting for treatment regimen and inhibitors) and haemophilia treatment centre (HTC) and healthcare professional utilisation have not been investigated.

Aims: To examine associations between activity risk (lower/medium/higher) and HTC and healthcare professional utilisation in adults, taking absence (WOI) or presence (WI) of inhibitors and treatment (on-demand vs. prophylactic) regimen into account.

Methods: A post-hoc descriptive analysis of data from adults ≥ 18 years participating in the Hemophilia Experiences, Results and Opportunities (HERO) Study from eight countries with home treatment.

Results: Overall, 515 adult (431 without inhibitors) responded, with treatment mainly divided between on-demand (n = 180) and prophylaxis (n = 203). The distribution of activity risk was shifted toward higher-risk activities for adults WOI on prophylaxis (lower/medium/higher: 44%/40%/16%) vs. on-demand (50%/40%/10%). While there were few total numbers of adults WI reporting moderate- to higher-risk activities, a similar shift was noted for those on prophylaxis (72%/17%/10%) vs. on-demand (82%/15%/3%). Adults reporting higher-risk activities tended to be younger (median age: 41/36/31 years), except for adults WI on on-demand (median age: 36/31/41 years). Employment rates were higher in those reporting higher-risk activities (57%/68%/77%), regardless of treatment regimen or inhibitor status. For adults WOI on prophylaxis, mean bleeds/year were greater with higher-risk activity (10/14/29); however, median values and interquartile ranges were similar across risk groups. Data were more variable for adults WOI on on-demand and for adults WI. Regardless of treatment regimen, adults WOI reporting higher-risk activities were more likely to report no/little pain interference in the prior 4 weeks (68% prophylaxis, 71% on-demand) than those reporting lower-risk activity (45% prophylaxis, 47% on-demand). Mean/median number of HTC visits/year did not differ by activity risk level. In adults WOI on prophylaxis, nurse and social worker involvement in haemophilia management increased with higher-risk activity (42%/64%/68% and 13%/27%/21%, respectively); in contrast, physiotherapist involvement was similar regardless of activity risk level (37%/39%/43%). For adults WOI on on-demand, nurse/physiotherapist involvement declined and social worker involvement increased with increasing activity risk. Data were more variable for adults WI.

Conclusions: Activity is encouraged for adults as a means to maintain joint function and overall health. However, the interaction between activity risk level, treatment regimens and inhibitors is complex, even when assessed in large global data sets like HERO. While the HERO data suggest adults WOI engaged in higher-risk activities are younger, more often employed and more often on prophylaxis, the associations are more difficult to study in those WI even in this large dataset. While activity risk did not seem to significantly impact HTC visit frequency, we observed that those WOI on prophylaxis doing higher risk activities may have higher bleeding rates and may be more likely to report nursing and social work support to management of their disease. More complex multivariate analyses of the HERO data and additional focused prospective research may help to further investigate these interrelationships between activity, bleeding and HTC monitoring.

PO 128

Association of treatment regimen and location with bleed frequency, quality of life and comorbidities in adults and children with haemophilia from the HERO study

Iorio A[1] and Buzzi A[2]

[1]McMaster University, Hamilton, Canada; [2]Fondazione Paracelso Onlus, Milan, Italy

Background: Congenital haemophilia with inhibitors or without inhibitors is primarily treated with on-demand factor replacement or prophylaxis, administered at home or at a haemophilia treatment centre (HTC). Little is known about the relationships of treatment regimen and location with bleed frequency, quality of life (QoL) or comorbidities in haemophilia.

Aims: To examine the associations of treatment regimen, treatment location, bleed frequency, QoL indicators and comorbidities in adults with haemophilia (adults) and bleed frequency in children with haemophilia (children) from the Haemophilia Experiences, Results and Opportunities (HERO) Study.

Methods: A post-hoc analysis of data from adults ≥ 18 years and parents of children < 18 years. QoL in adults was assessed using EQ-5D-3L.

Results: Overall, 648 adults responded and were treated with factor concentrates. Most were treated with either on-demand (n = 289) or prophylaxis (n = 207), with fewer reporting on-demand plus situational prophylaxis (n = 146); 6 responded they did not know or declined to answer. Of 79 adults with inhibitors who responded on treatment, most were treated with either on-demand (n = 43) or prophylaxis (n = 29), with few reporting on-demand plus situational prophylaxis (n = 7). Most adults were treated primarily at home (76%), with 50% treated 'always at home' and 26% treated 'mostly at home but sometimes at the HTC'. Overall, mean/median annual bleed frequency did not differ amongst adults receiving on-demand (13.9/5.0) vs. prophylaxis (14.8/5.0); for those treated on-demand plus situational prophylaxis, mean/median was 28.9/20.0. Mean/median annual bleed frequency was higher for adults treated at home (20.0/8.0) than at the HTC (10.8/4.0). More adults treated at home reported any comorbidity (home: 85.9%; HTC: 73.9%) and, specifically, arthritis (home: 55.0%; HTC: 28.8%). Likewise, more adults with inhibitors treated at home reported any comorbidity (home: 100%; HTC: 81.5%) and arthritis (home: 59.6%; HTC: 14.8%). Overall, fewer adults treated with prophylaxis (prophylaxis: 36.2%; on-demand: 47.8) or at home (home: 37.5%; HTC: 54.9%) reported no issues with EQ-5D mobility, as did adults with inhibitors treated at home (home: 32.7%; HTC: 74.1%). More adults receiving on-demand reported no pain/discomfort (on-demand: 32.9%; prophylaxis: 20.8%); there was no difference attributable to treatment location. Overall, there were no differences in mean/median EQ-5D index by treatment regimen (on-demand: 0.750/0.800; prophylaxis: 0.747/0.778) or location (home: 0.736/0.778; HTC: 0.753/0.800). However, adults with inhibitors treated at home had a lower mean/medianEQ-5D index (home: 0.687/0.764; HTC: 0.760/0.816). Overall, 547 parents of children treated with factor concentrates rsponded; most children were treated with prophylaxis (prophylaxis: n = 356; on-demand: n = 143) and at home (home: n = 397; HTC: n = 146). Mean/median annual bleed frequency was lower for children treated with prophylaxis (6.2/3.0) than on-demand (12.0/6.0). Bleed frequency did not differ by treatment location in children.

Conclusions: Whereas bleed frequency did not differ by treatment regimen in adults, children on prophylaxis reported a lower annual bleed rate than for children on on-demand. Amongst this nonhomogenous patient population, adults who were treated at home and received prophylaxis were the most frequent bleeders and more difficult to treat. In HERO, patients and parents reported treatment modalities and HERO is not designed to evaluate the different treatment regimens.

PO 129

Association between treatment regimen and quality of life assessed by EQ-5D-3L and pain interference in adults with haemophilia with and without inhibitors in the HERO study

Iorio A[1], Buzzi A[2], Benchikh El Fegoun S[3] and Cooper D[4]
[1]McMaster University, Hamilton, Canada; [2]Fondazione Paracelso Onlus, Milan, Italy; [3]Novo Nordisk, Zurich, Switzerland; [4]Novo Nordisk Inc., Princeton, USA

Background: Treatment options for haemophilia A (HA) and B (HB), with or without inhibitors, include on-demand and prophylactic factor replacement. Little is known about the relationship between treatment regimen and quality of life in adults with haemophilia, with and without inhibitors.
Aims: To examine the association between treatment regimen and quality of life in adults with and without inhibitors from the Haemophilia Experiences, Results and Opportunities (HERO) Study.
Methods: A post-hoc analysis of data from adults ≥ 18 years from 10 countries participating in the HERO Study. Adults completed a standard EQ-5D-3L assessment; EQ-5D index was calculated based on Shaw et al, 2005.
Results: In total, 675 adults completed qualitative and quantitative questions on quality of life and well-being. Most adults reported HA (498), 86 reported HB and 91 reported HA/HB with inhibitors. Half (n = 45) of those reporting inhibitors were from the US. Adults with inhibitors were younger (median/maximum age 34/69 years) than those without inhibitors (36/86 years). At a global level, treatment was split between on-demand (289, 43%) and prophylaxis (207, 31%); fewer reported on-demand plus situational prophylaxis (146, 22%). This was similar for adults with inhibitors (on-demand 43 [47%], including 20 US; prophylaxis 29 [32%], including 22 US; on-demand with situational prophylaxis 7 [8%]). Most adults (598, 89%) and adults with inhibitors (86, 95%) reported pain had interfered with their daily life in the past 4 weeks; of those, 301 (50%) reported constant pain (38 [44%] with inhibitors). Mean EQ-5D index for adults with inhibitors was 0.707; it was 0.745 for HA and 0.741 for HB. Median EQ-5D index was the same for HA, HB and adults with inhibitors (0.778). Mean EQ-5D for adults on prophylaxis was 0.707, 0.712 for adults on-demand and 0.731 for adults treated on-demand with situational prophylaxis. Almost half reported no issues with mobility (HA: 41%; HB: 38%; inhibitors: 44%). Most adults reported no issues with usual activity (HA: 81%; HB: 79%; inhibitors: 74%). For adults with inhibitors, the percentage reporting no issues with usual activity was similar across treatment regimens (on-demand: 72%; prophylaxis: 79%; on-demand with situational prophylaxis: 71%). Approximately half reported no issues with self-care (HA: 56%; HB, 49%; inhibitors: 43%) or anxiety/depression (HA: 54%; HB: 53%; inhibitors: 54%). Few denied any pain/discomfort (HA: 26%; HB: 28%; inhibitors: 19%). Self-care is the only index that shows a significant difference amongst the types of haemophilia. Statistical comparison for mobility and usual activity was not possible due to the small number who responded to each question.
Conclusions: Globally, adults with inhibitors in HERO had a lower mean EQ-5D index and more frequently reported problems in individual EQ-5D domains than those without inhibitors. While differences in age and treatment regimen across participating countries limit descriptive analysis, multivariate analyses may yield further insights. The underlying reasons for selecting treatment regimens (e.g. pain vs. bleed control, desired activity participation, employment) likely also impact quality of life and need to be factored into future studies.

PO 130

Patient survey – Pain therapy in haemophilia in Germany

Kalnins W[1], Schelle G[2], Jost K[3], Eberl W[4] and Tiede A[5]
[1]Deutsche Hämophiliegesellschaft, Marmagen; [2]Interessengemeinschaft Hämophiler (IGH), Bonn; [3]Bayer HealthCare, Leverkusen, Germany; [4]Städtisches Klinikum Braunschweig, Braunschweig; [5]Medizinische Hochschule Hannover, Hannover, Germany

Background: Pain management for patients with haemophilia is assumed to be highly relevant. As a result from the disease and its complications, patients with haemophilia often suffer from pain, which has to be treated adequately. One challenge, among others, is the selection and application of appropriate analgesics.
Aims: We have conducted a patient survey on 'pain therapy in haemophilia', which aims to evaluate the current situation of pain management for patients with haemophilia and to identify potential areas for improvement.
Methods: A pain management survey was developed in a joint effort by physicians, patient representatives and Bayer. In cooperation with two major patient organisations in Germany, the Deutsche Hämophiliegesellschaft (DHG) and the Interessengemeinschaft Hämophiler (IGH), about 1.960 copies were sent to patients with haemophilia A and B. Parents of children with haemophilia were requested to fill in the questionnaire on their behalf. Questions concern the types of pain, frequency and severity, medical specialists consulted, types of pain therapies, and the patients' level of satisfaction with the pain management.
Results: The survey started in September 2012 and was completed by the end of October. Six hundred and eighty-five questionnaires were filled in and sent back, i. e. a 35% response rate. Preliminary results show that 86% of respondents experienced episodes of pain. About half of the patients have used physiotherapy as a measure of pain management. Joint pain is the most common type of pain, remarkably so even in young patients. The comprehensive evaluation of the patients' view is underway. It is expected to contribute important insights on the current pain management situation in haemophilia, thus helping to identify factors for improvement.
Conclusions: Patient and physician surveys are powerful tools, which we have used for the assessment of the current situation in pain management for patients with haemophilia. Following the complete evaluation of results, measures for optimization will be developed in order to improve the long-term care of patients with haemophilia.

PO 131

An experience of use of Traumastem P in control of spontaneous mucosal bleeding in patients with inherited bleeding disorders in Southern Iran

Karimi M, Haghpanah S and Zahedi Z
Hematology Research Center, Shiraz University of Medical Sciences, Shiraz, Iran

Background: Bleeding complications are the most important complications in patients with inherited bleeding disorders. Use of local haemostatic agents could help to decrease blood loss, need to blood transfusion, systemic coagulation therapy and consequently duration of hospital stay especially in patients with inherited bleeding disorders due to more susceptibility of bleeding.

Aim: We evaluated the safety and efficacy of Traumastem P for the management of spontaneous mucosal bleeding in patients with congenital bleeding disorders.
Methods: In this case series, 12 patients with inherited bleeding disorders who were complicated by nose or mouth bleeding were investigated from May to August 2012 in southern Iran. Our participants selected from the patients who were registered at the Hemophilia center of Shiraz University of Medical Sciences. Traumastem P (Emoxicel Polvere)(Bioster company, Czech Republic) was used in all patients as hemostat agent without factor infusion. Response to this haemostatic powder was evaluated in patients. Complete stop bleeding in a 1–4 min period was considered as good response, stop bleeding in a 4–30 min period was considered as fair response and not stop bleeding as no response. Patients were followed for any adverse reactions till 72 h after administration. The study protocol was approved by the Ethics Committee of Shiraz University of Medical Sciences. Informed consent was obtained from all patients or the parents of children.
Results: Participants consisted of five female and seven male; six patients with hemophilia type A, two Factor VII deficiency, two von Willebrand disease (vWD) type III, one vWD type I, and one glanzmann's thrombasthenia. Mean age of the patients was 13.4 ± 9.9 years with median age of 10.5, and range of 1–34 years. From eight hemophilia patients, five had severe (< 1%) factor deficiency. The Level of factor deficiency in other patients was ranged between 3.5% and 26.8%. Age at diagnosis of the patients ranged from at birth to 20 years old. All patients came with nose bleeding except one with mouth bleeding. All patients showed good response to Traumastem P except one with fair response; a 34-year-old man with severe hemophilia A and complicated by mouth bleeding who had been diagnosed at birth.
Conclusion: Traumastem P can use as a safe and effective local hemostatic agent for control of nose bleeding in patients with inherited bleeding disorders. Subsequently it could be an economically valuable hemostatic agent in these patients. Further studies are needed to evaluate the effect of Traumastem P for control of other site of bleeding in these patients.

PO 132

Areas of concern for caregivers of children with hemophilia A and B: results of a cross-sectional survey in the US

Kelley L[1], Pham H[2], DeKoven M[3], Lee W[3], Powers J[3], Cooper D[2] and Wisniewski T[2]

[1]LA Kelley Communications, Georgetown; [2]Novo Nordisk, Princeton; [3]IMS Health, Alexandria, USA

Background: Hemophilia is a bleeding disorder resulting from reduced or absent clotting factors. It is a life-long condition characterized by recurring joint bleeds that can lead to chronic pain. Treatment of bleeds and pain in children are typically managed at home by parents or other relatives (i.e. caregivers), who may be affected by the management of the disorder. Previous research with hemophilia caregivers suggested that caregivers are affected by emotional stress, financial issues, personal sacrifice, medical management, child's pain and transportation issues when caring for children with hemophilia.
Aims: To quantify the overall burden of hemophilia on caregivers and to identify specific areas of concerns.
Methods: A caregiver opt-in-research database was used to invite 681 caregivers to complete an on-line survey. The survey included 64 questions on caregiver demographics, six burden domains (emotional stress, financial, sacrifice, medical management, child's pain, and transportation), and three visual analogue scales (VAS). The three VAS scales (0–10) measured overall burden, current child's pain and burden when seeing child in pain. For each survey question, respondents were asked to rate their burden on a scale from 1 to 5 where '1' represented 'never burdened' and '5' represented 'nearly always' burdened. Survey questions were reviewed with three caregivers prior to implementation. IRB approval was obtained.
Results: Of the 681 caregivers invited, 310 (45.5%) caregivers completed the on-line survey. Most respondents were mothers (88%) between 18 and 54 years; 73.9% of respondents reported taking care of 1 child with hemophilia. Most children (86.45%) had been diagnosed with hemophilia A and (85.81%) had been diagnosed more than 2 years ago. On a scale from 0 to 10, the mean level of burden felt by caregivers when a child is in pain was 7.54 (SD 2.62) and the most common response (29.7%) was a '10'. Of the six survey domains, 'Child's pain' was the most burdensome (mean = 3.54 out of 5). Fifty-nine percent and 77% of caregivers reported they were 'quite frequently to nearly always' burdened with worrying about the child's joint and bleeding pain and wishing they can take their child's pain away, respectively. Emotional stress was the second most burdensome domain (mean = 2.79); 51% reported they 'quite frequently' or 'nearly always' are concerned with the child's future when they are not around. Other areas of concern identified by those reporting they were 'quite frequently' or 'nearly always' burdened included: extra planning involved when traveling (42%), rising co-payments over time (33.5%), accessing child's vein or port (24.5%), and the expectation that life would be different at this age (22.6%) .
Conclusions: Hemophilia caregivers are impacted by the burden of their child's pain. Parents also report concerns with the child's future, venous access, travel planning, and rising co-payments. Recognizing these factors is important when considering educational programs to lessen caregiver burden. Future research that incorporates these findings into the formal validation of an instrument to assess caregiver burden should be explored.

PO 133

Immune tolerance induction in children with severe hemophilia A and inhibitor in Poland

Klukowska A[1], Laguna P[1], Dobaczewski G[2], Janik-Moszant A[3], Kamienska E[4], Koltan A[5], Pietrys D[6] and Waleszkiewicz-Majewska B[7]

[1]Warsaw Medical University; [2]Medical University, Wroclaw; [3]Silesian Medical University, Zabrze; [4]Pomeranian Medical University, Szczecin; [5]Collegium Medicum Nicolaus Copernicus University, Bydgoszcz; [6]Jagiellonian University, Krakow; [7]Department of Laboratory Diagnostics and Immunology, Warsaw, Poland

Background: The development of factor VIII inhibitors (FVIII) is the most serious complication in patients with haemophilia today. The highest risk of developing inhibitors is during the first 20 exposure days. First-line treatment for patients with haemophilia A and inhibitors is to attempt to induce immune tolerance by regular infusion of FVIII.
Aims: The results of immune tolerance induction (ITI) were presented in this study.
Methods: In 1993–2012 ITI were used in 31 children with severe hemophilia A and high titer of FVIII inhibitor in Poland. Inhibitors were measured according to Bethesda method in Nijmegen modification.
Results: The median age of patients was 18 months (ranged from 5 to 81 months) in the time of inhibitor detection. Inhibitor was detected within 3 to 100 exposure days to FVIII concentrates (median 19 exposure days). Median of maximal titer of FVIII inhibitors found before ITI start was 40 and ranged from 3.8 to 1024 BU/ml. Titers of FVIII inhibitors ranged from 3.1 to 151 BU/ml (median 16 BU/ml) at the initiation of ITI regimen. Most patients (23) were treated with plasma derived FVIII concentrates, medium or high-purity, seven patients with recombinant FVIII concentrates and one with cryoprecipitate before inhibitors were detected. In ITI usually the same type of concentrate was used. In 23 children ITI was started with single daily dose

of ≥ 100 IU/kg, in two patient daily dose of 50 IU/ml was given and in four children FVIII concentrate in a dose of 100 IU/kg was administered twice a day. In the 2 remaining patients doses of 50 IU/kg 2–3 times a week were repeated. Total elimination of factor VIII inhibitor was achieved in 22 patients. In the other two patients the ITI was partially effective and the recurrences of low titer inhibitor, below 1 BU/ml was observed. In another two patients immune tolerance was not achieved and ITI regimen was discontinued after 15 and 18 months. ITI is ongoing in five patients. Duration of ITI ranged from 2 to 83 months (median 12 months). In patients with positive results the median of ITI was 10.5 months. One boy started second procedure of ITI in 9 months after failure of first one. It was partially effective after 42 months but several doses of rituximab were added. The other patient with ITI evaluated as partially effective was treated with rituximab as well. After achievement of complete ITI, prophylaxis with FVIII concentrates was continued 2 or 3 times a week in dose of 20–50 IU/kg. Only 1 boy was treated on demand.

Conclusion: High efficacy of ITI was found in young children with severe haemophilia A.

PO 134

A systematic review of treatment patterns in Japanese haemophilia patients

Krishnan S[1], Wada K[2], Crawford B[2] and Lee-Grossman CW[1]

[1]Biogen Idec, Weston, USA; [2]Adelphi Values, Toyko, Japan

Background: Literature detailing the clinical patterns of haemophilia treatment and the economic and humanistic burden in Japan is scarce. This is the first review attempting to address the aforementioned issues.

Aims: To conduct a systematic review of epidemiology, clinical practice, economic and humanistic burden of hemophilia in Japan.

Methods: A systematic literature search was conducted to identify existing literature with clinical patterns of haemophilia and the economic and humanistic burden of haemophilia in Japan. We searched MEDLINE and JDream II using 'haemophilia' and 'Japan' as key words. The search included publications from January 2002 to October 2012 with both English and Japanese. JDream II was searched in Japanese. We also searched reports and presentations from professional associations and government agencies for grey literature.

Results: We identified 318 publications at the first round, and after removing duplicates and irrelevant articles, 50 were included in this systematic review. In a population-based report by the Japan Foundation of AIDS Prevention demonstrates that the prevalence of haemophilia in Japan is low with 4475 hemophilia A cases and 971 hemophilia B cases in 2011 (approximately 0.004% overall). Population-based studies found that 43–59% of patients with haemophilia are treated with prophylaxis. Of patients under 20 years old with severe and moderate haemophilia, 60–76.7% were on prophylaxis. Reported home treatment rate was high (66.3–83.5%), administered by either by patients themselves or parents, but poor adherence based on short dosing interval was reported among adolescents (aged 13–19 years). While prophylaxis and home-infusion are accepted as standard of care in most young and severe patients, patients preferred on-demand vs. prophylaxis. Search results revealed very little research focusing on humanistic and economic aspects for haemophilia.

Summary/Conclusions: This is the first systemic review on clinical patterns and utilization of haemophilia treatment in Japan. Clinical practice patterns are found to be very similar to the West with regard to recommending prophylaxis and offering convenient home treatment to patients. Nonetheless, adherence to prophylaxis regimens among adolescents and young adults is relatively low. Patient education and the options for new therapeutic regimens offering shorter dosing-interval should be explored further as they may aid in deterring long term consequences such as the development of target joints, arthropathy, and poor quality of life.

PO 135

Treatment strategy and outcomes among US haemophilia patients: results of a patient survey

Krishnan S[1], Vietri J[2] and Furlan R[2]

[1]Biogen Idec, Weston, FL, USA; [2]Kantar Health, Milan, Italy

Background: Haemophilia can be treated on an as-needed basis with episodic (on-demand) therapy or routinely with prophylaxis. Those treating on-demand may have more bleeding episodes relative to those on prophylaxis, poorer health outcomes, and greater use of healthcare resources.

Aims: To assess the relationship between use of on-demand vs. prophylactic treatment with patient-reported outcomes and adherence in adult US haemophilia patients.

Methods: Adults with haemophilia were identified through a panel of patients originally recruited from haemophilia treatment centers and associations. The study protocol received central institutional review board approval and all patients reported consent to be included in the study. Panelists reporting moderate or severe haemophilia were invited to complete an on-line questionnaire assessing experience with bleeding and joint problems, personal characteristics, and validated scales. The revised Short Form-12 Health Survey (SF-12v2) was included to assess health status, and the Validated Haemophilia Regimen Treatment Adherence Scale-Prophylaxis (VERITAS-Pro) was included to assess adherence to prophylactic treatment. Those using prophylactic treatment were compared to those treating on-demand using *t*-tests for continuous measures and chi-square for categorical variables. Comparisons were first conducted on a combined sample of A & B patients, and repeated among only those with haemophilia A. Limited sample sizes prevented separate analysis of patients with haemophilia B.

Results: A total of 76 patients with haemophilia (74 male, 2 female; 62 with haemophilia A, 14 with haemophilia B) completed the survey, with a mean age of 35.9 years, with most (62%) using prophylactic treatment for haemophilia. Relative to patients using prophylactic treatment, those treating on-demand were older (40.8 vs. 32.5 years, $P < 0.05$) and had lower physical component summary (PCS) scores (41.5 vs. 48.6, $P < 0.05$). These patients also reported more bleeding episodes in the past year 23.2 vs. 10.7, $P < 0.05$). Analyses limited to patients with haemophilia A (60 male, 2 female) yielded similar results mean age was 34 years, with most (68%) using prophylactic treatment. Haemophilia A patients using on-demand treatment were older (39.9 vs. 31.1 years, $P < 0.05$), had lower physical component summary (PCS) scores (39.1 vs. 48.9, $P < 0.05$), and more bleeding episodes in the past year (24.2 vs. 11.0, $P < 0.05$) vs. haemophilia A patients on prophylaxis. Only a minority of patients reported 'Always' doing prophylaxis infusions on scheduled days (38%), infusing the recommended number of times per week (38%), or adhering to the schedule provided by the treatment center (28%), though most (70%) reported always using the doctor-recommended dose.

Summary/Conclusions: Health status was worse and bleeding more common among moderate and severe adult haemophilia patients treated on-demand relative to those treated with prophylaxis, though most patients reported some non-adherence to the recommended treatment schedule. These conclusions support current clinical guidelines advocating prophylaxis as the current standard of care for haemophilia, though further efforts to improve patient adherence may be warranted.

PO 136

Regional factors influencing participation in clinical trials in hemophilia in the United States of America and South Africa

Kruse-Jarres R[1], Rodman A[1] and Mahlangu J[2]

[1]*Tulane University, New Orleans, USA;* [2]*University of the Witwatersrand Medical School and NHLS, Johannesburg, South Africa*

Background: Clinical trials are the gold standard for evaluating medical interventions and developing best practices in clinical care. Multicenter, multinational trials are common, especially in rare bleeding disorders such as haemophilia. Regional differences in perceptions about health research and decision making when engaging in such research will affect enrolment. We hypothesized that there are regional cultural differences in health research participation in the bleeding disorders communities in the USA and South Africa (SA).

Aim: To elicit factors influencing participation in clinical trials in patients with haemophilia and other congenital bleeding disorders in the USA compared to SA.

Methods: This was a collaborative cohort study conducted in the USA (Comprehensive Louisiana Hemophilia Care Center) and SA (Comprehensive Haemophilia Care Centre, Johannesburg). Both sites obtained ethics approval. Adult patients and parents of pediatric patient with congenital bleeding disorders at both participating hemophilia centers were invited to participate in a one-time, anonymous, on-line survey (implied consent).

Results: Seventy four (53 patients, 21 parents) participants in SA and 64 (28 patients, 35 parents) in the USA completed the survey. More participants in SA classified their disease as severe (78 vs. 59%). There was a comparable family history of a bleeding disorder (57 vs. 59%). Slightly fewer subjects in SA had participated in clinical trials before (41% vs. 52%). Both sites felt that the doctor had the highest level of responsibility in clinical studies, but both also felt high levels of responsibly lay with the patient. When asked how they were protected during clinical trials, most subjects in SA felt it was themselves (80% vs. 50% in USA, $P = 0.0002$) and at both sites not all patient felt that they were protected by their physician (68% in SA and 55% in USA felt protected by their physician). At both sites the most important reason to participate in clinical studies was to contribute to research in the field, a free gift/money was least important. More subjects in SA thought that participation in research was safe/very safe (88% in SA vs. 69% in USA, $P = 0.0067$). At both sites, the subject was the primary decision maker (over the doctor, nurse and family members) to participate in study. While family and health care team played a major role in decision making, spiritual/religious considerations, friends and co-workers did less so. Significantly more subjects in SA were willing to engage in clinical studies: phase I (26% vs. 8%, $P = 0.0039$) and phase II (86% vs. 52%, $P < 0.0005$), phase III (88% vs. 50%, $P < 0.0005$), phase IV (94% vs. 69%, $P = 0.0001$)

Summary/Conclusions: While the motivation to participate in clinical studies was similar in both SA and USA, it appeared that there was less trust and likelihood for participation at the USA site. This site has a higher percentage of African American patients than many other US sites. Knowing the sensitive history of human protection of African American subjects in the US, this raised the question whether there could be racial factors influencing decision making. We are collecting further data to make this analysis.

PO 137

The use of central venous catheters in children with haemophilia in Poland

Laguna P[1], Klukowska A[1], Rawicz M[2], Puchalski S[2] and Matysiak M[1]

[1]*Department of Ped. Hematology and Oncology;* [2]*Department of Paediatric Anaesthesia and Intensive Caremedical University of Warsaw, Warsaw, Poland*

Introduction: Central venous access devices (CVaDs) are essential in the management of haemophilia patients who need repeated urgent administration of coagulation factor concentrates. The use of a facilitates treatment of young children with difficult peripheral venous access.

Methods: Between 1997 and 2012 CVaDs were used in our department. Seventy-two CVaDs (port-a-cath) have been inserted in 53 patients aged 3 months to 18 years.

Results: Fifty-three patients had haemophilia A and 2 had haemophilia B. Twenty-one out of 53 had haemophilia A complicated by high-titre inhibitors and immune tolerance was used. In two patients CVaDs were inserted three times, in 11 patients these catheters were inserted twice and the remaining patients (44) they were inserted once. The period of vascuport use ranged from 2 to 103 months. CVaDs infections were observed 19 times in 12 children. All infected ports were successfully treated with antibiotics, thrombotic complications occurred in 7 boys 11 times. In 2 cases the ends of the CVaDs got torn and moved to the heart and in 2 other cases the reservoir stated leaking.

Discussion/Conclusion: Our investigations show that CVaDs are convenient in use but complications can occur. Central venous access devices are recommended for these children.

PO 138

Is venous or arterial thrombosis a clinical problem in patients with haemophilia? Experience from a Danish haemophilia centre

Larsen JB, Nielsen KBJ, Poulsen H and Bor MV

Aarhus University Hospital, Aarhus N, Denmark

Background: Theoretically, haemophilia patients are to some degree protected from arterial and venous thrombosis due to a hypocoagulable state. However, as life expectancy rises for these patients due to more effective treatment, with older age they can be faced with an increased risk of atherosclerosis, surgical procedures and cancer, which are all risk factors for thrombotic events. It could be feared that the risk of thrombosis in haemophilia patients is an underestimated and probably sometimes overlooked, and therefore the magnitude of the problem and the clinical implications are difficult to estimate. Thromboprophylaxis and treatmentof haemophilia patients with thrombosis is also a field where experience is limited, and approaches to treatment vary considerably.

Aim: The aim of the study was to examine the prevalence of arterial and venous thrombosis in the populations of haemophilia A and B patients. We furthermore reviewed how patients were treated medically in case of a thrombotic event and whether any bleeding tendency was seen in those patients.

Methods: We conducted a retrospective study, where medical records of all patients with haemophilia A and B registered at the Haemophilia and Thrombosis Centre, Aarhus University Hospital, Denmark from 1985 to 2011, were reviewed thoroughly and all the thrombotic events noted in the records were registered.

Results: Of 169 haemophilia A patients, 5 cases of arterial thrombosis, all in a coronary artery (3%), 3 cases of venous thrombosis (2%) and 2 cases of unclassified (eye vessel) thrombosis (1%) were found. Of 30 haemophilia B patients, 1 case of coronary artery thrombosis (3%), 1

case of cerebral artery thrombosis (3%) and no cases of venous thrombosis were found.
The antithrombotic treatment received differed considerably between cases, with acetylsalicylic acid and low molecular weight heparin as the most commonly used drugs. In 1 case, increased bleeding tendency was reported.
Summary/Conclusion: Arterial and venous thrombosis does occur and can be a clinical problem in hæmophilia patients, especially with co-existing risk factors. We found a prevalence of coronary artery thrombosis lower than the Danish male background population and comparable to that reported in the literature. Due to the small patient populations and the scarcity of literature in this field, however, it is not possible to characterize the magnitude of this problem. Further multicentre studies are needed, preferably prospective and cross-national.

PO 139

The importance of taking the *in vivo* recovery test as a routine evaluation for Hemophilia patients

Lee KS, Suh J and Kim UH

Kyungpook National University Hospital, Daegu, South-Korea

Background: As the replacement therapy evolves, the general management of hemophilia is getting more important nowadays. Having regular standardized evaluations including musculoskeletal issues, inhibitors, and transfusion transmitted infections, every 12 months, is mainly recommended by WFH guidelines for the management of hemophilia. However, through our precedent study, Individualized replacement of FVIII based on *in vivo* recovery (IVR) in hemophilia A patients during surgery, which was announced in the 17th congress of EHA, 2012, we found that it is very important to check IVR on all occasions and supply the coagulation factor VIII concentrates according to the result to maximize the therapeautic effect. Since then, we have done IVR test as a routine evaluation for all the hemophilia patients who are managed in the Department of Pediatrics, Kyungpook National University Hospital, Daegu, Korea.
Aims: Through this study, we analyzed the results of IVR tests to emphasize the necessity of IVR test.
Methods: Ten hemophilia A patients who had IVR test as a routine evaluation from January 2011 to December 2012 were reviewed. All patients were checked coagulation factor VIII activity four times respectively, before, 15 min, 30 min, and 60 min after the injection of factor concentrates. Green mono® or Advate® was used. Coagulation factor VIII activity was measured using the STA-Unicalibrator analyzed by dilution with STA-Owren-Koller® buffer based on the parameter entered in the instrument (DIAGNSTICA STAGO, France).
Results: Two patients were severe (FVIII:C < 1 IU/dL), five patients were moderate (FVIII:C 1–5 IU/dL), and the remainder were mild (FVIII:C > 5 IU/dL) hemophilia A. They were all males. Their mean age at the time of IVR test was 21 (range from 0 to 41) years old. The peak coagulation factor VIII activity level was median 72.0% (range from 43.4–138.0%), and the time at peak coagulation factor VIII activity level was median 25, six were over 80%, one was under 60% and the other three were between 60 and 80%. Five patients (50%) had under expected peak coagulation factor VIII activity level.
Conclusions: This study shows that all the patients has his own patterns on recovery test. Therefore, having regular IVR tests should be included to the routine evaluations for all the hemophilia patients to produce the better result in the treatment process.

PO 140

Clinical study to investigate the immunogenicity, efficacy and safety of treatment with human-cl rhFVIII in previously untreated patients with severe haemophilia A

Liesner R[1], Jansen M[2] and Knaub S[3]

[1]*Great Ormond Street Haemophilia Centre, London, UK;* [2]*Octapharma, Vienna, Austria;* [3]*Octapharma AG, Lachen, Switzerland*

Background: *Human-cl rhFVIII* is a B-domain deleted, human cell-line derived recombinant FVIII concentrate for intravenous use, which will be provided in single use vials containing a nominal potency of 250, 500, 1000 or 2000 IU each of freeze-dried rFVIII concentrate to be reconstituted in 2.5 mL of WFI. Due to the absence of immunogenic epitopes seen in recombinant FVIII concentrates from hamster cell lines *Human-cl rhFVIII* is thought to be potentially less immunogenic.
Five prospective GCP studies with *Human-cl rhFVIII* were conducted in 135 adults and children with severe haemophilia A. In these studies pharmacokinetics, efficacy and safety of the product was evaluated. Observational period per patient was at least 6 months and at least 50 exposure days. The data indicate that Human-cl rhFVIII is bioequivalent to Kogenate FS (both analyzed by the one-stage and the chromogenic assay) and effective in the treatment and prophylaxis of bleeding episodes. There was no product related serious adverse event and none of the PTPs treated with *Human-cl rhFVIII* developed an inhibitor.
Aim: To assess the immunogenicity in previously untreated patients (PUPs), a prospective, multicentre, multinational, open-label, non-controlled clinical trial is planned in around 45 clinical centres worldwide, starting by the early 2013.
Methods: Hundred patients with severe haemophilia A without previous exposure to any FVIII concentrate or FVIII containing products will be enrolled.
An inhibitor assay according to modified Bethesda method will be performed pre-treatment, every 3–4 exposure days (ED 1–20) and every 10–12 EDs (ED 21–100) but at least every 3 months.
Secondary objectives are the assessment of the efficacy of *Human-cl rhFVIII* during prophylactic treatment (based on the frequency of spontaneous break-through bleeds), the assessment of the efficacy during treatment of bleeds, and in surgical prophylaxis. Also the safety and tolerability of *Human-cl rhFVIII* will be assessed. Furthermore pharmacooeconomic aspects of treatment with *Human-cl rhFVIII* will be assessed for the first time. The optional assessment of predictive factors for the development of inhibitors is included in the study protocol.
Results: The study is planned to start in Q1 2013.
Conclusion: Based on available data in PTPs *Human-cl rhFVIII* seems to be bioequivalent to a licensed full-length rFVIII and safe and effective in the treatment and prevention of bleeding episodes with no occurrence of an inhibitor. A global GCP-study is currently started in order to investigate whether the reduced immunogenic profile of Human-cl rhFVIII will translate into a lowered inhibitor incidence in PUPs.

PO 141

A new board game to assess coping and perception of children with hemophilia: validation and evaluation

Limperg PF, Haverman L, Colland VT, Van Ommen H, Peters M and Grootenhuis MA

Emma Children's Hospital AMC, Amsterdam, The Netherlands

Background: How children cope with and perceive their disease is an important predictor of self-management and Health Related Quality Of Life (HRQOL). The Hemophilia Coping and Perception Test (HCPT) for children is a new tool (a board game) to assess coping,

perception and knowledge of children with hemophilia. The HCPT is based on the Asthma Coping and Perception Test (ACPT).

Aims: The aim of this study is to evaluate and validate the HCPT for boys with hemophilia between 8 and 12 years old in the The Netherlands.

Methods: The HCPT is a board game containing a comprehensive set of 33 questions about hemophilia, including knowledge, self-management, coping, anxiety and perception. Additional questions concern fun subjects or contain fun assignments. In this study, all boys from five hemophilia treatment centers in theNetherlands (Amsterdam, Groningen, Eindhoven, LeidenandRotterdam) with mild, moderate and severe hemophilia between 8 and 12 years old were eligible. To validate the HCPT, children and parents complete the HaemoQoL (Haemophilia Quality of Life questionnaire – short version), two coping questionnaires (CODI; Coping with a Disease and the Op Koers questionnaire) as well as the State-Trait Anxiety Inventory for Children (STAIC). After finishing the HCPT, children and parents respond to an evaluation questionnaire about the HCPT.

Preliminary results and hypotheses: So far, a total of 32 boys (response rate 50%) played the HCPT (mean age 9.8 ± 1.7). Both parents and children report the HCPT to be informative and entertaining. We expect the HCPT to be a valid and effective tool to detect problems regarding coping, disease management, anxiety and the perception of children with hemophilia and facilitate communication with children with hemophilia.

Summary: To be able to provide tailored health care, it is important to get insight in children's knowledge, coping and perception of their disease. With the use of this new board game it is possible to get insight in these aspects in a playful, child friendly way.

PO 142

Satisfaction with self-reported annual bleed rates within a severe hemophilia a population

Lin VW and Epstein JD

Baxter BioScience, Westlake Village, USA

Background: Prospective clinical trials have demonstrated that Factor VIII prophylaxis can help patients with severe hemophilia A achieve or approach zero bleeding episodes per year. It is important to understand current bleeding rates outside of these clinical trials and to measure patient satisfaction with how frequently they are bleeding to identify opportunities to improve patient outcomes.

Aims: The objective was to compare patient self-reported ABR with their level of satisfaction with their current ABR.

Methods: Adult patients and parents of children (< 18 years old) with a self-reported physician diagnosis of severe hemophilia A in the United States were recruited and completed a web-based survey. The survey included questions regarding patient demographics, treatment regimen, ABR, and satisfaction with their ABR using a five-item Likert scale. ABR responses were sorted into five categories (0–1, 2–5, 6–11, 12–23, ≥ 24). Chi-square tests were used to test for statistically significant differences between ABR and satisfaction levels. All respondents provided online informed consent and the study complied with the Declaration of Helsinki, receiving ethics board approval.

Results: The final sample included 164 respondents. The average patient was 19.2 years old. One hundred and thirty-nine (85.8%) respondents reported that they currently receive prophylaxis (defined as infusions administered on an ongoing, regular schedule to prevent bleeds). The most frequently (57.1%) reported reason that the on-demand patients gave for not receiving prophylaxis was 'not bleeding enough to justify prophylaxis' and the mean ABR reported by these respondents was 10.4 (SD = 13.4). The mean reported ABR for all respondents was 7.8 (SD = 13.4). There were 44 (26.8%), 61 (37.2%), 29 (17.7%), 21 (12.8%) and 9 (5.5%) respondents who reported 0–1, 2–5, 6–11, 12–23 and ≥ 24 ABRs, respecitvely. Overall, 60 (36.6%) respondents were not satisfied with their self-reported ABR. Satisfaction with ABR differed significantly by ABR category ($P < 0.0001$). While 88.6% of those who reported zero to one ABR were 'very satisfied' with their bleeding rate, the percentage of respondents reporting they were 'very satisfied' significantly declined as ABRs increased (with 50.8%, 6.9%, 9.5% and 0% reporting 'very satisfied' with ABRs of 2–5, 6–11, 12–23 and ≥ 24, respectively). There was a statistically significant difference in satisfaction levels between the 0–1 and 2–5 ABR categories (each $P < 0.0001$). In those who reported having two bleeds or more per month (≥ 24 ABR), 66.7% reported 'neither satisfied nor dissatisfied' with the remaining third reporting either 'somewhat dissatisfied' or 'very dissatisfied'.

Conclusions: As would be expected, severe hemophilia A patients who reported zero to one ABR were highly satisfied with their bleeding frequency. Healthcare professionals should be aware that patient satisfaction was significantly lower for patients reporting ABRs between 2 and 5, implying that many of these patients may envision having fewer bleeds. Additionally, the majority of patients reporting an ABR ≥ 24 were not dissatisfied with their ABR. Healthcare professionals may consider engaging these patients regarding the consequences of a high ABR and ensure that these patients are familiar with recent clinical trial results that demonstrate the effectiveness of prophylaxis when patients are adherent to the regimen.

PO 143

Immune tolerance induction (ITI) according to the Bonn protocol in haemophilia A patients with inhibitors using a plasma-derived VWF-containing factor VIII concentrate: two paediatric case reports

Lohse J[1], Gehrisch S[1], Escuriola-Ettingshausen C[2], Kreuz W[2] and Knoefler R[1]

[1]University Hospital Dresden, Dresden; [2]Johann-Wolfgang-Goethe University Hospital, Frankfurt am Main, Germany

Background: ITI is the treatment of choice in haemophilia A patients with high titre factor VIII (FVIII) inhibitors. Whether the source of F VIII (plasma-derived-pd or recombinant-r) used for ITI has any impact on success is discussed controversially. We report on two paediatric haemophilia A patients with high titre inhibitors who underwent successful ITI using VWF containing F VIII for first line as well as a second line ITI.

Case 1: Due to a positive family history a severe haemophilia A was diagnosed in the first patient after birth. Genetic analysis revealed a splice site mutation which is associated with a low risk to develop inhibitors. Since the age of 7 months the boy had several exposures to rFVIII due to bleeds and surgery (herniotomy). After 23 FVIII exposures he developed a high-titre inhibitor (maximal 31 BU). ITI was started with the same rFVIII product (2 × 100 U/kg/d) leading to a decrease of the inhibitor titre. After 5 months of treatment the inhibitor titre rose again to 13 BU despite any changes of treatment or any detectable triggers. The patient was switched to a VWF-containing FVIII concentrate. *In vitro* testing showed a lower inhibitory activity against VWF-containing F VIII concentrate compared to r FVIII. After 8 weeks the inhibitor was not measurable any more. FVIII recovery and half-life became normal.

Case 2: The second child presented with an extended soft tissue bleeding after vein puncture at the age of 7 months leading to the diagnosis of a severe haemophilia A caused by a large deletion in exons 24 and 25 of FVIII gene which is associated with a high risk to develop inhibitors. Prophylaxis with r FVIII was started at the age of 26 months. After 7 exposure days the child developed a high-titre inhibitor (maximal 12 BU). Again *in vitro* testing showed a lower inhibitory activity against VWF-containing concentrates. ITI according to the Bonn protocol was started using a pd VWF-containing FVIII product leading to a complete elimination of the inhibitor within 7 months.

Conclusions: Case 1 supports the fact that intensive treatment, such as a surgical procedure within the first 20 exposure days increases the risk of inhibitor development in severe haemophilia A patients markedly.

As reported by others, both cases indicate that patients may benefit from the use of a plasma-derived VWF-containing FVIII concentrate in the frame of ITI. The relevance of *in vitro* testing in patients undergoing ITI is investigated in the OBSITI study in which both patients were included.

PO 144

Identification of carriers of mutations in the factor VIII gene that cause severe hemophilia A: first study in Venezuela

López-Vásquez L[1], Ruiz-Sáez A[2], Boadas A[2], Porco A[1] and Albánez S[1]

[1]Laboratorio de Genética Molecular Humana B, Universidad Simón Bolívar; [2]Centro Nacional de Hemofilia, Banco Municipal de Sangre del Distrito Capital, Caracas, Venezuela

Haemophilia A (HA) is a genetic, recessive and X-linked hemorrhagic disease caused by mutations in the coagulation factor VIII (F8) gene. Severe HA is characterized by the lowest levels of F8 and is caused primarily by the intron 22 inversion and by the intron 1 inversion; the rest of the causative mutations are greatly diverse. Since this is an X-linked disease, half of the male offspring of a HA carrier woman will probably inherit the disease. This makes the identification of carriers and genetic counseling very important to the control of HA. Therefore, the aim of this study was to determine whether eleven mothers of severe HA patients have the mutations in the F8 gene previously found in their sons (either in this study or in a previous one). First, in twelve severe HA patients and then in potential carriers, the presence of the intron 22 inversion and of the intron 1 inversion was investigated, using an inverse and a regular PCR, respectively. There were also diagnosed potential carriers of large deletions through real-time PCR, and potential carriers of point mutations through sequencing of the involved region of the F8 gene. The intron 22 inversion was found in three out of twelve severe HA patients (frequency: 27.3%) and it was found in all five mothers of severe HA patients who had it. Intron 1 inversion was found in none of the patients analyzed. None of the two mothers of patients with large deletions are carriers and all four mothers of patients with point mutations are carriers. The frequency of severe HA carriers was 81.8%. This is the first study conducted in Venezuela and it will allow to establish the detection of carriers in our country.

PO 145

Implementation of a Mobile Haemophilia Outpatient's Care in Germany – results of the HomeMHA project

Von Mackensen S[1], Schleicher C[2], Freidinger K[2], Heine S[3], Graf N[3] and Eichler H[2]

[1]University Medical Centre Hamburg-Eppendorf; [2]Institute of Clinical Haemostaseology and Transfusion Medicine; [3]Department for Paediatric Oncology/Haematology, Homburg, Germany

Background: Several haemophilia patients are facing obstacles visiting their Haemophilia Treatment Centre (HTC) which is due to poor infrastructure in some rural regions inGermany or patients' impaired health condition. Those patients would benefit from a mobile health care centre.

Aim: The major goal was to build up a mobile haemophilia outpatient's care implementing a more extensive social and medical care by getting knowledge about disease-specific problems in the direct private environment of haemophilia patients (e.g. at kindergarten, school, job, or within the family home).

Methods: The 3-years longitudinal project into the implementation of a Mobile Haemophilia Outpatient's Care (Homburger Mobile Haemophilie Ambulanz = HomeMHA) started in 2010 at the HTC of theSaarlandUniversityHospital. Haemophilia patients and their families were visited by a social education worker and/or a physician of the HTC with a project car. The project included home visits and interviews to measure patients' health-related quality of life (HRQoL) and treatment satisfaction (TS) by means of validated questionnaires (HRQoL: paediatric Haemo-QoL, adult Haem-A-QoL; TS: Hemo-Sat); adult patients and parents of paediatric patients were asked as well about their needs and wishes for a HomeMHA. In addition sociodemographic and clinical data were collected.

Results: In total 56 adult haemophilia patients (78.6% haemophilia A, 60.7% severely affected, 48.2% on prophylaxis) with a mean age of 37.4 ± 16.4 years and 23 paediatric patients (82.6% haemophilia A, 69.6% severely affected, 60.9% on prophylaxis) with a mean age of 9.8 ± 4.2 years and their parents were interviewed. The median distance from patients' home to the HTC was 45 km (range 3–200 km) and travel time was in median 40 min (10–120). More than 90% of the haemophilia patients and parents considered an intense binding to the HTC and the implementation of the HomeMHA as 'rather/very important'. A 35.7% of haemophilia patients and parents would use the services of the HomeMHA, especially for counselling and due to their immobility. Adult patients reported a good HRQoL (Haem-A-QoL total score 23.09 ± 17.1) with highest impairments in the domain 'sport & leisure' as did young children aged 4–7 years (M = 54.76 ± 28.4), while children aged 8–12 years reported highest impairments in the domain 'friends' (M = 57.64 ± 17.4) and adolescents in the domain 'dealing' (M = 38.93 ± 28.4). Adult patients were highly satisfied with their haemophilia treatment (M = 16.9 ± 14.6) and were mainly unsatisfied in the domain 'ease & convenience' (Hemo-Sat); by contrast parents of haemophilic children reported most impairments in the domain 'burden' (M = 33.85 ± 20.7).

Conclusions: Haemophilia patients were generally very satisfied with the implementation of the HomeMHA and felt quite supported by their haemophilia care which was as well reflected in their HRQoL and TS.

PO 146

Sub-visible particles in recombinant FVIII products: increased risk for immunogenicity?

Malisauskas M, Lubich C, Prenninger T, Matthiessen P, Turecek P, Scheiflinger F and Reipert BM

Baxter BioScience, Vienna, Austria

Background: The development of neutralizing antibodies against FVIII is the most challenging complication in current therapy for hemophilia A patients. Despite progress in explaining the regulation of anti-FVIII immune responses, the root cause for development of FVIII inhibitors is still unknown. Studies with other protein therapeutics have shown that certain types of protein aggregates, e.g. sub-visible particles, are associated with an increased risk for immunogenicity. The formation of such protein aggregates can be caused by physical stress factors such as elevated temperature, freeze/thaw cycles or shear stress. The sensitivity of different recombinant FVIII (rFVIII) products to form sub-visible particles when exposed to physical stress has not been previously investigated.

Aim: To assess quantities and properties of sub-visible (0.75–70 μm) particles in different rFVIII products including full-length and B-domain deleted products, and to analyze the sensitivity of different rFVIII products to form sub-visible particles under conditions of physical stress.

Methods: Two full-length rFVIII products and two B-domain deleted rFVIII products were analyzed. Sub-visible particles were assessed (1) immediately after reconstitution of the products and (2) after exposure of reconstituted products to physical stresses. Three different lots were included for each product.

Samples were analyzed using a flow cytometry-based method based on a combination of size calibration beads, counting beads and a number

of different fluorescent probes that bind to distinct structural elements of sub-visible particles. This method allows assessment of the amount, size and nature (e.g. protein and non-protein particles) of sub-visible particles. Moreover, we used the fluorescent dye 4-(dicyanovinyl)-julolidine (DCVJ) to obtain structural information of the sub-visible particles. DCVJ binds to cross-beta-sheet structures in amyloid-like protein particles (Hawe at al. Pharm Research 2008). Amyloid-like protein particles could be associated with an activation of the innate immune system as was demonstrated for Amyloid beta peptides. For comparison, we used Micro-Flow Imaging, a state of the art technology for the quantification of sub-visible particles.

Results: Immediately after reconstitution, the concentration of sub-visible particles varied significantly between the different rFVIII products analyzed. The structural properties of the detected sub-visible particles were similar in all freshly reconstituted products.

After exposure of freshly reconstituted rFVIII products to physical stress, the total number of sub-visible particles increased significantly in products containing B-domain deleted rFVIII, but remained constant in products containing full length rFVIII. In addition, an increased concentration of cross-beta-sheet containing sub-visible particles was found in B-domain deleted rFVIII products but not in full length rFVIII products.

Conclusions: We conclude that rFVIII products containing full-length rFVIII and products containing B-domain deleted rFVIII differ in their intrinsic propensity to form sub-visible particles when exposed to physical stress. Furthermore, products containing B-domain deleted rFVIII seem prone towards formation of cross-beta-sheet containing sub-visible particles when exposed to the physical stress conditions tested in our studies. This could be due to the lack of glycosylation sites contained in the B domain of FVIII. Whether these cross-beta-sheet containing sub-visible particles are associated with increased immunogenicity of FVIII remains to be investigated.

PO 147

Evaluation causes of deaths among individuals with inherited haemophilia A & B in North-eastern Iran

Mansouritorghabeh H[1], Lida M[2] and Modaresi A[3]

[1]Ghaem Hospital; [2]Hematology Lab; [3]Dr. Sheikh Hospital, Mashhad, Iran

Introduction: Inherited haemophilia A & B (HA & HB) are worldwide bleeding disorders that affect all ethnic groups. It is estimated that about 1,000,000 affected peoples with haemophilia exist in worldwide. Determination of causes of death in haemophilia may be useful for healthcare officials to program for elimination causes terminate to death in haemophilia.

Patients and Methods: We know 552 cases with inherited bleeding disorders in North-eastern Iran. Among them, there are 287 cases with HA and 92 with HB. To determine number of death and causes of deaths among them, a call phone established to each affected ones to extract data and record in questionnaire form. The rough data entered to software Prism version 5 and descriptive methods of analysis presented here.

Results: Overall among 379 cases with HA & HB, there were 43 deaths as follow:

HA: Among 287 cases, there were 143 (49.8%) with severe type, 59 (20.6%) with moderate and 85 (29.6%) with mild. We could find 38 deaths among them youngest one was 3 months year old and oldest one was 70 years old and mean of age among dead ones was 25.84 year. The oldest death was happened 52 years ago and newest one has happened 2 years ago and mean of time passed of death time was 15.6 years. The dead one included 29 severe type (76.31%), 5 moderate (13.15%) and 4 mild type (10.5%). The death's causes included 10 episodes of central nervous system (CNS) bleeding (26.3%), 6 cases with post trauma bleeding (15.7%), 6 cases with various cancers (15.7%), 4 cases with cirrhosis of liver (10.5%), 4 cases due to various uncontrolled bleeding (10.5%), 3 cases due to HIV infection (7.8%), 2 cases due to unknown cause (5.2%), and a case due to heart problem (2.6%) and another a case due to uncontrolled post surgery bleeding (2.6%).

HB: Among 92 cases, there were 43 (46.7%) with severe type, 33 (35.9%) with moderate and 16 (17.4%) with mild. We could find 5 deaths among them youngest one was 28 year old and oldest one was 76 years old with mean of 46.2 year. The oldest death was happened 50 years ago and newest one has happened 6 years ago and mean of time passed of death time was 16.2 years. The dead one included 2 severe type, a moderate and 2 mild type. The death's causes included 2 episodes of CNS bleeding (40%), 2 cases of liver cirrhosis (40%), and 1 case with severe nose bleeding.

Discussion: The most common cause of death in the group under survey was spontaneous or post trauma bleeding in CNS. As most of patients in the current group are on-demand infusion of relevant coagulation factors, it seems prophylaxis regimens may be useful in prevention at least part of deaths due to CNS bleeding.

PO 148

Meta-analysis of Post Authorization Safety Studies: worldwide postmarking surveillance of hemophilia A patients treated with antihemophilic factor recombinant plasma/albumin-free method rAHF-PFM

Marcucci M[1], Cheng J[1], Oldenburg J[2], Schoenig-Diesing C[3], Matovinovic E[3], Romanov V[3], Thabane L[1] and Iorio A[1]

[1]McMaster University, Hamilton, Canada; [2]University Clinic Bonn, Bonn, Germany; [3]Baxter Healthcare Corporation, Westlake Village, USA

Background: A rigorously designed Post-Authorization Safety Surveillance (PASS) program on rAHF-PFM use in hemophilia A patients has been conducted in Europe, US, Australia, Korea, Taiwan and Japan to identify adverse events (AEs), strengthen inhibitor risk estimates obtained from pivotal trials, and explore product effectiveness.

Aims: To synthesize evidence on rAHF-PFM safety in a standard clinical setting by analyzing available data collected from registered PASS studies conducted from 2004 to 2012.

Methods: Summary data was extracted from clinical study reports for hemophilia A patients enrolled in rAHF-PFM-PASS in Europe (11 countries plus Italy as a stand-alone data collection), US, Taiwan and Australia. Outcomes included: AEs (total, serious [SAEs] and treatment-related), including inhibitors (total, high responding [HR], *de novo*). Incidence rates were calculated using exact binomial method and then pooled using random effects model, with heterogeneity measured using I^2. Subgroup analyses consisted of the following: disease severity, previous exposure to FVIII concentrates at enrollment (< or ≥ 50 exposure days [EDs]), inhibitor history, and on-demand/prophylaxis regimen.

Results: Overall 883 patients were included, followed up for over 1 year, mean EDs from 85 to 103 across 5 studies; 611 (69.2%) had severe disease (FVIII:C < 1%), mean age ranged from 12.1 to 31.4 years. 524 of 596 (11.6%) patients reporting the number of previous EDs at enrollment were treated for ≥ 50 EDs. During the study, 440/883 patients (49.8%) were treated only on-demand, 353 (40.0%) only according to a prophylaxis regimen. About 741 total AEs and 36 rAHF-PFM-related AEs (22 of which were inhibitors) occurred at a rate of 2.2 (95% CI 1.2–3.3, I^2 99%) AEs every 100 infusions and 3 (95% CI 0.7–6, I^2 70%) rAHF-PFM-related AEs every 10,000 infusions. Total SAEs (n = 79) and rAHF-PFM-related SAEs (n = 24, 22 of which were inhibitors) occurred at a rate of 10 (95%CI 5–20, I^2 79%) SAEs and 2 (95%CI 0.3–3%, I^2 57%) rAHF-PFM-related SAEs every 10,000 infusions. The proportion of patients with at least one rAHF-PFM-related AE was not significantly different among those initially treated on-demand and those initially receiving prophylaxis (2.8% vs. 4.0%, OR [95%CI] = 0.65 [0.19, 2.20]). Among the 22 patients positive for inhibitor (2.0%, 95%CI 0.3–3.6%, I^2 39%), 10

were *de novo* (i.e. without history of inhibitor; data on inhibitor titer at enrollment was not available for every patient), 9 HR, and 6 were in severe patients. Six of 524 (1.1%, 95%CI 0.05–2.2%) patients with ≥ 50 previous EDs developed an inhibitor (4 *de novo*, 1 HR, 3 in severe patients).

Summary: Meta-analyzing data from rAHF-PFM-PASS conducted in different countries confirmed in the routine clinical setting the overall favorable safety profile of rAHF-PFM. Effectiveness and sources of heterogeneity will be explored.

PO 149

Mortality and cardiovascular disease in patients with haemophilia: a pilot study in a single centre

Martínez-Marini T, Costa-Pinto MJ, Gomez-del-Castillo M, Galego A, Carnero J, Echevarría P, Batlle J and López-Fernández MF

Complejo Hospitalario Universitario A Coruña, La Coruña, Spain

Improvements in haemophilia care and antiviral treatments led to increasing longevity for persons with congenital haemophilia. Older patients face not only challenges related to haemophilia but also to general comorbidity associated with aging such as cardiovascular disease (CVD) because the risk factors are expected to increase. The paucity of data is evident and there are no guidelines to help treaters to manage these patients.

Aims:

1 To analyze the morbidity and mortality of patients with haemophilia along the last 25 years in a single centre.
2 To investigate the cardiovascular risk factors and the actions taken according to them.

Methods: This is a retrospective study of patients with haemophilia A and B attending our hospital for the past 25 years (n = 144). The medical records were reviewed and separated in two groups: Group I – Dead patients until data analysis (n = 33) Group II – Patients attending regularly to our hospital (n = 81). A descriptive data analysis was made due to heterogeneity of population included.

Results: In Group I we observed that mean of age at time of death was 29.53 years and 75.8% (25/33) were HIV positive. Causes of death in HIV positive patients was in 30.3% (10/25) related to AIDS, 18.2% (6/25) related to hemorrhage, 12.2% (4/25) related to hepatitis C virus (HCV) infection and 5 other causes. Causes of death in HIV negative patients (8/33) were: 2 haemorrhages, 1 related to HCV, 1 lung cancer, 1 sepsis, 2 other causes and only 1 cardiovascular disease that suffered a intracraneal bleeding during a hypertensive crises.

In Group II (n = 81), 33.3%(n = 25) had severe haemophilia, 4%(n = 3) moderate and 70.6% (n = 53) mild. The mean age was 36.8 years. A 28.4% (n = 23) had less than 21 years old and 71.6% (n = 58) were older than 21 years. Comorbidities in adult's population was: 24.7% (20/81) had VHC infection being all adults, 8.6% (7/81) wereHIV positive, 4.9% (4/81) had malignancies. A 56% (32/58) of patients with more than 21 years had CVD risk factors (RF) (hypercholesterolemia, hypertrigliceridemia, diabetes, hypertension, smoker, over weight or obesity); 53.3% had 1RF, 31.2% had 2RF, 9.3% had 3RF and 6.2% had 4RF. Seven patients presented major cardiovascular complications. There were 3 venous thrombosis, one mesenteric thrombosis that needed a shunt portal-cava, 1 deep vein thrombosis treated with vitamin K antagonist for 6 months and 1 central catheter related thrombosis that needed anticoagulation with heparin. There was also 1 critic carotid stenosis, 1 mitral valve stenosis submitted to surgery biological prosthesis valvular and 1 ischemic cardiopathy, all of them treated with chronic antiagregation therapy. Finally 1 supraventricular tachycardia that needed a catheterism with heparin.

Conclusions: Hemophilia patients have higher life expentancy and morbid-mortality is changing to CVD and risk factors similar to the general population. These findings suggest the need of CVD prevention measures and establishment of guidelines to treat these patients.

PO 150

Effectiveness and safety of long-term treatment with recombinant factor VIII formulated with sucrose for hemophilia A in clinical practice of emerging-market countries

Meddeb B[1], Gouider E[1], Andreeva T[2], Al Zoebie A[3], Chernova T[4], Mehadzic S[5], Lyudmila N[6], Brunn M[7], Tueckmantel C[7] and Rauchensteiner S[7]

[1]*Service Hématologie Clinique Hôpital Aziza Othmana, Tunis, Tunisia;* [2]*City Polyclinic N. 37, St. Petersburg, Russia;* [3]*Sheikh Khalifa Medical City, Abu Dhabi, United Arab Emirates;* [4]*Kirov Institute of Hematology and Hemotransfusion of Federal Medico-Biological A, Kirov, Russia;* [5]*Klinika za Pedijatriju, Sarajevo, Bosnia-Herzegovina;* [6]*Akmolinskaya Regional Hospital, Kokshetau, Kazakhstan;* [7]*Bayer HealthCare Pharmaceuticals, Berlin, Germany*

Background: Full-length recombinant factor VIII formulated with sucrose (rFVIII-FS) was one of the first rFVIII products introduced for patients with hemophilia A in many emerging-market countries. In these countries, plasma-derived FVIII products are still used in the large majority of patients with hemophilia A. Therefore, clinical evidence on rFVIII products from these countries is still scarce.

Aims: This study aims to analyze the effectiveness of rFVIII-FS for the treatment of patients with mild, moderate, and severe hemophilia A under real-life conditions in countries from North Africa, the Middle East area, and Eastern Europe and to gain further insight into the safety profile of rFVIII-FS in daily practice.

Methods: Patients diagnosed with mild, moderate, or severe hemophilia A, treated according to standard clinical practice with rFVIII-FS as their only source of FVIII, were enrolled in this study. Informed consent was obtained by all study participants or their guardians. No additional limitations on inclusion criteria were made. Patient characteristics, treatment characteristics, joint status, laboratory tests including inhibitor measurements, and adverse events (AE) were documented on paper case report forms at enrollment, month 12, and month 24 by the treating physician. The patients recorded their infusions and bleeds in patient diaries. The study was approved by the relevant ethics committees or authorities.

Results: One hundred and eighty-six patients were included from 51 centers in 11 countries. Mean age was 12.8 years (range, 0–55). One hundred and seven (58%), 65 (35%), and 14 (8%) patients had severe (< 1% FVIII), moderate (1–5% FVIII), or mild (> 5% FVIII) hemophilia A, respectively. About half of the sample (54.3%) was treated with > 150 exposure days (EDs) before enrollment. One hundred and eight patients (58.1%) were on prophylaxis with 1, 2, or 3 injections per week from enrollment until study end, and 59 patients (31.7%) were treated only on demand. An additional 15 patients (8.1%) switched between prophylaxis and on-demand treatment during the study, and four patients (2.2%) received inhibitor-adapted therapy. About half of the patients (47.8%) had a target joint. Patient diaries were available for 155 patients (83.3%). Patients with severe hemophilia A on prophylaxis reported a median of 0.0 (range, 0–23.8) bleeds per year, whereas those treated on demand had a median of 14.6 (range, 2.1–50.9) bleeds per year. A 91.1% of bleeds in the whole sample were treated with 1–2 infusions. For 27 of the 186 patients (15%), a positive inhibitor test before enrollment was reported. 9/186 patients showed positive inhibitor test results during the study; of these, 5 tested positive before enrollment, and 4 (2.1%)- all with < 150 EDs – had no positive inhibitor test documented before study inclusion. Thirty-one patients (16.7%) reported 74 AEs, of which the 9 mentioned inhibitor cases were the only drug-related AEs.

Summary/Conclusions: This study reconfirms the evidence for rFVIII-FS in effectively treating acute bleeds in patients with mild, moderate, and severe hemophilia A as well as preventing bleeds via weekly prophylactic injections. The safety profile is as expected in hemophilia A.

PO 151

Utility of thrombin generation test in laboratory management of hemophilia A patients

Milos M, Coen Herak D, Zupancic-Salek S and Zadro R
Zagreb University Hospital Center, Zagreb, Croatia

Background: Based on FVIII activity, hemophilia A is classified as severe, moderate or mild. Large heterogeneity between FVIII activity and clinical severity has been observed among patients with hemophilia A, indicating that the residual level of FVIII is not the only determinant of the clinical phenotype. Nowadays, new laboratory methods that assess overall hemostatic potential have been developed, with intention to better diagnose and monitor hemophilia A patients.
Aims: The aim of this study was to compare new commercially available thrombin generation test (TGT) with laboratory methods routinely used for monitoring hemophilia A patients. Obtained results were correlated with known clinical parameters – age at first joint bleed, number of joints with hemophilic arthropathy, number of annual joint bleeds and annual FVIII consumption.
Methods: Total of 81 hemophilia A patients (all hemophilia A patients) were included in the study and divided in severe hemophilia A patients ($N = 37$) and non-severe hemophilia A patients ($N = 44$). TGT was performed with Endogenous Thrombin Potential Test, setting ETP-C for hemophilia patients on BCS-XP (Siemens Medical Solutions Diagnostics, Germany). Four ETP parameters were measured: area under the thrombin generation curve (AUC), peak thrombin concentration (Cmax), time to peak thrombin concentration (t-max) and time to signal beginning (t-lag). FVIII clotting activity (FVIIIclot) and FVIII chromogenic activity (FVIIIch) was performed on BCS (Siemens, Marburg, Germany).
Results: Weak correlation between AUC/Cmax and FVIIIclot/FVIIIch was found in all hemophilia A patients and non-severe hemophilia A patients (r = from 0.306 to 0.596). No correlation was found in all three groups of patients for t-lag and t-max parameters. Similarly, no correlation was found between ETP parameters and clinical parameters, except weak correlation between AUC/Cmax and age at first joint bleed ($r = 0.248$ and 0.291, respectively). The cut-off value of ≤ 25.6 mA for AUC, obtained by ROC analysis, allowed the discrimination of patients in two groups that statistically differ in all clinical parameters, with sensitivity and specificity of 86.5% and 47.7%, respectively.
Summary/Conclusions: Although the AUC was the best discriminating parameter in TGT, based on the obtained results, the used ETP-C method did not fulfill, for the time being, the goals expected for a routine laboratory method. It seems that weak thrombin signal obtained in hemophilia patients makes this method more sensitive to different analytical and preanalytical factors, that need to be resolved in the future.

PO 152

Progress report on the experience of immune tolerance induction with a VWF/FVIII concentrate in haemophilia a patients in Colombia

Montano C[1], David G[1], Rueda E[1], Estupiñan D[1], Maza A[1], De Los Reyes I[1], Martinez L[1], Gutierrez C[1], Escuriola C[2] and Kreuz W[2]
[1]Hemolife, Pereira, Colombia; [2]HZRM Hamophilie-Zentrum Rhein, Walldorf, Germany

Background: The development of inhibitors to FVIII in up to 40% of patients is currently a major medical obstacle affecting the quality of life of treated individuals and is associated with increased treatment costs. Immune Tolerance Induction (ITI) is the only therapy capable of eliminating inhibitors. This therapy has longer been considered that could not be done in developing countries because of its high cost, but today there are several pharmacoeconomic studies have shown that ITI is cost-effective compared to on-demand or prophylactic therapy with bypassing agents.
Since the Hemolife program establishment in 2006, has sought to improve the management of haemophilia patients in Colombia. In order to provide the best treatment for haemophilia patients with inhibitors, the Hemolife physician group decided to enrol their patients into the Observational Immune Tolerance Induction study (ObsITI).
Objectives: Evaluate and document data on the success rate of ITI in haemophilia A patients with FVIII inhibitors treated according to the Bonn protocol.
Compare the costs of ITI therapy with the costs of the prophylactic treatment with bypassing agents.
Methods: Since September 2009, 20 patients with inhibitors and poor-prognosis for ITI success have been treated with octanate for ITI according to the Bonn protocol. The outcome was assessed according to the stringent success criteria defined in the ObsITI study: Inhibitor elimination (< 0.6BU), FVIII *in vitro* recovery of > 80%, and FVIII half-life of > 7 h.
Results: Eight patients out of 20 were unfortunately excluded from the research program: one because of difficult venous access, three changes the treatment center, and 4 due to their insurance decision. The results from 12 patients will be presented. Seven of 12 patients have achieved negative inhibitor in a mean time of 3.7 months (range 2–8). Four of these 12 patients have continued ITI without achieving negative inhibitor in a mean time of 10.7 months (range 2–22) and the other patient stopped ITI after 24 months and inhibitor title > 480BU.
Five (41.6% of 12) out of seven patients that have achieved negative inhibitor title, have reached three success criteria in a mean time of 11.8 months (range 5–22). Of these, one patient has been on follow up prophylactic treatment with octanate for 12 months without relapse, and four patients are still in ITI and tailing-off the FVIII dose.
Cost-of-care analysis was performed for seven patients undergoing ITI with octanate, and the results were compared to prophylactic treatment with activated prothrombin complex concentrate (aPCC) and rFVIIa. Average savings of ITI over 10 years per patient were estimated at US$8.1 million compared with prophylactic treatment with aPCC, and US$12.4 million compared with prophylactic treatment with rFVIIa.
Conclusions: ITI with octanate has proven to be effective in inhibitor elimination. ITI therapy is cost-effective and allows major savings to the health system in comparison to the prophylactic treatment with aPCC and rFVIIa, so every time more patients, even from developing countries, should get the benefit of this therapy.

PO 153

Rapid immune tolerance induction following primary immunologic prophylaxis in a hemophilia A patient with high-titre inhibitor

Moorehead PC[1], Thibeault L[2], Tuttle A[3], Grabell J[3], Dwyre L[2], Silva M[3], James P[3] and Lillicrap D[3]
[1]Janeway Child Health and Rehabilitation Centre, St. John's; [2]Kingston General Hospital; [3]Queen's University, Kingston, ON, Canada

Background: Observational studies suggest that primary immunologic prophylaxis (PIP) – starting factor VIII (FVIII) exposure early and in the absence of immunologic 'danger signals'- may decrease the incidence of FVIII inhibitors in hemophilia A patients. It is unknown whether PIP might have other effects, such as altering the ability to achieve tolerance in patients who do develop inhibitors or altering the biologic parameters of their anti-FVIII immune response. The longitudinal behaviour of anti-FVIII IgG1 and IgG4 levels during the early phase of inhibitor development and immune tolerance induction (ITI) has not previously been described. We report a case of rapidly successful ITI in a boy with severe hemophilia A who developed an inhibitor after PIP, along with analysis of his anti-FVIII IgG1 and IgG4 levels over time.

Methods: A boy with severe hemophilia A caused by a five base pair insertion into exon 14 of the *F8* gene started PIP with recombinant FVIII (Advate) 10 IU/kg once weekly at 11 months of age, without prior bleeding events or FVIII exposures. ITI, when started, was with FVIII (Advate) 100 IU/kg once daily. Patient plasma collected at various times was assayed for FVIII inhibitory activity with the Nijmegen modification of the Bethesda assay. Plasma was assayed by ELISA for anti-FVIII total IgG, IgG1 and IgG4. For total IgG and IgG1, positivity was defined as optical density at 490 nm (OD) more than 3 SD above the mean OD of six normal plasma samples. For IgG4, OD above blank values were obtained, without a positivity criterion.
Results: An inhibitor was detected after 5 exposure days (ED) with a titre of 1.5 Bethesda units (BU). FVIII exposure continued until 19 ED. Nine days after last FVIII exposure, the inhibitor peaked at 19 BU. ITI started 8 weeks after last FVIII exposure at a titre of 9 BU. No inhibitor was detectable 6 weeks after initiating ITI. Levels of anti-FVIII IgG1 and total IgG paralleled the Bethesda titres, with both being below positivity at the same time that inhibitory activity became undetectable. Levels of anti-FVIII IgG4 became detectable later than IgG1 and FVIII inhibitory activity were found, and continued to increase after these other parameters had plateaued. IgG4 had decreased significantly when the other parameters became undetectable.
Conclusions: Our patient underwent successful ITI in less than 6 weeks. Given that his Bethesda titre peaked at 19 BU, it should not be assumed that this was a transient inhibitor. It may be that although PIP did not prevent an inhibitor, it predisposed him toward rapid tolerance induction. The sequential generation of anti-FVIII IgG1 and IgG4 is a novel finding, but the significance and generality of these as prognostic biomarkers of the anti-FVIII immune response must be established. Similar investigations should be undertaken in more patients, with and without PIP.

PO 154

Frequency of FVIII inhibitor in patients treated with plasma derived FVIII concentrates

Morongova A[1], Batorova A[1], Bubanska E[2], Jankovicova D[1] and Prigancova T[1]
[1]National Hemophilia Center, Bratislava; [2]Regional Hemophilia Center, Banska Bystrica, Slovakia

Background: Development of the inhibitors against FVIII is the most challenging complication of the treatment of hemophilia. In the era of using high purity FVIII concentrates we are witnessing the increasing frequency of inhibitors in severere hemophilia. The results of studies comparing inhibitor incidence in patients treated with plasma derived FVIII (pdFVIII) and recombinant products (rFVIII) are inconclusive. Most recently Gouw et al. (NEJM 2013) demonstrated the cumulative incidence of clinically relevant inhibitors in 33.1% (high titer inhibitors 25.7%) of patients treated with pdFVIII, the frequency similar to that, observed after rFVIII products. In Slovakia so far the majority of hemophilia patients have been treated with pdFVIII concentrates, so we evaluated the incidence of inhibitors in this patients group.
Methods: Since 1997 all severe hemophilia patients have been followed systematically for the development of inhibitor, which was tested after each 5, 10 and 20 exposure doses (ED) until the first 20, 50 and 80 exposures to FVIII, later on every 6 months. Inhibitors above 0.7 BU or 0.5 Nijmegen BU confirmed by three consecutive tests were considered positive.
Results: Cumulative incidence of inhibitors was evaluated in 45 previously untreated patients (PUP′s) with severe hemophilia A (FVIII < 1 IU/dL) born between 1997 and 2011 and followed at our two centres. Thirty nine PUP′s have been treated with pdFVIII, out of them 33 PUP′s reached more than 80 ED of pdFVIII. Eight and one patient switched for rFVIII after reaching 80–100 and 4 ED of pdFVIII, respectively. Inhibitors developed in 5/38 (13.2%) pdFVIII treated patients after a mean 22 ED (10–27). The mean age at the inhibitor detection was of 39 months (22–68). One, two and two inhibitors were transient, low titre and high titre, respectively. No inhibitor was observed in eight patients who switched for rFVIII after 80–100 ED of pdFVIII, however, a patient with four exposures to pdFVIII developed low titre inhibitor after consecutive 21 ED of rFVIII. Yet rFVIII was used from the beginning of replacement therapy in only four PUP′ s. Two of them developed high titre inhibitor at age of 14 and 18 months, after 20 and 40 ED of rFVIII, respectively, in absence of risk factors such as major bleed, vaccination, infection, surgery and/or intensive treatment.
All but one patient, who had transient inhibitor, have been treated with immune tolerance induction (ITI) with a succesful outcome in 2 low and 3 high responders, respectively. The high dose ITI is still ongoing in two high rersponders developing inhibitor after rFVIII.
Conclusion: Cumulative incidence of inhibitors in our severe hemophilia patients treated with pdFVIII was 13.2% (high titer-inhibitors 5.3%), much lower than that reported most recently in the literature. Our group of patients is too small to evaluate the role of other confoundig inhibitor risk factors. However, the development of high-titer inhibitors in 2/4 PUP ′s treated exclusively with rFVIII resulting in a challenging management of this complication, is worying.

PO 155

Situation with haemophilia in Ukraine – the first results of work of regional haemophilia center

Moroz G[1], Gartovska I[1], Derbeneva N[2] and Vydyborets S[1]
[1]National Medical Academy for Postgraduate Education; [2]Kyiv regional oncological hospital, Kyiv, Ukraine

Organization of care for patients with hereditary diseases is an extremely difficult problem. In historical terms, the model of care for patients with haemophilia varied depending on the availability of drugs clotting factors for substitution therapy. But the greatest positive effect on the dynamics of care to patients with impaired blood clotting was observed in those countries that are centres for comprehensive health services for patients with haemophilia. This model of care was one of the most successful public health programs in the developed world. In Ukraine, mainly the organization of care for patients with haemophilia was sent for treatment of complications of the disease. This model of care for patients with haemophilia in the absence of clotting factor concentrates, and then in a large deficit drugs had the right to life, because doctors could only provide treatment of complications of haemophilia in haematology departments.
Today Ukraine is gradually increasing funding and provision of patient clotting drugs. In 2011–2012 pp. centralized purchasing and procurement through regional budgets have been significantly increased. In 2011, only for children had purchased 14 million IU, in 2012 – 16 million IU through centralized procurement for state programs. Additionally, each region held purchase factors for patients in their region. Therefore, the provision of children in 2012 averaged 39,000 IU per one patient. The further increase in funding the purchase of drugs, approved clinical protocols dramatically increase the possibility of selecting certain types of treatment. The most effective way to solve these problems is to create a multidisciplinary team of specialists (haemophilia centers) in each region of Ukraine, which can provide medical qualified service.
In 2012 regional haemophilia center for patients of Kyiv region was established. For diagnostic coagulation studies and laboratory monitoring of therapy was purchased coagulometer and reagents. Under the supervision of specialists regional center for haemophilia and other disorders of haemostasis are 35 patients with severe haemophilia, including – 23 patients with severe haemophilia A (13 – adults and 10 children), 11 patients with severe haemophilia B (8 – adults and 3 children), and one patient with severe von Willebrand disease. Today Regional Hemophilia Center provides diagnosis haemophilia,

conducts qualitative and quantitative determination of inhibitors, clinical and laboratory monitoring of treatment.
Thus, the regional haemophilia of Kyiv region commenced the implementation of modern principles of care for patients with haemophilia and other disorders of haemostasis.

PO 156

Moba-Roku – a new internet assisted monitoring system of home infusion program for hemophilia care in Japan

Nakadate H, Ishiguro A, Namiki C, Furuoya Y, Mastmoto S and Saito J

National Center for Child Health and Development, Tokyo, Japan

Background: In Japan, home infusion program for hemophilia patients has become very popular. Many hemophilia patients have been treated with home infusions of FXI or FVIII products by themselves or by their parents. In this program, complete monitoring of infusion records is priority of good care management for patients and for their health care providers. We have two way of recording system of this program, one is classical printed form type, another is new one – an internet assisted infusion recording system, which is through a mobile phone and/or a personal computer (PC). With this system, patients, their parents and health care providers can easily access the graphical collections of data which have contained of bleeding sites, date of bleedings occur, number of infusions, type of products, and etc., via internet. We call this in Japanese 'Moba-Roku' which means mobile phone assisted infusion recording system, provided by Baxter Japan, and it is coming into wide use. This is the first presentation of the internet assisted infusion monitoring system 'Moba-Roku'.
Aims: In this report, we have evaluated the quality of this new monitoring system of home infusion program for hemophilia care.
Methods: We conducted two surveys aimed to evaluate this new monitoring system in August 2011 and April 2012. The questionnaires were distributed among registered 'Moba-Roku' users who were patients and their parents by email. Thirty-seven users responded to 1st survey and 14 users responded to 2nd survey.
Results: In Japan, before introducing 'Moba-Roku', when hemophilia patients had underwent infusion therapies, they had recorded home infusion data through classical printed form type only, always recording; 62.2%, sometime; 10.8%, seldom; 27.0%, respectively. But almost of those records were kept left at their home, very few were seen by their health care providers, therefore they might have not enough medical consultation of disease status based on bleeding and infusion records. After introducing 'Moba-Roku', they had recorded home infusion data, always; 71.5%, sometime; 14.3%, seldom; 14.3%, respectively. When they were going to record their infusion data with this internet assisted monitoring system, through a mobile phone; 57.2%, through a PC; 35.7%, through either; 7.1%, respectively. There no difference of frequency of infusion recording between the classical printed form type and the new internet assisted one. But after introducing 'Moba-Roku', 57.1% of patients and their parents had consulted their health care providers with these graphical collections of infusion data, when they had visited their clinics. Since 2010, our facility also has introduced 'Moba-Roku' to 10 patients and it enhances our daily practice communication between patients and our hemophilia care team (physicians, nurses, pharmacists, etc.). We have regarded it contributes to the good care of hemophilia patients.
Conclusion: The new internet assisted infusion monitoring system 'Moba-Roku' might enhance the quality of care management for hemophilia patients themselves and also for their health care providers.

PO 157

Causes of death in a cohort of patients with haemophilia in a Haemophilia Care Center in the last 5 years

Nuñez RJ and Perez-Garrido R

Hemophilia Unit, Seville, Spain

Background: The increased life expectancy of the hemophilia population, as a result of advances in factor replacement therapy and the introduction of highly active antiretroviral therapy (HAART) has enabled hemophiliacs to reach an older age. Since the 1970s, mortality in the hemophilia population has been dominated by human immunodeficiency virus (HIV) and hepatitis C virus (HCV)-associated complications. However, age-related diseases such as cardiovascular disorders and cancer, are being increasingly recognized in such patients.
Aims: This abstract describes causas of death in a cohorte of patient with haemophilia in a haemophilia care center in the last 5 years.
Method: A causes of death analysis was conducted among 257 patients with haemophilia A and B (68 severe, 39 moderate and 152 mild haemophiliacs), who were treated at the haemophilia care center in Sevilla. Information on mortality in our patient cohort was obtained from the medical records.
We analized data on age, type and severity of haemophilia, modality of treatment, inhibitor development, HIV and HCV status and cause of death.
Results: Among the 257 haemophiliacs patients treated at our haemophilia center, eight deaths were observedbetween January 2008 and December 2012. Their average age was 45.8 years (range 40–60). Hemophilia type was A in all cases and severe in six cases, moderate and mild in the other two patients, respectively. All patients were on demand treatment, 4 with plasma-derived and 3 with recombinant factor VIII concentrates. One patient presented a high-titer inhibitor, treated with bypass agent on demand. Six patients were HIV-positive, all of them well controlled withHAARTand five of then were coinfected with HCV. Two patients presented chronic HCV infection. One patient died of lung cancer, smoker as a risk factor. One severe haemophiliac died of a spontaneous intracranial haemorrhage. Two patients died of HCV-associated complications; one of them, coinfected with HIV and cirrhosis status and previus failure of conventional treatment of chronic HCV infection, developed fatal hydropic decompensation in relation to a new antiviral treatment. The other patient died of endstage liver disease. Four patients died of cardiovascular disease. A haemophiliac A severe suffered an acute myocardial infarction after administration of recombinant FVIII and died of a fatal ventricular arrhythmias after apercutaneous coronary intervention. The second patient, a haemophiliac with inhibitor, had a first coronary event after infusion of a single dose of bypass agent; after 2 years in relation to a surgery episode, he suffered a massive acute myocardial infarction. The third patient, a moderate haemophiliac with several aging diseases (atrial fibrillation, cardiac valvulopathy and cirrhosis), died of an acute myocardial infarction. The last patient died of a ruptured abdominal aorta aneurysm.
Conclusion: Infection with HIV and HCV continue to play dominant roles in the older hemophilia population. However, after introduction of HAART the causes of mortality are changing in the last years. The results of this study show that cardiovascular diseases have become a new challenge for physicians working in hemophilia centers and underline the need to optimize the management of ischemic heart disease in hemophiliacs.

PO 158

Filling the gap on long-term joint health and HRQoL outcomes data in hemophilia A using a single product (rAHF-PFM), non-interventional registry, AHEAD

Oldenburg J[1], Tsakiris D[2], Abraham I[3], Brondke H[3], Pirck M[4], Engl W[4], Loew-Baselli A[4], Pina P[4] and Spotts G[5]

[1]Institute for Experimental Haematology and Transfusion Medicine, Bonn, Germany; [2]Uniersity Hospital Basel, Basel, Switzerland; [3]Baxter Deutschland GmbH, Unterschleißheim, Germany; [4]Baxter Innovations GmbH, Vienna, Austria; [5]Baxter Healthcare Corporation, Westlake Village, CA, USA

Background/Aims: Hemophilic arthropathy resulting from recurrent joint bleeds leading to joint damage – is a major cause of disability in patients with hemophilia A. Most post-approval safety surveillance studies in hemophilia A however only monitor safety and effectiveness for 6–12 months leaving a gap in our understanding of longer-term joint health outcomes and health-related quality of life (HRQoL). The ADVATE (rAHF-PFM) Hemophilia A Database (AHEAD) study is designed to capture long-term outcomes data on patients with hemophilia A in Germany and other European countries receiving treatment under routine practice setting including on-demand therapy, primary or secondary prophylaxis, or immune tolerance induction therapy. Data is being collected from patients prescribed rAHF-PFM using standard dosing treatment regimens as well as emerging treatment practices including individualized pharmacokinetic (PK)-guided prophylaxis dosing. Study endpoints include long-term joint health outcome and other hemophilia-related co-morbidities, HRQoL, effectiveness and safety.

Materials and Methods: Eight hundred and fifty subjects with hemophilia A (FVIII ≤ 5%) are to be enrolled (500 in Germany; 350 from other European countries). Informed Consent is required; study to comply with Declaration of Helsinki. Joint health will be assessed using physical examination as well as routinely used imaging technologies. HRQoL will be measured using validated questionnaires such as SF-10 or SF-12, hemophilia-related co-morbidities and safety and effectiveness will be measured using standard methods. The protocol has been amended to capture additional data on the determination of individual PK parameters and dose calculations used in PK-guided prophylaxis dosing. Study enrollment began in 2010 in Germany and 2011 in other European countries. Subjects will be observed for 4 years; enrollment continues through 2015.

Results: As of January 2013, 469 patients (318 in Germany and 151 in other European countries) have been enrolled at 43 initiated sites in Belgium, Czech Republic, Denmark, Greece, Hungary, Italy, Portugal, Spain, Sweden, Switzerland, and the UK, and from 30 sites in Germany.

The mean age (range) for the 'European' and German cohorts is 20.8 (0–68) and 28.6 (1–80) years, respectively. In both study arms, most patients had severe hemophilia A (FVIII < 1%): 52% in 'Europe' (n = 78) and 76% in Germany (n = 242), and were receiving prophylaxis: 66% in 'Europe' (n = 100) and 74% in Germany (n = 236). At baseline, 35% of patients in the 'European' cohort showed at least one joint with arthropathy. In the German cohort, 40% of patients exhibited at least one joint with arthropathy at baseline. Of the 469 enrolled patients, 19 patients in Germany have been followed for 2 years, and 123 for 1 year; 38 patients in 'Europe' have been followed for 1 year.

Conclusions: The AHEAD study will capture important long-term outcomes data on a broad patient population using rAHF-PFM in routine clinical practice. The amended protocol will also facilitate collection of outcomes data on new, emerging treatment practices such as individualized PK-guided dosing. These data will fill an important gap in the current literature and may provide insights on best treatment practices and patient variables related to good long-term outcomes.

PO 159

A study of risk factors for the development of FVIII inhibitors in Indian severe haemophilia A patients

Pinto P, Ghosh K and Shetty S

National Institute of Immunohaematology (Indian Council of Medical Research), Mumbai, India

Background: Development of 'FVIII Inhibitors' or alloantibodies to Factor VIII in patients with congenital haemophilia A is a serious complication of FVIII replacement therapy. It prevents the efficient clinical management of these patients, particularly those with severe haemophilia A, and leads to a substantial increase in mortality, as well as in the frequency and cost of management of bleeds among these patients, especially post-operatively. Inhibitor development in haemophilia A patients is thought to be complex and influenced by various genetic and non-genetic risk factors. Associations with various risk factors have been suggested in different populations. In earlier studies in Indian haemophilia A patients, *IL10* haplotypes and *TNFA rs1799724* promoter polymorphisms have been found to be significantly associated with inhibitor development, while four exonic non-synonymous *FVIII* SNPs, G1679A [R484H], A2554G [R776G], C3951G [D1241E], and A6940G [M2238V], whose haplotypes encode six wild-type FVIII proteins (H1 – H6) have not been found significant.

Aim: The aim of this study was to analyse the association of other genetic (HLA) and non-genetic (treatment-related) risk factors with inhibitor development in Indian severe haemophilia A patients.

Methods: One Hundred Indian severe hemophilia A patients, (40 consecutive inhibitor positive patients and 20 concordant/discordant family members, as well as 40 consecutive inhibitor negative control patients (over 10 years of age with > 10 exposures to treatment products) were included in the study after their informed consent. The study was approved by the Institutional Ethics Committee for Research on Human Subjects of the National Institute of Immunohaematology (ICMR), Mumbai. A clinical proforma was designed to record patient details. *HLA- DRB1* and *DQB1* alleles were genotyped by PCR with Sequence Specific Primers (SSP), using the AllSet^{+}™ Gold SSP HLA-DQ and HLA-DR Low Resolution kits (Invitrogen, USA). The results were analysed for statistical significance by Fisher's exact test.

Results: The mean age of the inhibitor positive patients was 24.57 (6–55 years) and mean lifetime exposures to treatment products was 19.22 (4–43); and the mean age of the inhibitor negative patients was 28.30 (12–65 years) with 43.625 (15–220) mean lifetime exposures. Among the inhibitor positive patients, 31/40 (77.5%) patients were high-responders (> 5 BU/ml). The HLA-DRB1*13 allele (P: 0.048) and the HLA-DQB1*05/*06 (P: 0.025) genotype were found to be significantly higher in the inhibitor positive samples as compared to the controls, in the samples studied so far. Treatment-related risk factors such as type of treatment product and exposure to treatment products before the first year of life (22.5% inhibitor positive patients vs. 12.5% inhibitor negative patients) were not significantly different.

Conclusion: The association of these factors with other risk factors such as FVIII mutations also, could provide useful insights into the FVIII immune response, and possibly influence timely prediction, prevention and treatment of FVIII inhibitors.

PO 160

Impact of rAHF-PFM prophylactic treatment on annual bleeding rate and health-related quality of life of adults with severe hemophilia A

Quon DV[1], Shapiro AD[2], Santagostino E[3], Valentino LA[4], Epstein JD[5], Guzman-Becerra N[5], Schroth PH[5] and Wong WY[5]
[1]Los Angeles Orthopaedic Hospital, Los Angeles; [2]Indiana Hemophilia and Thrombosis Center, Indianapolis, IN, USA; [3]IRCCS Maggiore Hos, Milan, Italy; [4]Rush University Medical Center, Chicago; [5]Baxter Healthcare, Westlake Village, CA, USA

Background: Limited prospective data exists comparing on-demand and secondary prophylaxis in an adult-only population.
Aims: Assess the annual bleeding rate (ABR) and health-related quality of life (HRQOL) for adults who switched from on-demand to secondary prophylaxis in the rAHF-PFM Prophylaxis Study.
Methods: Patients previously treated on-demand with FVIII levels ≤ 2% received 6 months of on-demand treatment and were then randomized to 12 months of either standard (20–40 IU/kg every other day) or pharmacokinetic (PK)-tailored (20–80 IU/kg every third day) prophylaxis. All adults (≥ 18 years) from this study were selected for this post-hoc, subgroup analysis. ABR and HRQOL (measured using the SF-36) were compared between the end of the on-demand and prophylaxis phases. Bleeding events and HRQOL were also assessed longitudinally to understand how quickly prophylaxis impacted these outcomes. Informed patient consent and ethics board approval was received for this study.
Results: The intent-to-treat adult subset analysis included 55 subjects. The median (range) patient age was 30 (18–59) years. The median (IQR) ABR during on-demand treatment was significantly reduced from 43.7 (26.1) to 1.0 (4.1) using either prophylaxis regimen ($P < 0.0001$). During on-demand therapy, the median interval between bleeding episodes was 7.1 days, however, after initiating prophylaxis, patients experienced a median of 155.3 consecutive bleed-free days ($P < 0.0001$). Statistically and clinically significant improvements in physical HRQOL were reported following 12 months of prophylaxis ($P = 0.0035$). This improvement was explained by significant improvement ($P < 0.001$) in Bodily Pain after 3 months of prophylaxis which approached average pain levels reported by the general US population and was sustained for the entire 12-month period.
Summary/Conclusions: Adults patients who initiated secondary prophylaxis quickly saw a significant reduction in their ABR and subsequent improvement in their physical HRQOL.

PO 161

Prophylaxis in adults hemophiliac patients with severe arthropathy

Ramirez CA[1], Valencia G[2], Arias D[3], Arteaga A[2] and Madrid M[2]
[1]IPS Especializad, [2]IPS Especializada; [3]IPS Especializaa, Bogota, Colombia

Primary Prophylaxis is the standard management for patients with haemophilia. Prophylaxis started in adulthood improves orthopedic scores, decreases hemarthrosis frequency, physical disability, hospitalization rates, school/work absenteeism and has a positive impact on quality of life. However, prophylaxis in adults has many barriers and involves very high cost. Scientific evidence is limited. We described a cohort of patients treated in a developing country.
Methods and Results: Twenty-four adult hemophliac patientes, treated in a hemophlia center in Bogotá, Colombia has been followed during 18 months. Age: 32.years (-range 18–63). Eighty percent with Hemophilia A, 20% hemophilia B. Seventy-six percent received plasma-derived factor, 22% is given recombinant factor. One patient with inhibitors is receiving FEIBA. All patients have severe arthropaty, 32% refers permanent or most of the time joint pain and 24% are complety disabled. Prophylaxis infusion frequency (number/week) 2.28 (2–3), prophylaxis dose (IU/kg week): 15.6 (7.8–23). Mean number of bleeds in 18 months was 3.8. During following there were no life-threatening bleedings. There were only two hospitalizations due to hemorrhage. Quality of life was assessed with SF-36. Emotional role, mental health, social function and livelness were score above 70.
Conclusions: Prophylaxis in adults with hemophilia and artropathy is feasible in a developing country. Our patients has very low bleeding and hospitalization rates, prophylaxis factor dose is relative low in comparison with established doses for other series. Prophylaxis has a positive impact on quality of life.

PO 162

Immune tolerance induction in adult severe haemophilia a patients with a single FVIII/VWF product: the UK experience

Rangarajan S[1], Yee TT[2] and Roy A[3]
[1]Hampshire Hospital NHS Foundation Trust, Basingstoke; [2]Royal Free Hospital, London; [3]Basignstoke and North Hampshire Hospital, Basignstoke, UK

Background: In haemophilia A patients, the development of neutralising antibodies against their replaced exogenous Factor VIII treatment greatly increases the risk of developing major bleeding complications. Immune tolerance induction (ITI) treatment protocols based on the regular infusion of FVIII are the currently recommended intervention for this serious complication, with the goal to eradicate the inhibitor and to return to effective treatment with FVIII.
Aim: To evaluate the outcome of primary and rescue ITI in adult severe haemophilia A patients with a single plasma derived FVIII/VWF product (Fanhdi®, Grifols, Barcelona, Spain).
Methods: Retrospective data were analyzed from severe hemophilia A patients (FVIII < 1%) with inhibitors from threeUKcenters. Complete success was assessed as clearance of the inhibitor, partial success when the inhibitor was reduced to less than 5 BU and the patient responds effectively to Factor VIII replacement without needing bypassing therapy. Results:Results are presented for nine adult patients (ages 28–74) who underwent primary ITI (8 patients) or rescue ITI (1 patient) with FVIII/VWF concentrate. Treatment regimens ranged from 40 IU/kg three times a week to 200 IU/kg per day. In the primary ITI patients, mean peak inhibitor was 30.5 BU (range 0.9–93), mean titre at start of ITI was 6.1 BU (range 0.6–22.9) and mean ITI duration was 6.9 months (range 1–16). In the rescue ITI patient, peak inhibitor was 1000 BU, titre at start of ITI was 16 BU and ITI duration was 12 months. Immune tolerance was achieved in all eight primary ITI patients, of which 7/8 achieved complete success. Partial success was achieved in one patient. ITI failed in the one and only rescue patient. The overall rate of complete success was 77.7%. No patients were observed to relapse in a mean follow-up period of 5 years (range 1.3–6.7).
Conclusion: The observed outcomes in ITI with Fanhdi® confirm other recently published data which demonstrate high success rates with this type of product.

PO 163

Intracranial hemorrhage in hereditary bleeding disorders: the experience of Çukurova University Hemophilia Center

Sasmaz I, Antmen B, Karagun BS, Leblebisatan G, Yilmaz M and Kilinc Y
Cukurova University, Adana, Turkey

Background: Intracranial hemorrhage (ICH) is a life threatening complication of hereditary bleeding disorders in childhood resulting in high rates of mortality and disabling sequelae.

Aim: In this study, we evaluated our patients with intracranial hemorrhage and compared with literature.
Patients and Methods: From 1995 to 2012, 21 patients with intracranial hemorrhage were diagnosed and evaluated in Çukurova University Hemophilia Center. ICH episodes, the findings of physical examination, CT scan or MRI and treatment strategies including surgical interventions were reviewed retrospectively.
Results: We evaluated 22 episodes of ICH from 21 patients with hereditary congenital factor deficiencies (CFD). Age range was from 9 days to 12 years. There were 15 patients with hemophilia A, 2 patients with hemophilia B, 2 patients with factor VII deficiency, 1 patient with factor X deficiency, 1 patient with von Willebrand disease. Two patients with factor VII deficiency, 1 patient with factor X deficiency and 1 patient with von Willebrand disease were female. Except one patient with factor X deficiency, all patients had one bleeding episode. Two patients had a high titer inhibitor against factor VIII. The most important factor was trauma. A history of recent trauma was documented in 10 patients. Intracerebral and subdural hematoma were more frequently seen. The most frequent symptoms were seizure and headache. The diagnosis of hemophilia was established in five patients after intracranial hemorrhage who referred to our center with ICH. In nine patients, hematoma was evacuated. Three hemophilia patients died due to ICH and four patients presented late sequelae.
Conclusion: Intracranial hemorrhage is the most serious complication in childhood, especially for hereditary bleeding disorders. Urgent establishing diagnosis and treatment with prompt doses of factors to initially maintain a normal concentration of circulating factor is mandatory. Despite the prompt treatment, death and late sequelae can be seen in this patients group.

PO 164

Treatment of outpatient dental extractions in persons with inherited bleeding disorders

Schafer KL, Funke EA, Ducore JM and Powell J
University of California, Davis, Sacramento, CA, USA

Background: Excessive bleeding after tooth extraction is a common risk for patients with Hemophilia A, Hemophilia B and von Willebrand disease. Current treatment uses clotting factors or desmopressin acetate and oral antifibrinolytics to prevent prolonged bleeding; however, there are few well-defined protocols based on prospective studies available for the prevention of post-dental extraction bleeding.
Aims: We completed a retrospective review of our treatment center's experience in the management of patients undergoing dental extraction to evaluate the effectiveness of our protocol in preventing delayed bleeding. We evaluated use of additional clotting factor, hospitalization or patients who had delayed bleeding.
Methods: Four hundred and fifty charts of persons with bleeding disorders were reviewed and 27 patients who had undergone dental extractions were identified. The protocol included collaboration with community dentists and local hematologists. For patients with moderate or severe Hemophilia A or B, and von Willebrand Type II or III, a factor infusion was administered to raise factor levels to at least a predicted 80% correction. In some patients, this peak was measured by appropriate laboratory tests. Patients with von Willebrand disease, type I were treated with a dose of desmopressin acetate nasal spray one h prior to procedure. All patients were treated with oral aminocaproic acid, 100 mg/kg every 6 h for 5–7 days. A phone call was made immediately after the procedure to assess bleeding complications. Further follow up was determined as needed.
Results: Twenty-seven patients with hemophilia A ($n = 12$) or Hemophilia B ($n = 8$) and von Willebrand disease (5 = type 1, 2 = type 2 or 3) underwent single extractions, third molar extractions or multiple extractions in outpatient dental offices. Twenty-two patients with uncomplicated bleeding disorders did not experience delayed bleeding nor did they require treatment with additional doses of factor or admission to the hospital. All delayed bleeding episodes occurred in patients with complicated bleeding disorders. One patient with an active high titer inhibitor required additional treatment with bypassing agents for 3 weeks; one patient stopped his oral antifibrinolytics at day 2, experienced delayed gingival oozing and required five additional doses of factor daily; one patient with a psychiatric history was treated with factor infusions daily for 1 week for complete dental extraction. Two patients with complicated medical histories were admitted to the hospital and not treated with the usual protocol: one with a history of intracranial hemorrhage and transportation difficulties and one with HIV and Hepatitis C-related thrombocytopenia.
Summary/Conclusion: Our data indicate that the treatment protocol we use for routine dental extraction is safe and effective in preventing excessive bleeding after tooth extraction in persons with uncomplicated Hemophilia A, B and von Willebrand disease. Our experience suggests that persons with complicated bleeding disorders should be considered for additional treatment. Our protocol, when used in collaboration with community dentists, could be used as a guide for those treating patients with inherited bleeding disorders, and as a protocol for prospective studies of treatment regimens for dental procedures.

PO 165

Surgery in hemophilia – a real therapeutic challenge for a low-resource country

Serban M[1], Poenaru D[2], Ionita H[2], Patrascu JM[2], Ursu CE[3], Savescu D[3], Jinca C[3], Talpos-Niculescu S[2], Lacatusu A[4] and Ritli L[5]
[1]Children Emergency Hospital Louis Turcanu Timisoara; [2]University of Medicine and Pharmacy 'Victor Babes'; [3]Children Emergency Hospital 'Louis Turcanu', Timisoara; [4]Medical center of evaluation and rehabilitation for children 'Cristian Serban', Buzias; [5]University of Medicine and Pharmacy Oradea, Oradea, Romania

Introduction: Surgery is a big challenge in the developing world because of low accessibility and availability to an adequate substitution.
Objectives: We aimed at evaluating the outcomes of surgical procedures in our conditions of substitution, of obstacles and difficulties we met during surgery, assessing the risks and complications we were confronted with.
Patients and Methods: Our descriptive observational retrospective study included 171 surgical procedures, undertaken on 101 patients (83- hemophilia A, 13 -hemophilia B and 5- von Willebrand disease, 92.07% of them with severe form) over a period of 11 years. In 15.84% of cases-2, in other 10.89% of cases – 3 and in 14.85% more than 3 interventions have been undertaken, respectively.
Methods: Invasive elective procedures were predominant (84.80%) vs. emergency measures (15.20%). We considered that 35.67% of surgical interventions were major, 21.63% intermediate and 42.69% minor. By the type of surgery, the orthopedic interventions prevailed (69%), followed by complex stomatological (17.54%) and thoraco-abdominal surgery (11.69%). The rate of complications was highest in major surgery (67.79%), compared with moderate (20.33%) and minor (11.86%) interventions. Their proportion was more important in patients who underwent emergency (63, 63%) vs. programmed interventions (46.83%). The main obstacles were: low dosage (10.89%), short duration of substitution (21.78%) or/and usage of native blood products (6.93%), leading to increased postsurgical bleeding (38.61%) and post-hemorrhagic anemia (25.74%); local infections complicated the evolution in 8.91% of cases; the main threatening complication was the development or increase of low (3.96%) or high (2.97%) titer inhibitors; the risk of blood borne infection or thrombotic accident was low (0.99%). The general outcome was encouraging: life-saving in 32.67%, improving the quality of life with assurance of professional and social insertion in 67.32%.
Conclusion: Surgery is a high demanding intervention in hemophilia, which cannot be ignored in a low resource country. It acts as lifesav-

ing, life prolonging and quality of life improving measure. An emergency depot is needed in each Hemophilia Treatment Center, and a latent therapeutic demand of factor concentrates has to be calculated in order to avoid the use of native blood products and complications.

PO 166

Quality of life and well-being of haemophilia patients and parents in China: subgroup analysis of the HERO study

Sun J[1], Yang R[2], Zhao Y[3], Wang X[4], Wu J[5], Zhang X[6], Guan T[7] and Iorio A[8]

[1]Nanfang Hospital, Southern Medical University, Guangzhou; [2]Institute of Hematology & Blood Diseases Hospital Chinese Academy of Medical Sci, Tianjin; [3]Peking Union Medical College Hospital, Beijing; [4]Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai; [5]Anhui Provincial Hospital, Hefei; [6]Blood Centre of Shandong Province, Jinan; [7]Hemophilia Home of China, Beijing; [8]McMaster University, Hamilton, ON, Canada

Background: Haemophilia A (HA) and B (HB) are serious congenital bleeding disorders, whose prognosis and outcomes are improved by comprehensive care and access to treatment. Bleeding and complications have negative influence on patients' and parents' daily life and social relationships, and can induce psychosocial problems. The Haemophilia Experiences, Results and Opportunities (HERO) study's primary objective was to quantify the impact of key psychosocial factors affecting people with haemophilia (PWH). Questionnaires targeting PWH $\geq$ 18 years and parents of patients < 18 years were used to collect information on demography, social relationships and treatment in this survey involving 10 countries. EuroQoL-5D (EQ-5D) Index was used to assess quality of life (QoL).

Aims: To present and compare data on QoL and well-being in the HERO study between China and other countries.

Methods: A descriptive comparative analysis of Chinese patients' and parents' subgroups.

Results: Overall, 675 patients and 561 parents were recruited, of which 110 (16.3%) patients and 58 (10.3%) parents were from China. There were 40.0% and 89.7% of Chinese patients and parents married or in a long-term relationship (60.0%, $P < 0.01$ and 83.5%, $P = 0.22$ for non-Chinese). For Chinese PWH: The overall mean EQ-5D score (healthy subject score = 1.00) was 0.71 (0.75 for non-China, $P = 0.07$). Mean scores for subgroups by disease were 0.72 (HA) and 0.68 (HB), and mean scores for subgroups by treatment were 0.70 (on-demand), 0.87 (prophylaxis) and 0.73 (on-demand with situational prophylaxis). Issues with mobility (71.8%), self-care (27.3%), usual activities (58.2%), pain/discomfort (65.5%) and anxiety/depression (60.0%) were noted in higher percentage than those reported in non-China except pain/discomfort. Overall, 36.4% (28.7% for non-China, $P = 0.11$) reported self-assessing 'health' scores $\leq$ 50 using a 100-point scale. And 13.6% (7.4% for non-China, $P < 0.05$) thought that pain interfered 'extremely' with their daily life, while 32.7% (14.9% for non-China, $P < 0.0001$) rated this as 'quite a lot'. Only 7.3% received psychological treatment in the past year (25.3% for non-China, $P < 0.01$). For Chinese parents: The percentages of Chinese vs. non-Chinese parents hiding haemophilia from others (60.3% vs. 13.3%, $P < 0.0001$), feeling too much pressure (37.9% vs. 17.1%, $P < 0.01$), considering that the close relationship with partner was hampered (27.6% vs. 16.7%, $P < 0.05$) and preventing patients from 'too dangerous' sports (89.7% vs. 50.9%, $P < 0.0001$) were significantly higher. Significantly less Chinese parents thought that haemophilia 'did not prevent desired holidays' (37.9% vs. 69.6%, $P < 0.0001$) or 'did not influence their son's school relationships' (36.2% vs. 56.1%, $P < 0.01$). Altogether, 25.9% received psychological treatment in the past year (24.3% for non-China, $P = 0.79$). On a 7-point scale (where a higher score indicated more optimistic attitude) for patient/parent future outlook, the mean score in China was 4.22/3.96 (5.13/5.64 for non-China, $P < 0.0001/P < 0.0001$), with a significantly lower percentage scoring 7 point (very optimistic) than their counterparts in non-China (11.8%/0.0% vs. 23.5%/30.6%, $P < 0.01/P < 0.0001$).

Conclusion: Haemophilia impacted QoL of patients and families more in China than in other countries in the study. A few of Chinese patients and parents received psychological support and treatment. Chinese patients and parents were not as optimistic about future outlook as their counterparts from other countries.

PO 167

Adult onset high titer inhibitor disappeared in a patient with congenital hemophilia A after immune tolerance induction therapy

Suzuki T

Tokyo Medical University, Tokyo, Japan

Background: Factor VIII (FVIII) inhibitors most frequently develop in patients with severe hemophilia A during relatively young ages and in the early stage of their replacement therapy.

Objective: We report the case of a 38 year-old male patient with severe hemophilia A in whom recently developed FVIII inhibitor was eradicated after immune tolerance induction therapy (ITI).

Clinical course: The patient was diagnosed at 3 months of age because of his bleeding tendency, which was not present in any of his family members. The patient was treated with plasma-derived FVIII concentrate until 2003 and recombinant product (rFVIII) thereafter. On first detection in 2002, his FVIII inhibitor titer was 1.6Bethesda Units (BU)/ml. Thereafter, the inhibitor titer increased gradually to 2.4 BU/ml in 2004 and 5 BU/ml in 2007. The patient and his general practitioner did not attempt to rectify the low inhibitor titer because the FVIII concentrate continued to be effective for his subcutaneous and joint bleeding. The frequency of his subcutaneous hemorrhages increased from around 2004 and increased doses of FVIII concentrate ceased to provide an adequate hemostatic effect. Thus, he visited another general hospital. In 2008, his inhibitor titer rose to 8 BU/ml. In 2009, when he moved to the hemophilia treatment center in our university hospital to plan his therapeutic options, his inhibitor titer was 17.9 BU/ml. His screening examination showed no significant findings with respect to autoimmune diseases. Episodic on-demand treatment with FVIII concentrates was discontinued and treatment with a low-dose protocol of ITI, 50 U/kg of rFVIII, Advate® (Baxter Inc.), 3 times a week, was introduced.

Result: After starting ITI, his inhibitor titer reached a maximum 36.8 BU/ml in the third week of treatment. However the titer declined slowly and episodic bleedings decreased. After 1 year of ITI treatment, the inhibitor was eradicated (< 0.6 BU/ml, more than 70% of the recovery). At present the patient has been receiving the same regimen as a regular replacement and there has been no relapse. At the time of writing, only a few results regarding the usage of ITI in adult patients with congenital hemophilia A has been reported.

Conclusion: ITI treatment was thought to be worth considering for inhibitor patients who have not yet received it, and even for older patients or patients in whom ITI treatment failed without the patient receiving sufficient dose or completing the full course of treatment.

Informed consent was obtained from the patient concerned and the authors state that they have no conflict of interest in this study.

PO 168

Surgery in FVIII inhibitor patients: single center experience of 13 procedures in 8 patients

Teitel J[1], Sholzberg M[1] and Floros G[2]

[1]*University of Toronto;* [2]*St. Michael's Hospital, Toronto, ON, Canada*

Background: Surgery in congenital and acquired hemophilia A patients with factor VIII inhibitors is problematic. There are no widely accepted consensus guidelines for managing surgery in these patients. As inhibitor patients are generally refractory to replacement therapy with factor VIII concentrates, achieving hemostasis requires the use of the inhibitor bypassing agents activated prothrombin complex concentrate (APCC) or recombinant activated factor VII (rFVIIa). Porcine plasma-derived factor VIII was used as a bypassing agent in the past, but is no longer available. Bypassing agents are less reliably effective than replacement therapy, and there are no widely available or validated laboratory assays to monitor their efficacy.

Aims: Our aim is to share our experience of consecutive major and minor surgical procedures in inhibitor patients done in a single adult hemophilia treatment center over a period of 14 years.

Methods: Between 1998 and 2012 we performed 13 surgical procedures in eight inhibitor patients using all three inhibitor bypassing agents. The nature of the procedures, hemostatic management protocols, and outcomes of these consecutive, unselected cases will be reviewed.

Results: Six patients had severe and one had mild congenital hemophilia A; one had acquired hemophilia. All had longstanding factor VIII inhibitors. Patient ages at the time of surgery ranged from 20 to 74 years. The surgeries included: 4 major orthopedic procedures in three patients (2 total knee arthroplasties, 1 ankle arthroplasty, 1 ankle fusion); four dental surgeries in two patients; one pacemaker implantation (in the acquired hemophilia patient); two nasopharyngoscopies with biopsies and cauterization (in the same patient); one craniotomy (bilateral burr holes); and 1 tracheostomy. The surgeries were done under cover of treatment with APCC, rFVIIa, or porcine factor VIII concentrate. One procedure, a tooth extraction done with APCC in a congenital hemophilia patient, had a poor outcome; he had severe bleeding which required intensive care admission, sequential rFVIIa and APCC, and lingual artery embolization. One knee arthroplasty done with APCC had a fair outcome; early re-bleeding occurred, which was felt to be due to excessively rapid tapering of APCC, and which responded to more intensive APCC administration. All other surgeries had good or excellent outcomes. For major procedures, coagulation parameters were followed in part to confirm perturbation of the hemostatic system but mainly as surveillance for consumption coagulopathy. Thromboprophylaxis was not given to those treated as hospital in-patients.

Summary and Conclusions: We observed excellent or good outcomes in 11 of 13 surgical procedures in inhibitor patients, a fair outcome in 1, and a poor outcome in 1. The use of global hemostasis assays might have proven helpful for monitoring therapy but the value of these modalities in surgery needs to be validated. Necessary surgery should not be withheld in hemophilia A patients because of the presence of a factor VIII inhibitor. Although access to a specialized coagulation laboratory is not necessary to guide therapy, these procedures should only be performed in hemophilia treatment centers, under the care of physicians and surgeons experienced in managing patients with complex bleeding disorders.

PO 169

Use of factor VIII after inhibitor clearance in patients with moderate hemophilia

Tran Q[1], Harvey DR[1], Meeks S[2], Chapman R[2] and Kempton C[2]

[1]*Emory University, Atlanta;* [2]*Emory University, Children's Healthcare of Atlanta, Atlanta, GA, USA*

Background: Anti-factor VIII (FVIII) inhibitory antibodies (inhibitor) are a major complication of hemophilia A (HA) and can be seen in up to 30% of persons with severe HA and about 0.9–7% of those with mild or moderate HA. Inhibitors can be eradicated through the use of immune tolerance induction (ITI), rituximab, or other immune modulating treatments. It is unknown whether persons with moderate HA (MHA) who develop an inhibitor can restart factor replacement therapy after resolution of their inhibitor in the absence of ITI. To our knowledge, there are no published reports describing the re-initiation of FVIII replacement therapy in persons with MHA complicated by an inhibitor.

Aims: To review a single institution's experience with re-initiation of FVIII treatment in patients with MHA after clearance of their inhibitor without ITI.

Methods: Persons with MHA with inhibitor were identified from a database of current patients treated at the Emory/Children's Hospital of Atlanta (CHOA) Hemophilia Treatment Center (HTC). Their medical record was reviewed. Information collected includes baseline FVIII levels, *f8* gene mutation, the occurrence of intensive FVIII exposure (> 5 days) prior to inhibitor development, the peak inhibitor titer, inhibitor eradication treatment received, and when the patient restarted FVIII replacement.

Results: At the Emory/CHOA HTC, 67 patients with MHA are followed routinely. Among this cohort, five were identified to have their course complicated by an inhibitor; 4/5 had high-titer inhibitor; 4/5 had prior intensive exposure; and 3/5 (Case #2, #4 and #5) had the N1922S mutation. One patient (Case #1) underwent ITI and was unsuccessful. Case #2 received rituximab without inhibitor clearance until 13 months after treatment. One month after inhibitor resolution, he restarted FVIII replacement therapy. At his first re-exposure to FVIII, his FVIII recovery was > 100% and half-life was 10.8 h. He continued to treat with FVIII (25 IU/kg) thrice weekly to prevent recurrent ankle bleeds. After 3 months of treatment, he had similar FVIII recovery and half-life and negative Bethesda assay and has continued on the same regimen for an additional 5 months of follow-up. Three patients did not receive any treatment and had resolution of their inhibitor after 36 months (Case #3), 23 months (Case #4), and 9 months (Case #5). Of these three that had spontaneous resolution, 2 are now receiving FVIII replacement therapy on-demand. Case #3 was re-exposed to FVIII, following 10 years of negative inhibitor titers, for treatment of persistent hematuria despite recombinant factor VIIa (rFVIIa) requiring hospitalization. After 3 days (6 doses) of FVIII treatment, he did not have an anamnestic response. He has received 1 FVIII infusion since re-initiation of FVIII replacement therapy. Case #4 had 3 months between undetectable inhibitor and re-exposure and has been treated on-demand for 17 years without recurrence. His current annual exposure is approximately 30 infusions. The third patient (Case #5) with spontaneous resolution has elected to continue to use rFVIIa to treat bleeding episodes.

Summary/Conclusion: Persons with moderate hemophilia A who clear their inhibitors without ITI may be successfully treated with FVIII without recurrence of inhibitors.

PO 170

Outcome of liver transplantation haemophilia patients in the Nordic countries

Tran HTT[1], Andersen I[2], Foss A[1], Berntorp E[3], Poulsen L[4], Lassila R[5], Tjønnfjord G[2] and Holme PA[2]

[1]Oslo University Hospital; [2]Institute of Clinical Medicine, Oslo, Norway; [3]Malmö University Hospital, Malmö, Sweden; [4]Århus Universitetshospital, Århus, Denmark; [5]Helsinki University Central Hospital, Helsinki, Finland

Background: Until the mid-1980s, the vast majority of persons with haemophilia who had received plasma-derived non-heat-treated coagulation factor concentrates became infected with hepatitis C virus, HIV or both. Of those, about 10–15% developed end stage liver disease (ESLD) or hepatocellular carcinoma and required liver transplantation. Liver transplantation (LTX) in haemophilia patients has the potential to cure haemophilia as the donor liver is able to synthesise the deficient coagulation factor. However, the coagulopathy associated with ESLD may carry an additional bleeding risk affecting the outcome of this surgical intervention. Previous reports from different LTX centers worldwide have in general concluded that the peri- and postoperative outcomes in haemophilia patients were similar to non-haemophilia patients but the recurrence of HCV infection remains the main challenge for longterm outcome. Nevertheless, little is known about the outcome of LTX in haemophilia patients in the Nordic countries.
Aims: The objective of this study was to evaluate the outcome of LTX in haemophilia patients in the Nordic countries.
Materials and Methods: Scandiatransplant is a Nordic organ exchange organization established for more than 40 years ago with a close collaboration between the transplant centers in the five Nordic countries (Norway, Iceland, Denmark, Sweden and Finland). The study included all haemophilia patients who have undergone liver transplantation in the involved countries. Data from the Nordic Liver Transplant Registry supplemented by clinical information obtained from medical records provided by each transplant centre were used for analysis. The Nordic Liver Transplant Registry is a prospective database of all patients undergoing LTX where data are updated regularly, at least once a year.
Results: From 1993 to 2011, a total number of nine patients with haemophilia underwent LTX (2 from Norway, 4 from Sweden, 1 from Finland and 2 from Denmark). The mean age at LTX was 59 (range 45–64) and the main indication for LTX was HCV related liver disease. Three are still alive while 6 have died. The mean survival time post LTX for those who died were 11 months (range 3–20 months). The longest survival among the patients who are still alive is 15 years. The causes of death were renal failure, gastrointestinal haemorrhage, non-anastomotic biliary complication, recurrence of original tumor, cerebrovascular event and bacterial infection. For those undergoing LTX between 2001 and 2008 only 20% in the haemophilia patient population had a 5 years survival compared to 83% in the non-haemophilia patients.. Among the three longterm survivers the mean age at LTX was 48 vs. 56 years for those who have died.
Conclusion: The study showed that LTX in haemophilia patients under the coverage of coagulation factor concentrates in the Nordic countries was safe and consistent with previous reports from other centers. However, the 5 years survival was substantially reduced in the haemophilia patients. The age at transplantation seemed to be the main factor associated with reduced survival in patients with haemophilia.

PO 171

Experience of home prophylactic treatment of inhibitory form of haemophilia A in children using recombinant activated FVII

Vdovin V[1], Svirin P[2], Shiller E[2], Luchinkina E[2], Malkova O[2] and Ageenkova E[2]

[1]Izmailovskaya Children Hospital; [2]Izmaylovski Children Hospital, Moscow, Russia

Background: Prophylactic treatment of children with Haemophilia A and FVIII inhibitor by recombinant activated factor VII (rFVIIa) has wide dose range from 90 to 300 mkg/kg for obtaining effective hemostasis.
Aims: To assess the efficiency of rFVIIa – Koagil-VII ('GENERIUM', Russia) which was used in individual doses and schemes for reduction of hemartrosis and severe bleedings frequency, also for prevention of complications (chronic synoviitis, arthropathy etc.).
Methods: Four patients obtained home prophylactic treatment by Koagil-VII within 1 year (since June 2011 to June 2012) with the following doses: from 141 to 257 mkg/kg with interval of 12 or 24 h. The quantity of bleedings and conditions of target joints were compared with results of prior year treatment (since May 2010 to May 2011). Treatment was 'on demand' and after serious bleeding patients got short courses of prophylactic treatment during up to 3 months with the following doses: from 90 to 120 mkg/kg with interval of 48 h.
Results: Patient 1: 2.6 years old. Weight – 14 kg. Inhibitor > 40 BE. Treatment scheme: 171.4 mkg/kg with interval of 12 h during 4 months, further 257.1 mkg/kg in the morning and 171.4 mkg/kg in the evening during 8 months. Bleedings amount before prophylactic was 29 (16 hemarthrosis), bleedings amount during prophylactic – 9 (2 hemarthrosis). Patient 2: 6 years old. Weight – 25 kg. Inhibitor – 27 BE. Treatment scheme: 120 mkg/kg with interval of 12 h during 12 months. Bleedings amount before prophylactic – 25 (20 hemarthrosis), bleedings amount during prophylactic – 4 (3 hemarthrosis). Patient 3: 6.3 years old. Weight – 30 kg. Inhibitor – 36 BE. Treatment scheme: 160 mkg/kg with interval of 48 h during 1 month, subsequently 160 mkg/kg with interval of 24 h during 11 months. Bleedings amount before prophylactic – 28 (17 hemarthrosis), bleedings amount during prophylactic – 13 (7 hemarthrosis). Patient 4: 14 years old. Weight – 34 kg. Inhibitor > 40 BE. Treatment scheme: 141.1 mkg/kg with interval of 24 h during 162 days, further 141.1 mkg/kg with interval of 12 h during 187 days. Bleedings amount before prophylactic – 8 (3 hemarthrosis, 1 extensive hematoma of thigh, 3 retroperitoneal hematomas, 1 renal bleeding), bleedings amount during prophylactic – 6 (2 hemarthrosis, 3 small hematomas, 1 renal bleeding). Regression of chronic synoviitis in the target joints took place in all patients. During the prophylactic period all identified hemartrosis and hematomas occur after injuries. No side effects of Koagil-VII was identified.
Summary/Conclusion: Prophylactic treatment of children with FVIII inhibitor by recombinant activated factor VII (rFVIIa) – Koagil-VII is efficient when individual high doses and treatment schemes are determined. It resulted in reduction of bleedings in 1.5–6 times and stopped of arthropathy progress.

PO 172

Diagnosis of inherited coagulation disorders – when and why?

Vukelic-Damijani N, Balen S, Ivankovic E and Katalinic N

Clinical Hospital Center Rijeka, Rijeka, Croatia

Background: The testing of inherited coagulation disorders has been carried out in our institution for more than 35 years. The total number of patients with coagulation disorder was 107, as follows: 39 with hemophilia A, 12 with hemophilia B, 8 with FXI deficiency, 15 with von Willebrand's disease, and 33 patients had rare coagulation disorder.

Aim: Analysis of the age of diagnosis and the reason why coagulation disorder has been diagnosed.
Method: Analysis and statistics elaboration of medical and laboratory data.
Results: Hemophilia A has been diagnosed in 39 patients. Severe hemophilia A has been diagnosed in 18% (7/39), which is 3/7 (43%) in the first year of life while the other 57% (4/7) till the third year of life. All the mentioned above have been tested for the same reason, which is bleeding. Moderate hemophilia A has been diagnosed in 23% (9/39), within the ranging of diagnosis from 1 till 40 years of age. Reason for testing was bleeding in 67% (6/9), preoperative screening in11% (1/9) and family screening in 22% (2/9). Mild hemophilia A has been diagnosed in 23 cases (59%), in the range from 2 months till 50 years of age. The reason for testing was bleeding in 43% (10/23), family screening in 26% (6/23) and preoperative testing in 30% (7/23) of cases.
Hemophilia B was found in 12 patients. One patient (8%) had severe hemophilia B, the reason for testing was bleeding in the child's first year of life. Moderate hemophilia B has been diagnosed in 50% (6/12) of cases in the range from the 1st year of age till they were 40 years old, and the reason for testing was bleeding in 66% (4/6) of cases, preoperative screening as well as family screening was reason in 17% (1/6). Mild hemophilia B has been diagnosed in five cases (42%) from the first year of age till the age of 60. The bleeding was reason for 2/5 (40%) of patients to get tested, preoperative screening diagnosed 2/5 (40%), while family screening diagnosed 1/5 (20%) of cases.
The factor XI deficiency was proved in eight patients, ranging from 20 years till 70 years of age. In 7/8 (87%) of cases the reason for being tested was preoperative screening while in 1/8 (13%) of cases was bleeding. Von Willebrand's disease was diagnosed in 15 patients from 3 months of age till 40 years of age. The reason for being tested was bleeding in 67% (10/15), preoperative testing in 13% (2/15) and family screening in 20% (3/15) of cases.
Other rare coagulation disorders, as the FI, FV, FVII, FX, FXIII deficiency or combined deficiency have been found in 33 patients.
Conclusion: severe cases of hemophilia and severe hereditary coagulation disorders have been diagnosed at an early stage of life, mostly due to bleeding. Milder cases of hemophilia and coagulation disorders have been diagnosed at a rather wider range of age span and it was mainly due to preoperative testing or family screening.

PO 173

Successful anticoagulation with concomitant factor VIII replacement in a severe haemophilia A patient suffering a life threatening thrombotic event

Xavier F[1], Maahs J[1], Hallett RL[2], Nakar C[1], Rampersad AG[1], Gupta S[1] and Shapiro AD[1]

[1]Indiana Hemophilia & Thrombosis Ctr; [2]Northwest Radiology, Indianapolis, IN, USA

Background: Venous thromboembolic events (VTE) in severe hemophilic patients are rare, with spontaneous life-threatening thrombosis even scarcer. Literature is limited and clear guidelines regarding the management of anticoagulation (ACO) in hemophilic patients including factor replacement therapy, ACO agent, treatment duration, intensity, and safety of ACO are not available.
Aims: A teenage male with severe haemophilia A (HA) suffered a spontaneous life-threatening thrombosis requiring both FVIII replacement and ACO. The patient received 6 weeks of ACO comprised of initial unfractionated (UFH) then subsequent low-molecular-weight heparin (LMWH), and FVIII with complete resolution without recurrence (4.5 months follow-up). This case demonstrates the use of safe ACO in haemophilia.
Methods: An 11 year-old male with severe (< 1%) HA without inhibitor who was maintained on prophylaxis with recombinant FVIII (Xyntha®) via peripheral venous access (dosing tailored by pharmacokinetics (PK solutions®- SummitPK.com) with every other day infusion), presented to his local emergency room with acute incapacitating abdominal pain. A presumptive diagnosis of appendicitis was made and the patient infused with his standard FVIII dose (67 IU/kg) and transferred to our institution. Further evaluation revealed ischemic bowel syndrome due to a thrombosis with total occlusion of the superior mesenteric vein documented by Doppler ultrasonography and CT venogram. ACO was initiated within 6 h from acute pain onset. Protrhombotic evaluations performed at diagnosis, and as outpatient were negative for underlying risk factors (protein C, S, antithrombin deficiency; factor V Leiden mutation; protrhombin gene 20210A mutation; Lupus Anticoagulant/Phospholipid dependent antibodies; lipoprotein-a; homocystein; paroxysmal nocturnal hemoglobinuria, fibrinogen).
Results: Following 48 h of ACO with UFH (targeted anti-Xa 0.35–0.70 units/mL) and recombinant FVIII (rFVIII; Xyntha®) continuous infusion targeting FVIII > 80%, total clot resolution was observed via US Doppler. ACO was continued with UFH for 5 days with concurrent rFVIII (levels between > 80% and < 200%). Pain improved following 24 h, and resolved after 48 h of ACO. A transition to LMWH was performed 1 week after documentation of clot resolution (1 mg/kg/dose enoxaparin SC BID; targeted anti-Xa 0.5–1 units/ml). Following discharge on once daily bolus rFVIII the patient was unable to maintain trough FVIII activity > 10% despite a calculated 120% correction, therefore twice daily calculated 60% correction with rFVIII was initiated and resulted in troughs of 30–50% activity. Anatomical evaluations with MRI/MR venography revealed no underlying structural abnormality that contributed to the thrombotic event. The patient was maintained on ACO and twice daily rFVIII for 6 weeks without recurrence or bleeding complications.
Summary/Conclusion: Here we report successful and safe ACO covered with factor VIII replacement in a patient with severe HA suffering from a life threatening spontaneous VTE event. While occurrences of myocardial infarction and cerebrovascular accident in patients with HA have been documented, in contrast, little literature exists regarding venous thrombosis in these patients. It is extremely important that clear guidelines concerning the safety and duration of ACO following VTE be established in this specific patient population.

PO 174

Clinical experience with new third generation recombinant B-domain deleted factor VIII concentrate (beroctocog alpha) in a single center

Yoo KY[1] and Yoon HJ[2]

[1]Korea Hemophilia Foundation; [2]Department of Hematology-Oncology, College of Medicine, Kyung Hee University, Seoul, South-Korea

Background: Third generation recombinant factor VIII concentrates have become the prevailing drug for hemophilia A patients. By 2010, 2 types of the concentrates, 1 full-length recombinant factor VIII (octocog alfa) and 1 B-domain deleted factor VIII (moroctocog alfa), were available across the world. Recently new B-domain deleted factor VIII (beroctocog alfa) has been introduced in Korea.
Aims: We aimed to evaluate the efficacy and safety of the new drug. As for efficacy, we conducted *in vivo* recovery (IVR) and efficacy rating. Regarding safety, inhibitor titer and adverse events were monitored.
Methods: We reviewed 89 hemophilia A patients' medical records and surveyed for efficacy rating through telephone. Two previously untreated patients were included. Phenotype was severe in 63, moderate in 18, and mild in eight patient. Exposure days (ED) were available in 82 patients. IVR with dosage of 25 U/kg of the concentrate was carried out in 29 patients using one-stage assay. Inhibitor assay using Bethesda assay were available in 31 patients. At the time of inhibitor assay, their mean ED reached 17, and ED was 50 or more in 13

patients. In terms of efficacy rating, 45 patients responded as 4 point scale.

Results: IVR was 2.4%/u/kg and inhibitor titer 0.1 BU/ml with no development of inhibitor. Eighty-four percent of the patients rated the efficacy as excellent (42%) and good (42%). Sixteen percent of patient rated as fair. Six of 82 patients (8%) reported eight minor adverse events: posterior neck flushing sense (3), nausea (2), chest thightness (1), buring heart (1), dizziness (1).

Summary: The new third generation B-domain deleted factor VIII showed satisfactory IVR (2.4%/u/kg) and efficacy rating (84%). There was no inhibitor development in 31 patients with mean 17 ED. Only minor adverse events were observed.

PO 175

Spectrum of molecular events encountered in Hemophilia B in a referral hospital in North India

Das R, Ahluwalia J, Kaur J, Senee HK, Chopra G, Trehan A, Malhotra P and Marwaha RK

Postgraduate Institute of Medical Education & Research, Chandigarh, India

Background: Hemophilia B (MIM# 306900; HB) is the second most common severe inherited bleeding disorder encountered in our population. Due to a wide range of molecular heterogeneity, identification of the mutation is necessary to offer carrier detection and prenatal diagnosis.

Aims: We characterized the molecular events in eighteen patients (17 families) and performed carrier screening in family members to offer appropriate counselling.

Methods: Identification of cases of HB was carried out at our Institute by the coagulation screening tests followed by Factor IX assays. Genomic DNA was extracted from peripheral blood leucocytes using standard phenol-chloroform method. Coding regions including the splice junctions were amplified by PCR using specific sequences. Automated sequencing was performed on the ABI Prism 310 sequencer (Applied Biosystems, Foster City, CA, USA).The software Sequencher was used for evaluating the sequencing results, followed by base to base evaluation of results. Whenever possible the mother's sample was sequenced to identify the inheritance and sisters were evaluated for carrier status.

Results: Eighteen patients of HB in 17 families were analysed. Ten different point mutations were identified of which nine were missense mutation and one was an acceptor splice (b) Ex 2 (CAG→CGG). Three of the missense mutations resulted in a stop codon termination. Seven of the mutations involved the amino acid arginine and consequently a CpG island. Exon 2 was the commonest exon to be involved in a mutation/deletion (11 cases). The commonest recurring mutation was *c*. 6364 Cd -4(CGG→TGG) R-W in exon 2. Three cases showed deletions of which one case showed deletion of exons 1–3. Four novel mutations found were splice (b) Ex 2 (CAG→CGG), c.6436 Cd 20 (GAA→TAA) E-X, Cd 121 (CAG→CTG) Q-L with 26 nucleotide deletion (including beginning of intron 6) and Cd 169 (del actc) Fs X 28/29. Four mutations were found to be reported earlier in the Haemophilia B mutation database (version 13, 2004) http://www.kcl.ac.uk/ip/petergreen/haemBdatabase.html, but not from India. The Malmo polymorphism (rs6048:G>A; Ala194Thr in the primary translation product and Ala148Thr in the mature protein) in the activation peptide of the protein encoded by exon 6 was detected in 2 of 10 alleles.

Twelve mothers were tested for the specific mutation detected and all were found to be heterozygous. Carrier screening for twelve sisters showed six each to be carriers and normal. Prenatal diagnosis was carried out successfully in one family.

Summary/Conclusions: This study has characterized seventeen hemophiliac families from Northern India and identified four novel mutations/deletions. Additional four mutations not yet described from India were also found. Except for two mutations which were recurrent, all were single cases. No sporadic case has been identified as yet. Thirteen cases (72%) involved the PCR product amplifying exons 2 and 3 together and this can therefore be tested for initially. The analysis is useful to carry out carrier screening and prenatal diagnosis for our population.

PO 176

Real-life use of activated recombinant Factor VII (rFVIIa) in patients with haemophilia B with inhibitors – data from the UKHCDO/NHD registry

Hay CRM[1], Bjerre J[2] and Dolan G[3]

[1]Manchester Royal Infirmary, Manchester, UK; [2]Novo Nordisk, Bagsværd, Denmark; [3]Queens Medical Centre, Nottingham, UK

Background: Activated recombinant Factor VII (rFVIIa, NovoSeven®, Novo Nordisk, Denmark) is established as a well-tolerated and effective bypassing agent for the treatment of patients with haemophilia with inhibitors, and is approved for use at standard (3 × 90 μg/kg) and high (1 × 270 μg/kg) doses in the United Kingdom (UK). Data on the use of rFVIIa in patients with haemophilia B (HB) is limited because of the rarity of the condition; however, anecdotal reports suggest rFVIIa may be less effective in HB than haemophilia A (HA).

Aims: To assess the real-world use and safety of rFVIIa in patients with haemophilia with inhibitors in a post-marketing surveillance study, requested byEMA and conducted by the UK National Haemophilia Database (NHD) (1 Jan 2008 to30 June 2011).

Methods: The NHD collects treatment and adverse event data quarterly from all UK haemophilia centres, in accordance with the Declaration of Helsinki. Anonymised data on rFVIIa dosing and adverse event occurrence were reported from patients with haemophilia treated with rFVIIa. Dose regimens were determined by the managing clinician.

Results: Sixty-seven patients (median age 23.2 years) from 25 centres were included, involving 1057 treatment episodes with rFVIIa. Sixty HA patients reported 976 treatment episodes (42.1% in patients < 18 years old; 8.1% in those ≥ 65 years old) and seven HB patients (11%; median age 25 years) reported 81 episodes (40.7% in patients < 18 years old; none in those ≥ 40 years old). Most HB treatment episodes (76/81, 93.8%) involved acute, non-surgical bleeds, while two (2.5%) were treated prophylactically and three (3.7%) were for surgery. Patients with HB received a lower initial rFVIIa dose compared with HA (mean 139.5 μg/kg vs. 180.7 μg/kg; median 119.0 μg/kg vs. 148.1 μg/kg; range 23.6–291.6 vs. 11.0–491.8 μg/kg). Higher initial rFVIIa doses (≥ 180 μg/kg) were administered more frequently to patients with HA than HB (40.5% vs. 13.5%), although more patients had missing data in the HB group (32.1% vs. 8.4% for HA). Patients with HB received a higher mean number of rFVIIa doses than HA (5.2 vs. 4.5), had a longer mean duration of treatment (47.0 vs. 41.6 h) and received a higher mean total dose of rFVIIa (759.6 vs. 604.7 μg/kg). Single-dose regimens (a dose spaced > 26 h from previous and following doses) were used in 57.1% of patients with HB for treatment of 35.8% of episodes; this is substantially lower than the proportions of patients and episodes treated with single-dose regimens in the subgroup with HA (71.7% and 52.3%, respectively). There were no adverse events judged to be related to rFVIIa. No thromboembolic events or episodes of anti-rFVIIa antibody formation were reported.

Conclusions: These data reveal differences in the rFVIIa dose regimens used in patients with HB vs. HA in theUK. Patients with HB are treated with lower initial rFVIIa doses, and are more likely to receive multiple dosing than patients with HA. Treatment of HB may be improved by administering higher initial rFVIIa doses. There were no reports of adverse drug reactions and no thromboembolic events in HA or HB patients.

PO 177

RFVIIa prophylaxis for hemophilia B with recurrent high-titer inhibitors: a single patient experience

Kovalova Z, Grutupa M, Cebura E, Vishnevska-Preciniece Z, Nikulshin S and Medne G

University Children's Hospital, Riga, Latvia

Many patients with severe hemophilia develop inhibitors to coagulation factors, the presence of inhibitors makes the treatment very challenging for both patients and doctors. Hemostatic cover for bleeding episodes is costly and thus has a substantial economic impact on healthcare budget. Life quality of these patients usually deteriorates along with progression of arthropathies that lead to permanent disability.

We present a case of a male patient with severe hemophilia B born in 1997. The diagnosis was made at the age of 8 months (factor IX < 0.1%), deletion at Ex6 was detected. During first years of life he received *on demand* treatment with plasma-derived factor IX concentrate. In pre-school age two major target joints (right knee and left ankle) developed, followed later by other knee and ankle. In-hospital treatment usually was required 2–3 times per year due to recurrent severe bleeding episodes. In 2006 we performed Rifampicin synoviorthesis procedures for target joints, covered by factor IX. Between the procedures an allergic skin reaction (diffuse urticaria) to an unidentified agent (probably, FIX or rifampicin) was observed. Two weeks after synoviorthesis the patient developed severe hemorrhage after tooth extraction that was refractory to high-dose FIX, inhibitors > 250 BU were detected. Therapy was switched to rFVIIa *on-demand* treatment; still, frequent in-hospital treatments occurred. In July 2008 an episode of resistance to rFVIIa was detected when continuous bleeding after tooth extraction with hemostatic covering (rFVIIa) lasted for 4 days. Local treatment (surgical revision, orthodontic plate) and tranexamic acid were applied in combination with rFVIIa for 5 days, IVIG and Methylprednosolone. In 5 days clinical response was achieved, inhibitor titer at this time was 5 BU. Parents refused ITI that time, in 6 months during routine follow-up the inhibitors disappeared. Frequent hemorrhages occurred during next 3 years, leading to arthropathies in major leg joints. Twenty-seven bleeding episodes of different localizations were observed in January-November 2011 (mean rate – 2.5 bleeds per month), with monthly consumption of rFVIIa 516–2459 μg/kg.

The decision to start prophylactic treatment with rFVIIa was made in adolescence (14 years) due to progressively deteriorating quality of life. Low-dose empirical approach (90 μg/kg 3 times per week) was chosen. The prophylactic treatment was started in the end of November 2011. Only 5 bleeds occurred during 9 months of prophylaxis, with monthly consumption 800–1575 μg/kg. In August 2012 a massive spontaneous left leg soft tissues hematoma occurred that turned refractory. FIX was added with good clinical effect at the beginning, but the loss of hemostatic control occurred in 5–6 days, while titer of inhibitors rose > 16BU. After this episode we changed the prophylaxis to the current 230 μg/kg 3 times per week. With this regime only one nose bleeding was detected in 5 months period, monthly consumption of rFVIIa during the last months was 1900–3500 μg/kg. Thus, the number of bleeding diminished dramatically during the last year of prophylaxis, the compliance to therapy was very good. The optimal dosage remains unclear, repeated episodes of resistance to rFVIIa are still unpredictable.

PO 178

Treatment strategy and outcomes among US haemophilia B patients: results of a patient survey

Krishnan S[1], Furlan R[2] and Vietri J[2]

[1]*Biogen Idec, Weston, FL, USA;* [2]*Kantar Health, Surrey, UK*

Background: Information on patient-reported outcomes and adherence is scant in haemophilia B.

Aims: To describe the treatment characteristics and outcomes of US haemophilia B patients.

Methods: Adults and caregivers of children with haemophilia were identified through a panel of patients originally recruited from haemophilia treatment centers and associations. The study protocol received central institutional review board approval and all patients reported consent to be included in the study. Panelists reporting moderate or severe haemophilia were invited to complete an on-line questionnaire assessing experience with bleeding and joint problems, personal characteristics, and validated scales. The revised Short Form-12 Health Survey (SF-12v2) was included to assess adult health status, and the Short Form 10 Health Survey (SF-10) was used to assess health status in children. Adherence to treatment was measured with the VERITAS-Pro for patients treating prophylactically. The current analysis was limited to patients with haemophilia B.

Results: A total of 24 patients with haemophilia B (14 patients & 10 parents) completed the survey; more than half (14/24) were on prophylactic treatment. All patients/parents surveyed considered themselves/their child to have severe haemophilia. Relative to the average of US adults, adult haemophilia B patients had physical health status slightly below the average (PCS = 46.4) and mental health status slightly above the average (MCS = 53.8). The pattern among children was similar, with mean physical health status below population norms (PHS = 48.5) and psychosocial health slightly above the norm (PSS = 55.8). Over 70% of the patients (17/24) had experienced at least one bleed requiring replacement factor in the past year, and almost half of these patients (8/24) experienced 10 or more bleeds requiring replacement factor over the same period of time. Two thirds (16/24) had experienced joint pain in the past month, and almost 80% (19/24) had experienced joint pain in the past year. Two patients reported having at least one hospital stay due to bleeding and five patients at least one emergency room visit due to a bleeding episode in the past year. Approximately one-third of those using prophylactic treatment (5/14) were considered non-compliant based on the VERITAS-Pro (total score > 57.7 as suggested by literature), an instrument utilized to measure compliance within the haemophilia population.

Summary/Conclusions: Physical health among haemophilia B patients was low, and complications were common. One-third of those on prophylactic treatment were considered non-compliant to regimen. Further research is needed to characterize the relationship between adherence to therapy, health status, and clinical outcomes.

PO 179

Identification of mutations in the Factor IX gene in patients with Hemophilia B in Venezuela

Latorre L[1], Ruiz-Sáez A[2], Boadas A[2], De Bosch N[2] and Porco A[3]

[1]*Universidad Simon Bolivar;* [2]*Centro Nacional de Hemofilia. Banco Municipal de Sangre, Caracas, Venezuela;* [3]*Laboratorio de Genética Molecualr Humana B. Universidad Simón Bolívar, Caracas, Venezuela*

Hemophilia B (HB) is an X-linked disorder caused by genetic abnormalities in the coagulation factor IX (F9) gene. Severe HB (SHB) patients generally experience prolonged bleeding episodes, which, if not treated, could result in serious life-threatening complications. Mutations causing HB are entirely restricted to the F9 gene, which is located at Xq27, and the specific genetic lesion determines the severity of the disorder. The aim of this study was to determine the genetic alteration causing HB in a population from Venezuela and evaluate the possible effect of the mutation on the structure and function of the protein. Blood samples were obtained from the Banco Municipal de Sangre de Caracas and informed consents were obtained from all patients. In the Human Molecular Genetics Laboratory of the Universidad Simón Bolívar, we extracted the genomic DNA and detected the mutations present in the F9 gene using Conformation-Sensitive Gel Electrophoresis (CSGE) as a mutation screening method. Fifty

percent of the variations were found on the region corresponding to exon 8 (serine protease catalytic region), 13% to exon 6 and 5 (activation peptide and EFG-2 domain), and 6% to exons 4, 2 and 1 (corresponding to EFG-1, Gla domain, and signal peptide, respectively). The possible effect on the function of the protein of each of the mutations identified was analyzed, and its relationship with the severity of the disease was evaluated. This study allowed the identification of 11 new mutations non previously described, including 4 missense, 1 del/ins, 3 deletions, 1 nonsense and 2 mutations within critical splicing sites. This is the first time that molecular studies in the *F9* gene from patients with HB were performed in Venezuela, leading to the initiation of new studies where carrier identification in families with hemophilia B patients could be performed.

PO 180

Mitroaortic valve replacement in a haemophilic B patient with an intracardiac abscess and cerebral septic embolism. Case report

Nobre Fernandes S, Carvalho M, Lopes M and Araújo F
Centre of Thrombosis, Haemostasis and Vascular Biology, Department of Transfusio, Oporto, Portugal

Background: Life expectancy of persons with haemophilia has improved markedly. Around 1 in 30 patients with hemophilia will have intracranial hemorrhage at least once during their lives. When cerebral hemorrhage is associated with septic embolism, the scenario becomes more critical. Cardiac surgery constitutes a major hemostatic challenge because of sternotomy, heparinization, extracorporal circulation, hypothermia and cardiac arrest.
Case Report: A 28 years-old patient, with known mild haemophilia B (FIXC: 30%), entered in emergency room (ER) with a motor deficit in his right side and sphincter incontinence with 12 h evolution. His wife referred a 3 month history of headache and dizziness, with febrile evening peaks. Due to these symptoms, he went to a local hospital 3 weeks before, and was discharged with a diagnosis of a respiratory infection and 7 days of antibiotherapy. When he finished antibiotherapy, started to feel pain on his lower limbs, without limitations, that got worse. On admission on ER he was awaked and cooperating with no dizziness or headache at that time. Physical examination revealed a grade II mesosystolic murmur over aortic valve and a grade IV systolic murmur over mitral valve, tachycardia, normal blood pressure and afebrile. On neurologic evaluation he presented a Glasgow Score of 15, right side hemiparesis (involving face) and hypoesthesia without visual involvement. He was diagnosed a multifocal cerebral haemorrhage after computed tomography (CT). He was admitted on the stroke unit for conservative treatment. Transthoracic echocardiogram (TTE) detected moderate aortic insufficiency (bicuspid valve) and moderate to severe mitral insufficiency, slight thickening of mitral valve, with adherent vegetation on the anterior leaflet that extended to interatrial septum. Transesophageal echocardiography confirmed those findings. The abscess (38 mm length/11 mm thickness) was adjacent to anterior aortic leaflet, interatrial septum, and slightly on right atrium, continuing to anterior mitral leaflet. *Streptococcus mitis* was found in blood cultures and a diagnosis of cerebral haemorrhage as a result of a septic embolism from intracardiac abscess was made. Looking for the cause of infection, a dental abcess was found and three teeth extractions were performed.
Due to high risk of septicaemia and haemorrhage, he underwent cardiac surgery 1 month later. He needed aortic and mitral valve replacement with bioprosthesis and reconstruction of mitral aortic curtain (bovine graft). All the procedure was made under factor replacement. He was discharged 1 week after surgery and entered an intensive physical rehabilitation programme at a local hospital. Presently, 2 years after, the patient is on anticoagulation therapy with warfarin, without physiotherapy although lightly disabled, nevertheless he regained his drive license.
Conclusions: This report is a 'happy end' of a critical scenario in a haemophilic patient only achieved due to excellence clinical care in a haemophilia reference center, within a central hospital and a high experienced multidisciplinary team.

PO 181

Linkage analysis coupled with direct mutational screening in carrier detection and prenatal diagnosis of hemophilia B

Ranjan R, Akhter MS, Sharma A, Kumar S, Deka D and Saxena R
All India Institute of Medical Sciences, New Delhi, India

Background: Hemophilia B is an X-linked recessively inherited bleeding disorder characterized by deficiency of procoagulant factor IX (FIX). The treatment is expensive, hence to step down the incidence of this disease in developing countries, the method of choice is carrier detection followed by prenatal diagnosis.
Aim: The aim of the study was to find out potential carriers and affected fetus.
Methods: Fifty one (30 with family history & 21 sporadic) unrelated hemophilia B patients and their family members were the subjects of this study. Carrier detection by linkage analysis using the polymorphic markers Mnl I, Dde I, Hha I and Sal-I was performed in families with history of Hemophilia B. In sporadic families, the carrier status of female subjects was ascertained by conformation sensitive gel electrophoresis (CSGE) followed by sequencing. Prenatal diagnosis was performed in 28 fetus samples using chorionic villus sampling in 22 cases and 6 with cordocentesis depending on the gestational age and informativity of the linkage markers.
Results: Of the 30 families with positive family history, the defective X chromosome was tracked in 25 mothers. CSGE helped us to diagnose 21/26 (21 sporadic hemophilic and 5 uninformative families from linkage analysis) mothers. Fetuses affected with Hemophilia B were diagnosed in 8 (50%) by chorionic villus sampling whereas cord blood factor IX assay diagnosed 2 to be affected. Six of the fetus from the C vs. was diagnosed as a female child.
Conclusion: Carrier detection followed by prenatal diagnosis serves as an effective way to curb Hemophilia B in an Indian setting. We found that the choice of technique, chorionic villus or cordocentesis, is not really an alternative, but rather dependent on the gestational age of presentation.

PO 182

The efficacy and safety of Benefix in severe and moderate Hemophilia children in China: a signal centre observation study

Wu R[1], Wu X[1], Li G[1], Zhen Y[1], Zhang N[1], Wang Y[1], He W[1], Luke KH[2] and Poon M-C[3]
[1]Beijing Children's Hospital, Beijing, China; [2]University of Ottawa, Children's Hospital of Eastern Ontario, Ottawa; [3]University of Calgary, Foothills Hospital, Calgary, AB, Canada

Background: BendfiX as the only recombinant product for hemophilia B has been well comfirmed its effects, but not yet in Chinese pediatric hemophilia B.
Aims: To explore the efficacy and safety of the application of Benefix in Chinese severe and moderate Hemophilia B children for low-dose prophylaxis.
Methods: Benefix for low-dose prophylaxis 20 UI/kg, once a week for severe and moderate Hemophilia B children in Beijing Children's Hospital, observed (1) efficacy:Reduction of bleeding, improvement of daily life participation; (2) safety: the side-effect during the Benefix intervention and monitor the inhibitor during the prophylaxis period.

Results: There were 11 analyzable cases, the duration was mean 25 weeks (17–27 weeks); mean age 7 year and 2 month(range 9 months to 15 year-old); nine cases were severe and two cases moderated hemophilia B; six cases received on-demand, 4 received prophylaxis intervention methods and 1 case without any treatment before the observation, median exposure day was 68ED (range 0–> 150ED). (i) Efficacy: the total reduction of bleeding was 67.7%(78.6% reduction compared to original on-demand treatment and 47.8% for original prophylaxis cases; 8/9cases daily life participation improved (5/6 for original on-demand or without treatment and 3/3 for original prophylaxis treatment); (ii) Safety: there was no anaphylaxis during the Benefix intervention and only one person and one time = 0.6 BU/ml transient inhibitor presented and low-downed to 0 BU/ml in the end of observation for all cases.
Conclusions: There were the efficacy and safety for the Benefix application in Chinese severe and moderate Hemophilia B children for low-dose prophylaxis.

PO 183

Persistence of circulating heparin levels during maintenance hemodialysis in end stage renal disease patients

Bansal V[1], Kaneva K[2], Hoppensteadt D[1], Cunanan J[1], Syed D[1], Singh A[3] and Fareed J[1]

[1]Loyola University Medical Center; [2]Loyola University Stritch School of Medicine, Maywood; [3]Brigham and Women's Hospital, Boston, MA, USA

Background and Aims: Despite the development of newer oral anticoagulants, heparin has remained the anticoagulant of choice for hemodialysis patients. Wide variations in the heparinization responses have been observed in hemodialysis patients. The purpose of this investigation was to measure circulating heparin levels in patients prior to and after hemodialysis.
Methods: This study included 119 End Stage Renal Disease (ESRD) patients undergoing maintenance hemodialysis. For the 3–4 h hemodialysis duration, a heparin-loading dose of 1000 Units followed by two dosages of 500 Units/h were administered. Blood samples were collected prior to and immediately after the dialysis. Citrated plasma was frozen at −70 °C and analyzed utilizing Activated Partial Thromboplastin Time (APTT), Heptest and Prothrombinase Induced Clotting Time (PiCT). Circulating Anti-Xa levels were measured using a chromogenic substrate method. Thromboplastin induced thrombin generation (TGA) was also measured using a fluorogenic method. The Antithrombin (AT) levels were measured using functional assay. Heparin levels were determined using a calibration curve constructed from the heparin used in the dialysis unit. TFPI antigen levels were measured using an ELISA method.
Results: In the APTT and Heptest, no significant differences between pre and post plasma samples were noted. The circulating levels of heparin were from 0 to 1.08 U/ml with a mean of 0.07 ± 0.11 for the APTT and a range of 0 to 1.98 for the Heptest with a mean of 0.09 ± 0.26 U/ml. In the PiCT test the range was from 14.0 to 300 s for the pre dialysis samples with a mean of 32.0 ± 38.2, whereas for the post samples the range was from 15.2 to 110 with a mean of 29.6 ± 14.0. The circulating Anti-Xa levels in the pre dialysis samples ranged from 0 to 0.77 with a mean of 0.10 ± 0.14, whereas the post level ranged from 0 to 0.51 with a mean of 0.13 ± 0.11. For the thrombin generation, the% inhibition levels ranged from 0 to 100% pre dialysis with a mean of 34.2 ± 34% and ranged 0 to 100% post dialysis with a mean of 44.5 ± 34.4%. The Antithrombin levels ranged from 28 to 130% with a mean of 86.6 ± 9.5% in the pre dialysis samples. The TFPI levels were 88 ± 12 ng/ml in the pre-dialysis and increased to 106 ± 18 ng/ml after dialysis.
There was no significant difference between pre and post dialysis samples using APTT, Heptest, PiCT and TFPI, whereas the Thrombin generation and Anti-Xa resulted in a statistically significant P value < 0.05 when comparing the two groups.
Summary/Conclusion: Wide variations in circulating heparin levels are noted in maintenance hemodialysis patients at pre dialysis and post dialysis time periods. Some patients exhibit higher levels of heparin due to a vascular access flush. These results also suggest that the use of heparin in maintenance hemodialysis patients in repeated regimen results in a steady state hypocoagulation as evidenced by the inhibition of thrombin generation, circulating Anti-Xa level and the prolongation of various clotting times.

PO 184

The effect of empiric systemic anticoagulation prior to imaging for pulmonary embolism on mortality

Beam D[1], Kabrhel C[2] and Kline JA[1]

[1]Indiana University School of Medicine, Indianapolis; [2]Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA

Background: Current evidence is conflicting about the impact of administering heparin prior to results of imaging, or empiric systemic anticoagulation (ESA), for pulmonary embolism (PE). Prior work shows that delay in anticoagulation increases mortality, but patients selected for ESA are more ill and have increased overall mortality.
Aims: To create a propensity matching score which corrects for illness acuity in patients given ESA, and then retest the association of ESA with mortality.
Methods: Using an existing multicenter sample of 7940 emergency department patients who underwent testing for acute PE (n = 481), we used logistic regression to create a propensity score (propscore). The score was tested for accuracy at predicting ESA using receiver operating characteristic curve (ROC) analysis. The independent predictive effect of ESA was tested using conditional logistic regression, with cases (deaths, 1.3% of sample) and controls (survivors) matching by the propscore, and predictors: ESA, the pulmonary embolism severity index (PESI), respiratory distress, and end-stage condition.
Summary/Conclusions: The six propscore predictors for ESA (350/7940 or 4.4%) were: PE the most likely diagnosis, unilateral leg swelling, history of PE, active malignancy, O2 < 94%, and HR > 100. The area under the ROC for the propscore was 0.78 (95% CI 0.73–0.80) indicating fair accuracy for predicting ESA. Conditional logistic regression revealed odds ratios (95% CIs) for the prediction of death were as follows: PESI 1.04 (1.03–1.05), ESA 1.2 (0.6–2.4), Respiratory distress 1.2 (0.4–3.8), End stage disease 5.0 (2.8–8.9). After propensity matching, the use of ESA has no effect on mortality. The appearance of equipoise justifies the need for a randomized trial.

PO 185

Comparison of adherence to three times a day low dose unfractionated heparin for venous thromboembolism prophylaxis between surgical and medical ward patients

Bhatt SH and Seoane-Vazquez E

Massachusetts College of Pharmacy and Health Sciences, Boston, MA, USA

Background: Low dose unfractionated heparin (LDUH) received a Grade 1A recommendation for venous thromboembolism (VTE) prophylaxis. While the optimal daily LDUH dose is unclear, many institutions and guidelines recommend 5000 units subcutaneously three times per day. Adherence with three times daily administrations is challenging, and if suboptimal prophylaxis administration occurs, an increased risk for hospital acquired VTE may exist.
Aims: The purpose of this evaluation was to assess differences in adherence with three times daily LDUH VTE prophylaxis between

inpatient surgical and medically ill patients. The study also identified barriers to LDUH adherence.

Methods: After IRB approval, patient demographic and LDUH administration data was extracted from medical charts and pharmacy records of a random sample of hospitalized patients admitted for > 24 h and with active orders for three times per day LDUH VTE prophylaxis. The patients were grouped in two cohorts, surgical (patients in non orthopedic and intensive care surgical wards) and medical (i.e. patients in medical wards). The unit of analysis was the observation (i.e. hospital stay requiring LDUH VTE prophylaxis). Patients receiving therapeutic anticoagulation or LDUH < 24 h were excluded from analysis. Descriptive analysis, *t*-test and chi-square tests were performed in the analysis. The level of statistical significance was set *a priori* at 0.05.

Results: The study included 586 observations in the medical cohort and 141 observations in the surgical cohort corresponding to 554 and 125 patients, respectively. The average age of patients was higher in the medical cohort (63.5 ± 17.5) than in the surgical cohort (56.7 ± 16.9) ($P < 0.001$). The proportion of women was 51.9% and 50.5% in the medical and surgical cohorts, respectively (NS).

The surgical cohort had higher proportion of all potential doses received than the medical cohort (70.2% vs. 27.2%; $P < 0.001$) and lower average number of total given doses (7.74 ± 6.41 vs. 9.18 ± 9.79; $P < 0.05$). The average number of missing dosages was lower in the surgical than in the medical cohorts (0.44 ± 0.84 vs. 3.13 ± 5.49; $P < 0.001$). The average of the percentage of the total number of dosages received was higher in the surgical than in the medical cohort (94.30 ± 13.07 vs. 71.86 ± 31.69; $P < 0.001$).

The main documented reasons for missed doses were: patients off-floor ($n = 7$, 16.9% of 41 cases with missing doses), patient refusal ($n = 5$; 12.2%) and ambulation ($n = 1$; 2.4%) in the surgical cohort; and ambulation ($n = 119$; 28.0% of 425 cases with missing doses), patient refusal ($n = 89$, 20.9%) and patient off-floor ($n = 72$; 16.9%) in the medical cohorts.

Conclusions: Adherence to LDUH three times a day dosing is significantly greater in patients admitted to surgical wards vs. medical wards, even though the total potential doses for both cohorts were numerically similar. Barriers to adherence appeared to be higher in medical ward patients. The impact of lack of adherence on the risk of developing in-hospital VTE requires further investigation.

PO 186

Effects of novel oral anticoagulants on venous thrombosis model and bleeding time assay

Fonseca RJC, Cortez RF and Mourao PAS

Instituo de Bioquimica Medica, Rio de Janeiro, Brazil

Background: Heparin has been used for more than 50 years to treat and prevent thrombosis. Although heparin is the second most frequently used natural drug, its source is very limited since it is only obtained from pig intestine or bovine lung. Therefore, due to the increasing use of heparin there is an urgent need for new anticoagulants or alternative sources of heparin.

Objectives: In the present work, we compare the effect of novel oral anticoagulants such as dabigatran etexilate, rivaroxaban and apixaban using venous thrombosis model and bleeding time assays. Coagulation parameters were also evaluated and compared with fucosylated chondroitin sulfate, a potent anticoagulant polysaccharide extracted from sea cucumber.

Methods: Wistar were randomly divided into several groups. Antithrombotic activity was investigated in rats with the vena cava model using thromboplastin as the thrombogenic stimulus. Bleeding tendency was evaluated using the bleeding time model.

Results: Thrombus formation was completely inhibited at 20 mg/kg of apixaban and dabigatran etexilate, while rivaroxaban had a great variation effect in thrombus weight at this dose. Total inhibition of thrombus formation using fucosylated chondroitin sulfate was achieved only at 50 mg/kg. All novel anticoagulants caused intense blood loss, while fucosylated chondroitin sulfate and low molecular weight heparin had no effect on bleeding time assay.

Conclusion: The approach to study novel anticoagulants involves testing compounds with well-defined structures in different assays to define the multitude of their haemostatic effects. The complexity of the regulatory mechanisms involved in the action of these compounds makes it difficult to predict the *in vivo* effect exclusively using *in vitro* assays.

PO 187

No clinically relevant interaction between sugammadex and heparin (enoxaparin and unfractionated heparin) on coagulation

Kruithof A[1], De Kam PJ[2], El Galta R[3], Moerland M[1], Kluft C[4], Van Lierop MJ[3], Dennie J[2], Troyer M[2], Gutstein D[2] and Burggraaf J[1]

[1]Centre for Human Drug Research, Leiden, The Netherlands; [2]Merck, Whitehouse Station, NJ, USA; [3]MSD, Oss, The Netherlands; [4]Good Biomarker Sciences, Leiden, The Netherlands

Background: The selective relaxant binding agent sugammadex (Bridion®) is associated with limited and transient prolongation of activated partial thromboplastin time (APTT) and prothrombin time (PT) in healthy male volunteers. *In vitro* experiments indicated these effects may be explained by a transient decrease in Factor Xa formation and activity induced by sugammadex. This study assessed the potential interaction between sugammadex and heparin (enoxaparin and unfractionated heparin [UFH]).

Methods: A randomized, double-blind, placebo-controlled, 4-period, cross-over design was conducted in healthy male volunteers for enoxaparin (Part 1, 40 mg subcutaneously) and UFH (Part 2). In Part 1, 13 subjects (23.2 ± 3.7 years, BMI 22.6 ± 2.4 kg/m^2) received one of the following treatment sequences: placebo-sugammadex (4 mg/kg), enoxaparin-placebo, enoxaparin-sugammadex (4 mg/kg), or enoxaparin-sugammadex (16 mg/kg). Sugammadex/placebo was administered intravenously 3 h after enoxaparin/placebo administration. In Part 2, 43 subjects (24.3 ± 5.4 years, BMI 23.0 ± 2.8 kg/m^2) received similar treatments as in Part 1, however, 5000 units UFH replaced enoxaparin and the placebo-sugammadex combination was performed at 16 mg/kg. Anti-Xa activity, APTT, sugammadex plasma concentrations, and safety were assessed. Evaluation of clinically meaningful interaction was based on true geometric mean ratios (GMRs) and corresponding 2-sided 90% confidence intervals (CI) for different $AUEC_{3–30\ min}$ treatment comparisons. The pre-defined clinically meaningful effect margin for APTT and anti-Xa activity was 1.50.

Results: Enoxaparin treatment induced anti-Xa activity up to 0.35–0.37 IU/mL within 3 h after administration in all 3 treatments arms. Anti-Xa activity was not affected by additional sugammadex administration; the GMR and corresponding upper limit of CI for sugammadex co-administered with enoxaparin vs. enoxaparin alone excluded the pre-defined clinically meaningful effect margin of 1.50 (1.02–1.07 and 1.04–1.08, 4 and 16 mg/kg sugammadex, respectively). Enoxaparin prolonged APTT by approximately 5–6 s (2h55 min after enoxaparin: 36.3–37.4 s). Sugammadex induced an additional immediate limited prolongation of approximately 2 and 5 s (4 and 16 mg/kg, respectively), which disappeared within 1 h post-dose (GMR and upper limit CI for 16 kg/mg sugammadex with enoxaparin vs. enoxaparin alone: 1.09–1.13).

UFH prolonged APTT up to 1–2 s (2h55 min after UFH: 33.6–34.3). Sugammadex induced an immediate additional prolongation of approximately 2 and 7 s (4 and 16 mg/kg sugammadex, respectively), which gradually declined within 2–3 h. The GMR and corresponding upper limit of CI for sugammadex co-administered with UFH vs. UFH alone were below the pre-defined clinically meaningful effect margin of 1.50 (1.04–1.06 and 1.13–1.15, 4 and 16 mg/kg sugammadex, respectively). Anti-Xa activity was 0.05–0.06 IU/mL after UFH

treatment and did not differ between the treatment arms. Subsequent administration of sugammadex/placebo did not affect anti-Xa activity (GMR and upper limit CI for 16 kg/mg sugammadex with UFH vs. UFH alone: 1.05–1.09). The plasma concentration profiles of sugammadex were comparable in presence and absence of heparins. Sugammadex was well tolerated by all treated subjects (with and without heparin).

Conclusion: No clinically relevant interaction between sugammadex and heparin (enoxaparin and UFH): no additional effect of sugammadex on anti-Xa activity was observed, and the additional effect of sugammadex on APTT was limited and transient.

PO 188

Biossimilar enoxaparins available for clinical use in Brazil

De Oliveira S, Glauser B, Almeida GBF, Dos Santos G, Pereira M and Mourão P

Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Background: Patent protections for Low Molecular Weight Heparins (LMWHs) expired or will expire soon. As a consequence biossimilar drugs are trying to obtain approval for clinical use. Five biossimilar versions of enoxaparin are now available for clinical use in Brazil. However, there still skepticism about the possibility to obtain preparations of LMWHs similar to the reference drug because of the complexity involved in the process to generate LMWHs, starting from unfractionated heparin. Here, we performed a careful analysis of biossimilar *vs*. reference enoxaparin available for clinical use in Brazil.

Aim: We intend to use a detailed protocol to investigate the similarity of enoxaparins available for clinical used in Brazil. We employed a detailed structural analysis of the biossimilar *vs*. reference enoxaparins, test of their *in vitro* and *in vivo* anticoagulant and antithrombotic activities and finally their effects after continuous administrations to rats during a period of 30 days. We intend to assure the efficacy and safety of the biossimilar enoxaparins available for clinical use in Brazil.

Materials and Methods: We compared biossimilar *vs*. reference enoxaparins using a variety of methods. Their structures were investigated using high field nuclear magnetic resonance (NMR), including one dimensional and two dimensional spectra (^{1}H-^{1}H TOCSY and ^{13}C- ^{1}H HSQC), the molecular size distribution was determined by gel permeation chromatography and their anticoagulant activities were established based on the anti-Xa anti-IIa assays and on direct binding to antithrombin. Approximately 100 batches of biossimilar enoxaparins were included in this initial investigation. On a second stage selected bathes were tested on animal models of experimental thrombosis and bleeding, associated with determination of their pharmacodinamic. Finally, enoxaparins were administered continuous to rats over a period of 30 days in order to investigate possible toxic effects after a long period of administrations.

Results: The biossimilar and reference batches of enoxaparin available for clinical use in Brazil have similar structures and anticoagulant activities. They also showed equivalent responses in animal models of experimental thrombosis and bleeding, achieved similar plasma concentrations, showed no toxic effect after continuous administration over a period of 30 days.

Conclusions: Our results indicate that biossimilar enoxaparins available for clinical use in Brazil are similar to the reference drug. Of course, biossimilar enoxaparins are now produced by an increasing numbers of companies. Each preparation requires a carefully analysis to assure their efficacy and safety. We believe the protocol of our study may help to define a guide line for analysis of biossimilar LMWHs.

PO 189

A comprehensive evaluation of factors effecting range and precision for heparin Anti-IIa and Anti-Xa chromogenic assays

Shaklee P and Shaklee MJ

Provision Kinetics, Inc., Arlington, Wisconsin, WI, USA

In response to the heparin contamination crisis, regulatory agencies in the US, Europe, and Japan have begun implementing anti-factor IIa (Anti-IIa) and anti-factor Xa (Anti-Xa) testing requirements for manufacturers of unfractionated heparin. The present and proposed pharmacopeial assay protocols confine heparin concentrations to a relatively narrow range, which limits the general utility of these assays. In the present studies, we sought to optimize these Anti-IIa and Anti-Xa heparin assay protocols to allow for measurement of an expanded range of heparin concentrations while maintaining precision of the assay. Based upon the biochemistry and enzymology underlying these assays, we focused our study on two variables, namely, the initial concentration of antithrombin (AT), as well as the time of incubation allowed for AT-heparin complex formation. We hypothesized that decreasing either the AT concentration or the incubation time would result in a corresponding increase of the heparin measurement range of the assay. Due to the critical nature of precision for these heparin pharmacopeial assays, our studies sought to determine the test precision for each test (Anti-IIa and Anti-Xa) and for each parameter varied. Using three different automated hemostasis analyzers, our results demonstrated that it was possible to expand the heparin range at least 4-fold over the original pharmacopeial test concentrations using decreases in either AT concentration or incubation time, without a significant negative impact on test precision. These studies demonstrate that the Anti-IIa and Anti-Xa pharmacopeial assays can be made more versatile and widely applicable without sacrificing test precision.

PO 190

The assessment of patients with heparin-PF4 antibody positivity: the importance of expert haematological input remains

Bosworth JL, Austin S and Uprichard J

St George's Hospital, London, UK

Background: Heparin-induced thrombocytopenia (HIT) is an antibody-mediated reaction to heparin characterised by thrombocytopenia and increased thrombotic risk. Increased awareness and the need for early diagnosis have led to the requesting of HIT screens by physicians unfamiliar with their interpretation. As a tertiary referral centre with a large cardiothoracic practice, thrombocytopenia and suspected HIT occurs frequently.

Aims: To critically evaluate the indications, management and outcomes of patients with positive HIT screens over a 3-year period and address the need for a diagnostic algorithm involving haematologists.

Method: A single centre retrospective analysis of all positive HIT screens between 2010 and 2012 was undertaken. Paper and electronic records were reviewed.

Results: One hundred and eighty-one HIT screens using a GTI-PF4 ELISA were performed. Twenty-nine positive results were identified involving 27 evaluable patients – 6 females and 21 males with a median age of 70 years (range 3–89). Eleven patients had undergone cardiothoracic surgery in the preceding 30 days. Others were renal (5), surgical (5), orthopaedic (1), medical (4) and paediatric (1).

No patients had a high pre-test probability (4T score 6–8). The pre-test probability score was intermediate (4T score 4–5) in eight patients and low (4T score 0–3) in 19. In the latter group eight received an alternative anticoagulant (danaparoid). Eight continued heparin and in three, heparin was stopped but no alternative anticoagulant given during the episode of thrombocytopenia. No thrombotic events occurred in this group. One patient in the low pre-test probability group developed

skin necrosis whilst receiving unfractionated heparin on haemofiltration. Although HIT was felt to be clinically unlikely, in view of his strongly positive HIT ELISA (OD 4.1585) he was converted to danaparoid which continued until his death.

Seven of the eight patients with an intermediate 4T score were switched to danaparoid. Three of these had thrombotic events.

In five of the patients with positive HIT screens there was bleeding of WHO grade 2 or more. Two of these were patients in the intermediate score group.

Sixteen of the screen positive patients received platelet transfusions during the inpatient episode. These were administered therapeutically for haemorrhage and prophylactically before invasive procedures.

On review it was felt that five of the 27 patients with positive HIT screens were likely to have had HIT. Three of these experienced thrombotic complications. All were managed with danaparoid. The mean OD in this group was 2.55 (95% CI 1.18–3.92) compared to a mean OD in the others of 1.32 (95% CI 0.93–1.71).

Summary: Our local experience reveals that diagnosis of HIT remains complex. Recently at our centre there has been a reduction in the involvement of haematologists in suspected HIT. Our audit identified the overdiagnosis of a rare condition, with implications of inappropriate care. Despite the increased awareness of HIT, expert haematological involvement remains paramount. In response to these findings, we have developed a diagnostic algorithm involving haematological advice from the outset. We suggest that the accurate diagnosis of HIT depends on the involvement of the haematology service.

PO 191

Serotonin Release Assay (SRA) results for confirmation of Heparin Induced Thrombotic Thrombocytopenia (HITT)

Brighton TA, Kondo M, Prawitha D and Just S

SEALS, Prince of Wales Hospital, Sydney, NSW, Australia

Background: Heparin induced thrombocytopenia (HIT) is an immune mediated disorder associated with heparin therapy with clinically significant HIT defined when patients have both thrombocytopenia and thrombosis. Washed platelet assays such as the serotonin release assay (SRA) are the most useful in the detection of clinically significant HIT antibodies.

Aim: The aim was to assess the effectiveness of SRA in the confirmation of clinically significant HIT.

Method: The Haematology Department, South Eastern Area Laboratory Services (SEALS) located at the Prince of Wales Hospital, Sydney, Australia has been performing the SRA for HIT confirmation since the 1990's. Samples are received from laboratories around Australia and New Zealand. The serotonin release assay performed is the original assay described by Sheridan (Blood Vol 67, 1986). A review was carried out on all positive SRA samples tested in the last 2 years to determine whether the positive result correlated with a clinical picture of HIT in the patient.

Results: A total of 249 samples were tested for SRA in 2010 and of these 42 samples were positive. In 2011a total of 206 samples were tested for SRA and of these 37 samples tested positive.

The HIT screening test was positive for all cases in 2010 and for all cases except one in 2011, where the HIT screen was negative and the doctor insisted on the SRA due to the clinical history of the patient. The majority of the positive SRA tests that had clinical information provided were determined on the basis of this information to have clinically significant HIT, due to a low platelet count whilst on heparin therapy and a thrombotic event.

Negative SRA tests that had clinical information provided were also reviewed with the majority of the negative SRA tests only having thrombocytopenia whilst on heparin therapy with very few having both thrombocytopenia and thrombosis.

Conclusion: As thrombocytopenia on heparin is the trigger for HIT screening both negative and positive SRA patients were found to have thrombocytopenia. Thrombosis a serious complication of HIT along with thrombocytopenia occurred more commonly with SRA positive patients. Our review confirms the importance of SRA testing in patients suspected of HITT due to the high proportion of patients with positive SRA with both thrombocytopenia and thrombosis.

PO 192

Detection of of heparin-induced thrombocytopenia antibodies by functional and immunological methods and comparison with genetic risk factor (polymorphism of Fc? receptor)

Slavik L, Svobodova G, Ulehlova J, Krcova V, Hlusi A and Prochazkova J

University Hospital Olomouc, Olomouc, Czech Republic

Aim: In our study we investigated group of 100 plasma samples from patients with suspected HIT. The patients were sent for testing of HIT on basis 4 T's score. The aim of our study was to compare the results of the functional test (whole blood impedance aggregometry – WBIA) and immunoassay (ELISA) well as to determine the risk of a genetic predisposition for the development of HIT. From literature findings, was as genetic predisposition risk factor of developing HIT determined polymorphism of platelet receptor Fcγ (FCGR2A gene). The FCGR2A gene polymorphism is manifested as substitution amino acid arginine for histidine in position 131.

Method: The samples were tested by functional and immunological assay. We used WBIA as functional assay and ELISA as immunological assay.

The WBIA method uses determine the degree of activation of donor platelets in the presence of patient's plasma by heparin at concentration 0.5 IU/ml. The WBIA test was performed: 300 μL of citrated whole blood with donor platelets, 150 μL of heparin (final concentration of 0.5 resp. 100 IU/ml) and 300 μL of patient platelet-poor plasma (PPP). Changes in the aggregation was monitored for 20 min. The cut-off for screening assay was upper than 20 AUC. The confirmation with higher dose of heparin must provide negative results.

ELISA test were performed in IgG, IgA and IgM class and results were classified as negative for OD < 0.300, suspected (0.300–0.500) and positive OD > 0.500.

Genetic analysis for presence FCGR2A polymorphism was performed by real-time PCR on LightCycler. The assay was be performed on basis melting curve analysis. The temperature melting was determined for amino acid arginine 62 °C and histidine 52 °C.

Results and Conclusion: Method of WBIA were positive 10 patients and 90 negative patients in comparison to ELISA where were positive only four patients mostly in IgG class antibodies. The WBIA is easy examination with rapid turn-around time and warrants a multi-laboratory trial to complete its validation as a confirmatory assay for platelet activation. The measurement by WBIA provides in group of patients higher specificity and sensitivity than ELISA assay.

The genetics predisposition was detected significantly higher in group with positive results by WBIA than in patients with negative results by WBIA. The representation of normal alleles in the whole cohort was 20.2% and mutational state was 79.8%.

Supported by a grant LF-2013–04.

PO 193

A rheological study of incipient clots formed by heparinized plasma: assessing the health risk associated with HIT and exploring the use of Gel Point detection for therapeutic management

Thomas B[1], Evans A[1], John W[2], Rauova L[3], Cines DB[2], Williams R[1] and Hawkins KM[1]

[1]Swansea University, Swansea; [2]University of Pennsylvania; [3]Children's Hospital of Philadelphia, Philadelphia, PA, USA

Background and Aim: Unfractionated heparin (UFH) is often administered to cardiac and orthopedic patients undergoing surgery in order to prevent thrombosis. Occasionally, a fatal reaction to UFH, termed Heparin-Induced Thrombocytopenia (HIT), may occur. Rapid and accurate diagnosis of HIT is very important, as any delay in the cessation of UFH has been associated with an initial 5–10% daily risk of thrombosis, amputation, or death. Misdiagnosis of HIT can result in exposing thrombocytopenic patients to alternative anticoagulants, contributing to major hemorrhage.

Up to 5% of patients who receive UFH develop HIT-associated antibodies, causing platelet activation, leading to thrombocytopenia and thrombosis. Diagnostic tests such as the ELISA assay have limited specificity, alternatively, the SAR assay is highly specific but doesn't allow for real time results.[1] The purpose of the present work is to investigate the potential application of rheometrical measurements of incipient clots, as a novel diagnostic tool for detecting the onset of HIT. The work reported herein involves measuring changing gelation times and fractal dimensions,(d_f), of plasma samples at different concentrations of UFH (*Heparin sodium salt from porcine intestinal mucosa: H3149 Sigma-Aldrich)*.

Method: Platelet poor plasma, (PPP), represents an ideal model system, wherein the number of immeasurable variables associated with the coagulation process can be controlled, leaving only a quantifiable number of platelets and the remaining enzymes and proteins.

The rheometrical detection of the gel point (GP) of coagulating blood provides a method of determining the structural characteristics of incipient clots, which are dominated by a fibrin network. Thrombi with 'dense' fibrin networks are more difficult to lyse and are potentially more dangerous than those with 'more open' networks. Fractal analysis of the GP of coagulating blood provides a method of quantifying clot structure in terms of a d_f, as well as providing a normal clotting time, (CT). Previous rheometrical experiments on blood show that the CT and d_f of incipient clots formed in healthy volunteers are significantly altered by the *in-vitro* addition of heparin. Showing an increase in CT and a progressive decreases in d_f with increasing levels of heparin.

Results: Pooled PPP from healthy individuals, with the addition of 0.15NIH/ml of thrombin and 0.005 mg/ml of tissue factor, at 37 °C, have a normal CT = 147 s, ± 36.09 s. With a normal d_f = 1.92°, ± 0.12°. When 0.2 U/ml of Heparin is added to the PPP there is an increase in CT = 404 s, ± 156.82 s.

Current experiments include the addition of different concentrations of PF4, to optimize the ratio of PF4: UFH, neutralizing the UFH effect on the PPP. The last step will include the addition of anti-bodies to the model system and the measurement of any deviation of CT and d_f from normal heparinized PPP values.

Summary: This study is important to fully understand and elucidate the mechanisms of HIT and to explore the potential use of rheometry as a tool for monitoring *in-vivo* heparin therapy, in patients most at risk of developing HIT post-surgery.

PO 194

The utility of ELISA optical density as a prognostic tool in patients with confirmed heparin-induced thrombocytopenia

Turley E, Sandhu I, Wu C and Szkotak A

University of Alberta, Edmonton, AB, Canada

Background: Heparin-induced thrombocytopenia (HIT) is associated with anti-platelet factor-4 (PF4)/heparin antibodies that activate platelets, resulting in thrombocytopenia and a pro-thrombotic state. ELISA-based methods are commonly used to screen for the presence of these antibodies; however, only functional assays confirm their platelet-activating activity. At our institution, antibody-mediated platelet activation is demonstrated by lumi-aggregometry, a method validated previously against the gold standard (serotonin-release assay). It has been suggested that in ELISA positive patients higher optical density (OD) correlates with more frequent thrombotic manifestations. It is not well established whether this is because the magnitude of the OD correlates with the likelihood of HIT, or if the magnitude of the OD is also prognostic of thrombosis in patients with confirmed HIT.

Aims: The objective of this study was to evaluate the association of OD with thrombotic events in patients with HIT confirmed by lumi-aggregometry. The predictive value of the strength of the luminescence ratio was also evaluated.

Methods: Quantitative anti-PF4 detection was performed using an IgG-specific ELISA kit (Gen-Probe, San Diego) in patients with clinically suspected HIT. Then confirmatory testing by lumi-aggregometry was performed for samples with ELISA OD $\geq$ 0.400. HIT antibody-induced activation of washed healthy donor platelets was tested at therapeutic (0.1 and 0.5 U/mL) and high (100 U/mL) concentrations of porcine heparin. The degree of platelet activation was quantitated luminographically based on the light flash reaction of ATP (released from platelet dense-granules) with luciferin luciferase reagent. A ratio of therapeutic to high heparin luminescence amplitude of > 5.0 and platelet aggregation at therapeutic but not high concentration was considered a positive result. HIT assay results from September 2010 to July 2012 were reviewed to identify patients with positive HIT testing by lumi-aggregometry and to record ELISA OD and luminescence amplitude ratio data. Patient records were then reviewed to identify objectively confirmed new or recurrent venous or arterial thrombotic events occurring in the 5 days preceding or the 30 days following the date of positive HIT testing.

Results: Among 33 patients with confirmed HIT, 14 (42%) experienced HIT-associated thrombotic events. On average, patients with thromboembolic events had a significantly higher ELISA OD than those patients without (Mann-Whitney test, $P = 0.03$). However, the ratio of luminescence amplitude was not significantly different between the two groups ($P = 0.20$). There was no significant correlation between luminescence ratio and OD in patients with ($r_s = 0.40$, $P = 0.16$) or without thromboembolism ($r_s = 0.03$, $P = 0.92$).

Conclusion: In this large cohort of patients with HIT confirmed by lumi-aggregometry, OD, but not ratio of luminescence amplitude, is associated with thrombotic events. ELISA OD may be of value to prognosticate for thrombosis in patients with confirmed HIT.

PO 195

Recurrence of heparin-induced thrombocytopenia induced by the re-administration of heparin after negative conversion of HIT antibodies in a patient with hemodialysis

Wanaka K[1], Matsushima H[2], Kaneko C[3], Miyashita K[3], Walenga JM[4], Otani M[5] and Nakajima Y[5]

[1]Kobe Rearch Projects on Thrombosis and Haemostasis; [2]Matsushima Clinic; [3]Kobe Research Projects on Thrombosis and Haemostasis, Kobe, Japan; [4]Loyola University Medical Center, Illinois, IL, USA; [5]Kobe City Medical Center West Hospital, Kobe, Japan

The cause of heparin-induced thrombocytopenia (HIT) is the appearance of anti-PF4/heparin complex antibody (HIT antibodies), and the disease is characterized by thrombocytopenia and venous or arterial thrombosis. HIT antibodies are transient and disappear within about 100 days after the withdrawal of heparin. We have succeeded in use of heparin re-administered more than 100 days after the negative conversion of HIT antibodies in 14 patients who had developed HIT upon the introduction of dialysis. However, in the 15th patient HIT recurred upon heparin re-administration for dialysis.

The patient (69-year-old male) developed rapidly progressive glomerulonephritis and dialysis was introduced. Nafamostat mesilate (NM) was used as an anticoagulant for the initial dialysis. And then unfractionated heparin (UFH) was used from day 12. The platelet count was $291 \times 10^3/\mu L$ before the introduction of dialysis, but decreased to $95 \times 10^3/\mu L$ on day 12 and to $44 \times 10^3/\mu L$ on day 25. Suspecting HIT, heparin was withdrawn. Due to retinal bleeding, NM was used as an alternative anticoagulant, but was switched to argatroban on day 38. The platelet count rapidly recovered after the switch to argatroban. HIT antibodies were positive on both ELISA (PF-4 Enhanced®, GTI; Waukesha, WI, USA) and the ^{14}C-serotonin release assay (SRA). SRA and ELISA became negative on days 129 and 299, respectively. HIT antibody negativity (ELISA) was confirmed on day 402, and dialysis with heparin was initiated again on day 441. Dialysis with heparin was performed 4 times without any incident through day 448. Then blood coagulation was noted in the circuit on day 451 (10 days after restarting of heparin administration) and the platelet count decreased to $107 \times 10^3/\mu L$ on day 453. Suspecting HIT, administration of heparin was immediately discontinued, and argatroban was used as an anticoagulant. HIT antibodies became positive on both ELISA and SRA.

As an index of the level of enhanced coagulation, D-dimer (LPIA-ACE D-D dimer II; Mitsubishi Chemical Medience, Tokyo) was high (7.87 μg/ml) on day 66, but decreased along with a decrease of the HIT antibody level. The D-dimer level rose again (1.34 μg/ml) on day 479 (38 days after re-administration of heparin). The D-dimer level was higher during the initial episode of HIT than that of the second one, suggesting that the hypercoagulable state was more severe than that in the second episode of HIT.

Clinical symptoms of HIT including blood coagulation in the circuit and thrombocytopenia were observed after the fifth day from heparin administration in both episodes. In this patient, the conditions which induced the first HIT episode may have also been established in the second episode. It would seem logical to consider the second episode as a new development of HIT, rather than as a recurrence.

PO 196

Inherited thrombophilia and other risk factors in women with thrombotic complications of oral contraceptives

Batorova A, Jankovicova D, Prigancova T and Morongova A

University Hospital, Bratislava, Slovakia

Background: Venous thromboembolism (VTE), although rare, remains one of the serious adverse consequences of oral contraceptives (OC).

Aim and Methods: Clinical data, inherited thrombophilia and other thrombotic risk factors were evaluated in women with the contraceptives-related thrombosis referred to our centre for thrombophilia investigation.

Results: Out of seventy-one women with a median age of 32 years (19–45) 62 (87%) patients used oral contraceptives of the 3rd and 4th generation. Deep vein thrombosis (DVT), pulmonary embolism (PE), sinus vein thrombosis (SVT) and transitory ischemic attacks were diagnosed in 48/67.6%, 21/29.5%, 8/11.3% and 3/4% of the women, respectively. The source of embolisation was not revealed in 12/21 patients with pulmonary embolism. Even fifty-five (77.5%) women had at least one (28 pats) or a combination of more than two (27 pats) thrombotic risk factors in addition to the use of contraceptives (familial thrombosis 37, personal VTE history 2, obesity 5, trauma/surgery 6, smoking 5, inherited thrombophilia 25, lupus anticoagulant 2, mild hyperhomocysteinemia 1). Congenital thrombophilia was revealed in 25/71 (35.2%) women: heterozygous FVLeiden, heterozygous FIIG20210A and double heterozygous mutation in 20 (28%), 3 (4.2%) and 2 (2.8%) women, respectively. However, thrombophilia as the only additional risk factor of thombosis was present in 8/11.3% of all contraceptives users only. In seventeen of 25 (68.7%) thrombophilia patients an assotiation with other risk factor was present (familial thrombosis 13, DVT history 1, leg trauma 3). Eight patients developed sinus vein thrombosis, out of them 2, 2 and 1 had prothrombin mutation, lupus anticoagulant and mild hyperhomocysteinemia, respectively. In three SVT patients no other risk factor than the use of the OC was revealed.

Conclusion: Our study demonstrates a high prevalence of thrombotic risk factors in OC users who developed serious thrombotic complications. In fourty six (65%) patients the risk factors could have been identified and thrombotic complications avoided by thorough family/patient history and/or by providing adequate information to the women taking the pills. As the routine screening for inherited thrombophilia before prescribing the OC is not recommended, it is essential strictly to follow the medical eligibility criteria according to WHO recommendations for the use of oral contraceptives.

PO 197

Gynaecological problems in women with severe inherited platelet disorders – a single centre experience

Bowles L[1], Depala A[2] and Beski S[1]

[1]Barts Health; [2]Barts and The London School of Medicine, London, UK

Background: We present a series of 3 teenage and 3 adult females with inherited platelet disorders (5 Glanzmanns thrombasthenia [GT], 1 Bernard Soulier Syndrome [BSS]) and describe their gynaecological management in a joint Gynaecology & Bleeding Disorders Clinic from March 2010.

Results: Case 1: Thirteen year-old (P0 + 0) with GT presented with menorrhagia and iron deficiency anaemia (IDA) since menarche. She was initially managed with norethisterone and tranexamic acid (TA). Five months later, norethisterone was substituted for a progesterone-only pill (POP), with good effect.

Case 2: Fourteen year-old (P0 + 0) with BSS, presented with menorrhagia at menarche reporting continuous bleeding for 4 weeks. Her haemoglobin was 8.3 g/dL and she was given HLA matched platelets,

TA and norethisterone. Thereafter she switched to a POP and TA, but continued to have irregular bleeding. She then started a combined oral contraceptive pill (COCP) plus TA during withdrawal bleed, with good effect.

Case 3: Sixteen year-old (P0 + 0) with GT and longstanding severe gingival bleeding, frequently requiring red cell and HLA matched platelet transfusions, presented with menorrhagia shortly after menarche. She was given norethisterone and TA which helped initially. However, her menses became heavier and due to concerns about compliance, was switched to a combined contraceptive transdermal patch, then to a higher dose COCP and thereafter to a POP, plus TA. With the POP she has lighter menses, however remains transfusion dependent.

Case 4: Twenty-three year-old (P0 + 0) with GT, presented with right iliac fossa pain, and a right sided ovarian cyst (8 × 8 × 8 cm) on ultrasound (US). A right ovarian cystectomy was performed with perioperative transfusion of HLA matched platelets. A 12 cm ovarian cyst was removed, histology showed an endometrioma. She had a progersterone-only implant inserted subdermally and currently has minimal bleeding and no dysmenorrhea. Her most recent US is normal.

Case 5: Twenty-five year-old (P0 + 0) with GT, presented with menorrhagia and IDA since menarche. She was managed with the COCP continuously for 3 months plus TA during the withdrawal bleed. Despite this, she had intermenstrual bleeding (IMB), and on one occasion was admitted with heavy PV bleeding and transfused red cells and HLA matched platelets. She declined alternative hormonal therapies. Her haemoglobin remains satisfactory on 3 monthly COCP.

Case 6: Thirty-nine year-old (P0 + 0) with GT and anti IIb/IIIa antibodies, presented with menorrhagia and IDA. MRI showed bilateral endometriomas and left tubuo-ovarian complex (3 × 5 × 3 cm). Ca 125 normal. She opted for the subdermal progesterone-only implant with HLA matched platelet and rVIIa cover. She bled post insertion and had further doses of HLA matched platelets and rVIIa. Since, she has had no PV bleeding and is not iron deficient. Her latest MRI showed the endometrioma has resolved.

Conclusion: These cases demonstrate the severe nature of gynaecological issues in women with GT and BSS. Menorrhagia since menarche is a prominent feature, but there are other complications for example haemorrhagic ovarian cysts. Joint management with a gynaecologist and haemophilia specialist is vital for the complex management of these high risk patients.

PO 198

Prenatal diagnosis in haemophilia A and B families: combine cordocentesis and gene diagnosis

Dai J, Lu YL, Ding Q, Wang LH and Wang X

Shanghai Jiao Tong University School of Medicine Ruijin Hospital, Shanghai, China

Background: Haemophilia A (HA) and B (HB) are the two most common X-linked recessive inherited bleeding disorders. In developing countries like China, the burden ofhaemophilia is heavy as there is a poor social support and lack of appropriate therapeutic measures. Reducing the incidence of haemophilia is thus one of the main objectives of any haemophilia care centre.

Aim: In this study, we offered prenatal diagnosis for females who from haemophilia A or B familiies with absence of affected members in the family. Twenty-nine females were investigated in this study in their second trimester.

Methods:Fetal sample was collected with the help of Ultrasound-guided puncture between 19 and 23 weeks. PT, APTT and fibrinogen testing were performed in the fetal blood. A battery of coagulation factor assays were assessed by one-stage clotting method detected on IL coagulation analyser, including all the coagulation factors except factor XIII.

Results: Eight boy fetus were diagnosed as haemophilia A patient and three were haemophilia B patient. Factor VIII activity mean value during 19 and 23 weeks gestation is 36.58% with the range from 12% to 58%, to factor IX which is 11.97% with the range from 5.4% to 16%. The blood samples of two HA fetus and one HB fetus were tested using gene diagnosis requested by their family. Genetic defection were all be detected and the results are consistent.

Conclusion: The results show that it is possible to offer prenatal diagnosis in index-case-absent haemophilia family by combine cordocentesis and genetic diagnosis. But for haemophlia B, it is always difficult to judge the result for fetus if the index case in this family is a mild to moderate patient. For the affected member absent family, if the fetus is a patient, maybe it is a good news for them so they can do the genetic diagnosis which is a high accuracy technology for prenatal diagnosis.

PO 199

Antiplatelet effect of Tyrame [N-(3-hydroxy-1:3:5(10)-estratrien-17β-yl)-4-hydroxy-phenethylamine]

De La Peña A[1], Fernandez-G JM[1], Flores-Garcia M[2], Marin-Ocampo R[2], Uribe-Lezama C[1], Pinzon E[1], Fortoul T[1], Torres I[1] and Salgado V[1]

[1]Universidad Nacional Autónoma de México; [2]Instituto Nacional de Cardiologia, Mexico, Mexico

Background: Millions of women use oral contraceptives or estrogen replacement therapy even thought, it is known that estrogens increase the risk of venous thrombosis, myocardial infarction and stroke. To decrease dose pharmaceutical presentations has not completely offset this adverse effect. In the search for new compounds with estrogenic activity which do not favor a prothrombotic state were synthesized (amino-estrogens). We have previously communicated anticoagulant or antiplatelet effect of these compounds.

Aim: To design, synthesize and asses the antiplatelet aggregating effect of Tyrame, a new amino-estrogen.

Methods: Tyrame was synthesized by a condensation reaction between the corresponding amine and estrone. The compound was characterized by their physical constants and spectroscopic properties: melting point, infrared spectroscopy, mass spectrometry, FAB +, nuclear magnetic resonance and by X-ray crystallography.

Compounds were administered (1–4 mg/100 g weight, subcutaneously) to male mice, CD1, which are kept at a controlled temperature with food and water *ad libitum*, with light-dark cycles of 12–12 h. After 24 h, a blood sample was taken.

Whole blood platelet aggregation was performed using an aggregometer (Model 560 CA; software Model 810 AGGRO/LINK Chrono-log, Havertown, PA, USA). Briefly, 500 μL of saline and 500 μL of citrated blood were added into a test cell stirrer. After an incubation period of 5 min at 37 °C, the agonist was added and the recording started. During the following 6 min the ability of platelets to adhere and aggregate onto 2 metal wires was measured by the electrical resistance change between the sensor wires. The impedance change caused by the adhesion of the platelets onto the sensor surfaces was plotted against time and the top of the aggregation curve was quantified in arbitrary units (U).

The protocol was approved by the ethical committee of UNAM.

Results: The results show that Tyrame at 4 mg/100 g reduce 30% platelet aggregation induced by ADP.

Summary. Tyrame were designed and synthesized in the Institute of Chemistry of UNAM. It was characterized by their physical, spectroscopic constants and X-ray crystallography. Tyrame was administered subcutaneously and inhibit ADP-induced platelet aggregation in whole blood by 30%.

PO 200

Successful pregnancy outcome in a patient with factor XII deficiency and recurrent fetal loss

Ettorre CP, Malcangi G, Scarafile R, Iandolo V, Romano F and Marino R

Unviversity Hospital, Bari, Italy

Background: Factor XII (FXII) deficiency is a rare autosomal recessive disorder whose clinical implications are still undefined. It does not predispose towards a bleeding tendency and many reports have evidenced its association with an increased risk for both arterial and venous thrombosis. Its role in recurrent abortions is controversial.
We describe the successful outcome of a pregnancy in a woman with FXII deficiency and recurrent fetal loss.
Case Report: The patient is a 38-year old woman with an obstetric history of recurrent foetal loss (3 spontaneous miscarriages in the first trimester of pregnancy and a subsequent interruption of pregnancy due to a fetal abnormality). The endocrinological work-up revealed the presence of an autoimmune thyroiditis, treated initially with methimazole and subsequently with L-thyroxine. Familial and personal history was negative for thromboembolic and/or bleeding disorders. Coagulation tests evidenced a prolonged activated thromboplastin time, measured as ratio (R: 9.0) with a normal value of prothrombin time; clotting factors dosage showed the presence of a severe FXII deficiency (< 1%). Inherited trombophilia screening and antiphospholipid antibodies resulted negative; a moderate hyperhomocysteinemia was detected and treated with folate supplementation. At the age of 37 the patient planned a new pregnancy and started antithrombotic prophylaxis with enoxaparin (4000 IU/die) associated with folate therapy throughout the pregnancy. The antenatal period was uneventful and the woman underwent a caesarean section at term under general anaesthetic without any replacement therapy. No haemorragic or thrombotic complication were observed. Pharmacological thromboprophylaxis was continued in the post-partum period for a month.
Conclusion: Many reports have shown an association of FXII deficiency with recurrent miscarriages, even if such correlation has not been confirmed by other studies. In this patient with FXII deficiency the coexistence of other predisposing conditions, such as the hyperhomocysteinemia and the thyroid disease, may have contributed to the recurrent fetal loss. Thromboprophylaxis with enoxaparin resulted effective in venous thromboembolism prevention in absence of any bleeding event. Further data are needed to evaluate the possible role of low molecular weight heparin in supporting a positive outcome of pregnancy in FXII deficient women with recurrent foetal loss.

PO 201

Mutations within exon 8 of Protein Z gene of women with fetal loss: structural implications assessed by molecular dynamic simulations

Favuzzi G[1], Tiscia G[1], Caliandro R[2], Nico G[2], De Stefano V[3], Rossi E[3], Za T[3], Grandone E[1] and Margaglione M[4]

[1]I.R.C.C.S. 'Casa Sollievo della Sofferenza', San Giovanni Rotondo; [2]CNR, Bari; [3]Catholic University, Rome; [4]University of Foggia, Foggia, Italy

Background: Recently, several researches aimed at investigating the influence of Protein Z (PZ) on the pregnancy outcome. Women experienced fetal losses could present sporadic or polymorphic variants of PZ gene (PROZ), almost all with effect on the serine-protease (SP) domain. We previously reported a approximately 6-fold higher risk for fetal losses in women carrying mutations within PROZ exon 8. Crystal structures of PZ in complex with the PZ-dependent inhibitor (PZI) have been recently obtained.
Aims: To investigate structural implications of PROZ mutations for fetal loss events.
Methods: In two different Thrombosis Centres (San Giovanni Rotondo andRome), 611 women with previous recurrent fetal losses were recruited. As controls, 546 women with healthy pregnancies randomly selected from a Southern Italian general population without a history of VTE were enrolled. PZ levels were measured in all the controls and in 137 (22.4%) women with fetal losses. Direct sequencing of the exon 8 was performed. Eight sporadic mutations and two polymorphisms were found. Molecular dynamics simulations (10 ns) have been performed for the wild type PROZ and for 10 PROZ mutants observed in Italian patients, to investigate their structure in aqueous solution. Simulation data have been processed by novel tools to analyze the residue-by-residue backbone flexibility, and correlated with the statistics of the observed mutations. The study was approved by the local ethics committee and complies with Declaration of Helsinki. Participants gave their written informed consent for present and future use of the clinical data.
Results: All the mutations observed are located in the region coding for SP domain. Sporadic mutations have been associated with anomalous flexibility of residues belonging to specific regions. Among them, the most important is a loop region which is in contact with the longest helix of PZI. Other regions have been identified, which hold anomalous flexibility associated with potentially protective gene variants.
Summary/Conclusions: A possible interpretation of effects associated with observed gene variants is provided. The exploration of PZ/PZI interactions seems essential in explaining these effects.

PO 203

Successful anticoagulation to prevent recurrent miscarriage in two women with severe thrombophilia and von Willebrand disease

Heidinger K[1], Fischer R[1], Alrifai M[2], Kelm C[1], Kirsch- Altena A[1] and Kemkes- Matthes B[1]

[1]Haemostasis Center, University Hospitals Giessen and Marburg GmbH; [2]Haemostasis Center, Giessen, Germany

Background: We report about successful outcome of pregnancy of two patients with recurrent miscarriage and severe thrombophilia (one woman with homozygous factor V Leiden mutation, one woman with antiphospholipid syndrome) in addition to von Willebrand disease (VWD) type I. VWD is a common hereditary bleeding disorder. Affected women often show menorrhagia, bleeding complications occur in more than 50% of women after childbirth or pregnancy loss.
Aims: In spite of increased bleeding risk of these two women, anticoagulant treatment during pregnancy to prevent miscarriage was given. Patients were treated with low molecular weight heparin (LMWH) since beginning of gestation, one woman additionally received acetylsalicylic acid until gestational age of 36 weeks.
Methods: Women I (body weight 83 kg) had a history of two miscarriages (first trimester: < 13 weeks). No thromboembolism, no bleeding tendency in history. Homozygous factor V Leiden mutation and VWD type I (RisCo 39% of normal, VWF Ag 52% of normal) were diagnosed at the age of 30 years. Women II (body weight 76 kg) had a history of three miscarriages (first trimester). No thromboembolism, but bleeding symptoms since childhood. Antiphospholipid syndrome (ß2-glycoprotein type IgM was repeatedly increased: 32 U/mL, norm < 20 U/ml) and VWD type I (RisCo 47% of normal, VWF Ag 67% of normal) were diagnosed at the age of 29 years.
Results: With beginning of gestation both patients received LMWH (dalteparin 5000 IE/d). Patient I was treated during two pregnancies up to 6 weeks after delivery without any complications. No thromboembolism or bleeding complications occurred during both pregnancies and vaginal delivery. No substitution of VW concentrates was necessary. Patient II was additionally treated with acetylsalicylic acid 50 mg/d until gestational age of 36 weeks. Due to repeated vaginal bleeding and cervix hematoma treatment with acetylsalicylic acid was consistently interrupted for some days. VW parameters increased

during pregnancy up to normal levels (RisCo 115% of normal, VWF Ag 201% of normal). Vaginal delivery was performed without any complications, but 3 weeks postpartum curettage was needed because of bleeding.
Conclusions: Anticoagulant treatment (LMWH and acetylsalicylic acid, respectively) in women with VWD and severe thrombophilia to prevent miscarriage remains save and seems to be successful regarding live birth rate. Pregnancy requires close monitoring.

PO 204

Platelet hyperaggregability in patients with fetal loss: the selected gene polymorphisms

Kubisz P[1], Sokol J[1], Biringer K[1], Lisa L[1], Skornova I[1], Ivankova J[1], Skerenova M[1], Danko J[1] and Stasko J[1]
[1]*Jessenius Faculty of Medicine, Comenius University, Martin, Slovakia*

Aims: To evaluate selected polymorphisms of GAS6, MRVI1 and PEAR1 genes in patients with Sticky platelet syndrome (SPS) and fetal loss.
Methods: Twenty-three patients with SPS, manifested as fetal loss, 42 controls without SPS and with no history of fetal loss and thrombosis. SPS was diagnosed by platelet aggregometry (PACKS-4 aggregometer, Helena Laboratories, USA). Four single nucleotide polymorphisms (SNPs) of the GAS6 gene (rs7400002, rs1803628, rs8191974, rs9550270), two SNPs of the PEAR1 (rs12041331, rs12566888) and MRVI1 (rs7940646, rs1874445) genes were evaluated.
Results: We observed a significant higher occurrence of homozygotes for the variant C compared to holders of T allele (according to recessive association model of inheritance) at the rs7400002 (GAS6 gene) in the group of SPS patients with fetal loss vs. control subjects ($P < 0.049$). In addition, non-significant but still important result is that the haplotype C/C is associated with 8-fold increase risk of fetal loss vs. holders of T allele (odds ratio [OR] 8.632, 95% confidence interval [CI] 0.903–82.540). In adaptive model of inheritance, the results indicate that women carrying the genotype C/C have a significant 11-fold increased risk of fetal loss vs. holders of genotype C/T (odds ratio [OR] 11.429, 95% confidence interval [CI] 1.085–120.355). According to dominant model of inheritance, we identified a significant higher occurrence of homozygotes for the variant G compared to holders of T allele at a SNP in PEAR1 gene (rs12566888) in the group of SPS patients with fetal loss vs. control subjects ($P < 0.046$).
Summary/Conclusions: Our results can support an idea that selected GAS6 and PEAR1 gene polymorphism may be associated with the platelet hyperaggregability – a possible cause of fetal loss. SPS is likely a multifactorial inheritance disorders. Acknowledgement: Study was supported by project APVV 222-11, Vega 1/0016/12, UK/319/2012 and CEPV II (ITMS 26220120036) which is cofinanced from EC sources.

PO 205

Thrombophilia in ethiopathogenesis of IVF failure

Makatsaria A, Khizroeva D, Makatsariya N, Panfilova O, Stuleva N and Bitsadze V
I.M. Sechenov First Moscow State Medical University, Moscow, Russia

Background: IVF failure has recently been associated not only with embryo quality or endometrial receptivity but with thrombophilia.
Materials and Methods: we examined 109 patients after IVF failure. Among them – 76 after repeated IVF, and 33 pregnant women after IVF who received anticoagulant therapy at the period of planning of pregnancy. All of them had complicated obstetric history and venous thrombosis. Control group consisted of 100 healthy pregnant women. All patients were tested for acquired and inherited thrombophilia and hemostasis parameters.
Results: The prevalence of thrombophilia was found in all 109 patients with IVF failure and consisted 92%. The incidence of genetic thrombophilia was 45%. MTHFR mutation was found in 43%, prothrombin gene mutation -11%, Factor V Leiden mutation – 9%, PAI-I gene polymorphism – 71%, t-PA – 37%. Forty-four percent had circulation of antiphospholipid antibodies, 48% – anti-b2-GP I antibodies, 25% – anti-annexin V antibodies, and 11% – antibodies to prothrombin. Hyperhomocysteinemia was found in 57%. Multigenic thrombophilia was revealed in 78%, combination of genetic thrombophilic mutations and circulation of APA was identified in 61%. All women with pregnancy after IVF who received therapy from the fertile cycle and during all pregnancy (LMWH, antioxidants, aspirin, folic acid, natural progesterone, vitamins group B) were delivered with healthy newborn.
Comments: These data suggest that thrombophilia may play a role in the genesis of IVF failure, especially in cases of multigenic and combined thrombophilia. Since thrombophilia has been diagnosed antithrombotic therapy should be evaluated in patients with thrombophilia and IVF failure.

PO 206

LMWH and natural progesterone in patients with multiple pregnancy and thrombophilia

Makatsaria A, Makatsariya N, Bitsadze V, Khizroeva D and Panfilova O
I.M. Sechenov First Moscow State Medical University, Moscow, Russia

Background: thrombophilia play an important role in obstetric complications, especially in cases of multiple pregnancy. Normal pregnancy is a prothrombotic state and associated with profound alterations in the coagulation and fibrinolytic systems.
Materials and Methods: we examined 42 patients with multiple pregnancy, thrombophilia and complicated obstetric history. All pregnancies were dichorionic. Twenty-three women were after IVF. These patients were compared with group of 75 women examined retrospectively with multiple pregnancy, thrombophilia (78.5%) and obstetric complications (fetal loss syndrome 48%, antenatal fetal death 35%, IUGR 15%, neonatal death 13%, preeclampsia 64%, severe preeclampsia 10%, abruptio placentae 29%, preterm labor 28%) and did not receive anti-thrombotic therapy.
All patients had been examined for the genetic and acquired thrombophilia.
Results: Forty-seven percent of patients had circulation of antiphospholipid antibodies, 31% – hyperhomocysteinemia. The incidence of factor V Leiden mutation was 9%, prothrombin gene mutation – 13%. Eighty-four percent of patients had combined thrombophilia.
Anticoagulant therapy was started after first visit to a doctor: 21 women with IVF were cured from preparing to IVF, 12 – from the period of pregnancy planning, 9 – at the beginning of I trimester of pregnancy. All patients received LMWH, folic acid, vitamins B, Omega-3, micronized progesterone.
In 4 cases there was fetal reduction in woman pregnant with triplets. Mild preeclampsia was in five patients at term 30–34 weeks of pregnancy. Eleven women had Cesarean section as planned at 37 weeks. Twenty-two patients were delivered at term 34–36 weeks and 9 at 30–34 weeks. There were no cases of obstetrical complications.
Comments: Testing for thrombophilia should be performed in all patients with multiple pregnancy. Since thrombophilia has been diagnosed LMWH therapy and micronized progesterone should be started.

PO 207

Biosimilar LMWH in prevention of repeated thromboses at pregnant women with trombophilia

Makatsaria A, Bitsadze V, Panfilova O, Makatsariya N and Yashenina E

I.M. Sechenov First Moscow State Medical University, Moscow, Russia

Background: The biosimilar enoxaparin is effective and safe in prevention of repeated thromboses at pregnant women.

Materials and Methods: We examined 57 patients at the age of 29.4 ± 5.5 years with a history of venous tromboembolism and burdened obstetrical anamnesis. The control group consisted on 60 women with the physiological uncomplicated pregnancy course. Among the patients with tromboembolism 32 patients had deep veins thromboses, 14–thromboembolism of the pulmonary artery, 11 – thrombosis of atypical localizations (splenic, mesenterial, hepatic, ovarian veins). Eighty-two percent had burdened obstetrical history (fetal loss syndrome – in 57%, preeclampsia – in 40%, placental abruption – in 32%). We performed laboratory screening for genetic and acquired thrombophilia. We detected thrombophilic condition in 90% of all cases: in 23.5% – mutation of the factor V Leiden (heterozygous), a prothrombin mutation – in 13.7% (heterozygous). PAI-1 – in 41.2%(homozygous) and in 33.3% – heterozygous. Heterozygous form of MTHFR C677T was found in 52.9%) In 40% of cases hyperhomocysteinemia was detected. Circulation of antiphospholipid cofactors (beta-2 GP -1) was found in 27.5% of patients. *Polimorphismes of proinflammatory cytokines were detected in* 40% *of patients*. Both genetic and acquired thrombophilia were detected in 75% of all cases.

Results: there was no repeated trombotic complications in patients treated with Hemapaxan. Twenty-five (44%) women were undergone cesarean cection, 32(56%) women had uncomplicated vaginal delivery. Fifty-seven alive newborns were born.

Comment: biosimilar enoxaparin applied in women with repeated thromboses and thrombophilia allowed to prevent repeated thromboses in 100% of cases and improve perinatal outcomes.

PO 208

Pregnancy and arterial thrombosis

Makatsaria A, Akinshina S, Bitsadze V, Khizroeva D, Gadaeva Z, Makatsaria A and Stuleva N

I.M. Sechenov First Moscow State Medical University, Moscow, Russia

Background: The incidence of ischemic stroke associated with pregnancy is unknown but is estimated to be about 4.2–210 per 100,000 deliveries. Ischemic stroke is estimated to occur in 12–35% of women of 15–45 years old in association with pregnancy. Events occur most frequently in the III trimester of pregnancy or postpartum. Pregnancy is a kind of an essential spontaneous screening test for the risk of early stroke in women. Pregnancy augments the risk f stroke in 3–13%.

Materials and Methods: We observed 71 patients with history of arterial thrombotic complications and 60 healthy pregnant women (control group). Among 71 women with arterial thrombosis 5 of them had stroke and venous thromboembolic complications (VTE), 4 had myocardial infarction, three patients – acute arterial cerebral thromboembolism and thrombosis of prosthetic heart valves. Some women had history of stroke and ileo-femoral thrombosis and splenic infarction and thrombosis occurred in different other localizations (n = 19, 26.7%) including combination of ischemic stroke and retinal thrombosis, deep vein thrombosis, Takayasu syndrome and renal thrombosis, subclavian artery thrombosis, avascular necrosis of the femoral head and reoccurred cerebral thromboembolism in patients with catastrophic antiphospholipid syndrome.

I subgroup consists of 27 patients with history of arterial thrombosis. All these women were enrolled into the study from the fertile cycle or from the beginning of pregnancy andd therapy was started early. II subgroup accepted 23 patients from II or III trimesters of pregnancy and therapy was started after their admission. Thrombosis was associated with pregnancy in 17 women (28.8%). The remaining 21 patients with arterial thrombosis had thromboembolic complications during current pregnancy.

All included patients had been examined for the hemostasis system.

Results: risk factors of arterial thrombosis included systemic diseases (SLE, vasculitis) 16.9%, metabolic syndrome 37.3%, hypertonic disease 27.1%, cardiac arrhythmia 5.1%, the presence of prosthetic heart valves 6.8%, inadequate anticoagulant therapy, open foramen ovale 5.1%, intake of oral contraceptives 3.4%, surgery interventions 6.8%, septic complications 1.7%, vertebrobasilar abnormalities 11.9%.

Different forms of thrombophilia were present in 88.2% of patients. Multigenic inherited thrombophilia was recorded in 84.3% of patients (including one or more homozygous mutations), combined fibrinolytic defects in 76.5% patients, APA circulation in 41.2%, and hyperhomocysteinemia in 19.6%. It is important to pay attention to high prevalence of pre-eclampsia in patients with history of ischemic stroke (41.2% vs. 8.3% in control group, $P < 0.05$) but in II subgroup debut of pre-eclampsia occurred much earlier and was more severe probably because of lately started therapy.

All patients were delivered by cesarean section. Absolute indication for surgery was history of cerebral thromboembolism.

Conclusion: the revelation of the multigenic thrombophilic predisposition (84.3%) and especially fibrinolytic defects (76.5%) and APA circulation indicates an essential role of thrombophilia in the genesis of thrombotic complications. Early pathogenic anticoagulant therapy-from the fertile cycle when a women start to plan a pregnancy allows prevent reoccurred thrombotic events, severe obstetric complications and improve perinatal outcomes.

PO 209

Different clinical manifestations of APS in obstetric practice

Makatsaria A, Khizroeva D and Makatsaria A

I.M. Sechenov First Moscow State Medical University, Moscow, Russia

Background: obstetric complications such as fetal death, premature delivery, pre-eclampsia, fetal growth retardation, placental insufficiency and recurrent abortions are the characteristic manifestations of APS. They can occur in patients with known APS with previous arterial or venous events in any tissue or organ, or be its first or only manifestation.

Objectives: We determined different manifestations in the APS and assessed whether these clinical situations are due to the presence of antiphospholipid antibodies.

Methods: during 2000–2012 we observed more than 850 patients with different obstetric and gynecological complications and APS (recurrent miscarriage, preeclampsia, placental thrombosis, fetal growth retardation, metabolic syndrome, infertility, venous and arterial thrombosis, hypopituitarism Sheehans syndrome, failure of IVF, HRT, oral contraceptives and others).

Results: our investigation demonstrated that the presence of autoantibodies to various phospholipids and phospholipid-binding proteins (antibodies to beta-2-glycoprotein I, annexin V, prothrombin and to the antiphospholipid subtypes) has been identified in 64% of cases. In women with history of obstetric complications and circulation of APA fetal loss was found in 33.5% of cases, pre-eclampsia – 17.2%, thrombosis and placenta abruptio – 44%, stroke – 2.2%, IVF – 35.7%. In 71.5% APS was associated with genetic thrombophilia. Complex interactions of acquired and genetic thrombophilia are the worst combination and contribute to the causation of thrombotic events in most cases.

Conclusions: APS is one of the few treatable causes of pregnancy loss, and successful pregnancy rates of 70% or more can be achieved with

appropriate treatment. So, laboratory testing for aPL and antibodies to phospholipid-binding proteins has routinely to be recommended in the patients with suspected thrombophilia and attentive clinical care is required for best outcomes.

PO 210

Antithrombotic prohylaxis in pregnant patients with prosthetic heart valves

Makatsaria A, Akinshina S, Bitsadze V, Khizroeva D, Panfilova O and Makatsariya N

I.M. Sechenov First Moscow State Medical University, Moscow, Russia

In patients with prosthetic heart valves pregnancy and labor are associated with high thrombotic risk. Physiological hypercoagulation during pregnancy can reveal aquired and inherited hemostasis abnormalities which were asymptomatic before pregnancy.

Aim: To determine genetic thrombophilia and antiphospholipid antibodies (APA) in pregnant women with prosthetic valve thrombosis.

Material and Methods: Since 2000–2012 we have examined 11 pregnant women (at mean age 20–30 years) with mechanical valve thrombosis (mitral valve – $n = 8$, aortic valve – $n = 2$, tricuspid valve – $n = 1$) from 59 pts with prosthetic valves. Analysis of thrombophilia and APA was performed in all patients.

Results: History of obstetric complications (recurrent fetal loss, intrauterine growth restriction, preeclampsia, antenatal death) was observed in six women. Thromboembolic complications were observed in seven women (stroke – $n = 4$, renal and spleen thrombosis $n = 2$, iliofemoral thrombosis after cesarean section $n = 1$). Before the admission in our hospital (in 8–28 weeks of gestation) six patients received warfarin without regular monitoring, four patients – LMWH in low doses. One patient did not receive any anticoagulants in pregnancy during 1 month. Fetal mortality was 50%. One patient died due to pulmonary embolism 48 h after the simultaneous cesarean section and valve replacement. Thrombosis must be due to inadequate anticoagulation monitoring. Multigenic thrombophilia (≥ 4 mutations concomitantly) and APA were detected in 100%. MTHFR C677T, PAI-1 675 4G/5G, t-PA I/D, F Hageman 46C/T, fibrinogen – 455G/A, FV Leiden, prothrombin G20210A were detected in 6, 6, 2, 2, 4, 2 and 2 cases respectively. Lupus anticoagulant, anti-b2-glycoprotein I, anticardiolipins, anti-annexin V antibodies were detected in 4, 6, 3 and 4 patients respectively.

Conclusion: Pregnancy in patients with PHV carries significant risk. The presence of severe pregnancy complications, thrombotic events in anamnesis is an indication for the screening for genetic thrombophilia and antiphospholipid syndrome.

PO 211

Multiple pregnancy, chorion and placental abruption and thrombophilia

Makatsaria A, Bitsadze V, Panfilova O and Makatsariya N

I.M. Sechenov First Moscow State Medical University, Moscow, Russia

We examined 91 women with multiple pregnancy after IVF. Seventy percent of patients had ovarian hyperstimulation syndrome. All pregnancies were complicated: abruption placentae – in 51 cases, chorion detachement – in 40 cases. Sixty-two percent of patients had previous history of fetal loss syndrome, 78% – abruptio placentae associated with preeclampsia, 35% – burdened thrombotic anamnesis, 47% – burdened family thrombotic history.

Methods: Clinical and hemostasiological examination. Criteria of genetic thrombophilia: mutation of the factor V Leiden, mutations of prothrombin G20210A, antithrombin III deficiency, protein C deficiency, 3 homozygous thrombophilic polymorphisms, or 5 heterozygotic polymorphisms, moderate or heavy hyperhomocycteinemia and antiphospholipid syndrome.

Results: We detected thrombophilia in 83% of cases: mutation of factor V Leiden (±) in 20%, mutation of prothrombin G20210A (±)– in 13%, PAI-1 – in 72%, hyperhomocycteinemia – in 36%, antiphospholipid syndrome in 25%, polymorphisms of proinflammatory cytokines in 68%, inherited thrombophilia assotiated with antiphospholipid syndrome- in 45% of cases.

Conclusion: We suggest that thrombophilia plays important role in pathogenesis of complications of multiple pregnancy after IVF. We recommend to perform screening for genetic and aquired thrombophilias before IVF in patients with placental and chorion abruption and other pregnancy comlications in anamnesis. In case of detection of thrombophilic condition anticoagulant and antoxidant treatment and vitamins support is recommended in preparation to IVF, during gestation after IVF and in postnatal period.

PO 212

Massive obstetric bleedings and pathology of hemostasis system

Makatsaria A

I.M. Sechenov First Moscow State Medical University, Moscow, Russia

In spite of existing standards of hemorrhages prophylaxis maternal death from massive obstetric bleeding remains the main cause of maternal mortality in developing countries and occurs in developed countries. According to our 25 years independent experience massive obstetric bleeding can be divided into moderate and massive. Due to our experience since 1989 to 2012 (analyses of 200 cases massive of obstetric clinic) massive obstetric haemorrhage mostly is initially coagulopathic. At the same time coagulopathy and hemostasis insufficiency have different character.

Main risk factors that provoke massive obstetric bleedings are, besides obstetric reasons, hemostasiologic disturbances:

1. (a) acute forms of DIC; (b)conversion of the chronic form of DIC to the acute or sudden appearance of acute forms – placental abruption, chorioamnionitis, septic shock, heavy preeklampsia, anafilaktoid syndrome of pregnancy (amniotic embolism)
2. the hidden undiagnosed forms of hemorrhagic diathesis – Willebrand disease, thrombocytopathias, taking of medicines influencing on hemostasis, liver diseases (defect of synthesis of coagulation factors and their inhibitors), sudden appearance of inhibitors of coagulation in bloodstream (Factor VIII inhibitor). Analyzing 200 cases of maternal death from massive obstetric bleeding we found that 45% of medical reports these women consist of notes about hemorrhagic history. It indicates the absence of correct diagnostics of hemorrhages.
3. absence of adaptive hemostasiological changes that are typical in pregnancy.

We suggest that extend laboratory screening for latent coagulopathic disturbances is of high clinical value in correct diagnosis and treatment of massive obstetric.

During last 7 years we observed and examined 91 women, survived after massive obstetric bleeding. Blood loss was mire than 2.0 L. According to our data in patients with history of massive obstetric bleeding we revealed thrombophilic and hemorrhagic defects in hemostasis system including thrombophilia in 61% (genetic – 55, acquired – 28, multigenic – 14), platelet's defects in 31%, and Von Willebrand disease in 13%.

Dysplasia of connective tissue of vascular wall predispose to bleeding due to primary vascular platelets defects in vast wound surfaces during placenta separation in labor or abnormal placenta abruptio bleedings. Mechanical methods of bleeding arrest which are widely used recently can) In our practice since 1998 to 2012 we observed pregnancy and labor in 56 women with mesenchymal dysplasia (Marfan, Ehlers-Danlos,

Osler-Veber-Rendu syndromes) including subclinical forms of diseases in patients of ages 18–36 years.
Hemostasis abnormalities were discovered in 69.6%: in 45% – hypofunction of platelets and acquired von Willebrand disease.
All 56 were delivered by cesarean section. Vaginal delivery is contraindicated because of risk of uterus rupture and vessels rupture. There were no cases of bleeding because of fresh frozen plasma uses pre-, intra- and postoperatively.
We advised 1 case of sudden death of patient with undiagnosed earlier Marfan syndrome. Autopsy studies have found aortic rupture.
Hepatic disorders characterized by coagulopathy as well as thrombotic complications. In cases of diagnosed primarily coagulopathy massive obstetric hemorrages can be successfully prevented (before labor or cesarean).

PO 213

Successful pregnancy outcome in women with bad obstetric history and recurrent fetal loss due to thrombophilia: efficacy of combination of aspirin and heparin

Malato A, Saccullo G, Napolitano M, Lo Coco L, Raso S, Santoro M, Tarantino G, Vaccarella G and Siragusa S
Unit of Haematology and Transplantation, Paolo Giaccone University Hospital, Pal, Palermo, Italy

Backgound: Recent investigations highlight the potential role of thrombophilia for determining unfavorable pregnancy outcome including recurrent fetal loss. However, the results so far published furnish discordant results. There are differences of opinion whether these patients need to be treated with aspirin, unfractionated heparin, low' 'molecular weight heparin or corticosteroids.
Purpose: To evaluate the safety of anticoagulant agents, such as aspirin and heparin, in women with a history of at least two spontaneous miscarriages or one later intrauterine fetal death without apparent causes other than inherited thrombophilias.
Material and Methods: We studied, for the common tests for acquired and congenital thrombophilia, 108 women with previous adverse (i.e., preeclampsia, intrauterine growth restriction (IUGR), placental abruption, intrauterine fetal death and recurrent pregnancy loss). Low molecular weight heparin was given at 4000 IU subcutaneously once daily, started at positive pregnancy testing and followed until delivery. Aspirin, 100 mg daily, was given in addition to enoxaparin to women with and without antiphospholipid syndrome. The anticoagulation was continued 6 weeks in postpartum period.
Methods: All the women were positive either for a solitary or for a combination of acquired and heritable thrombophilia markers (FVLeiden, 13%, FII mutation 12%, MTHFR C677T 49% MTHFR A1298C 34.5% Combined defects 32.7% Fasting homocysteine levels 14.8%, LAC 22%); 52 out of 108 patients (48.1%) had subsequent pregnancies. They were treated with low' 'molecular weight heparin plus aspirin, and all of them had successful pregnancy outcome (live birth rate of 100%). None of the patients had any adverse reactions such as heparin-induced thrombocytopenia, thrombosis, or fracture. None of the patients had to interrupt the therapy for any adverse treatment-related complications.
Conclusions: Thromboprophylaxis with aspirin and heparin in women with bad obstetric history and recurrent fetal loss due to thrombophilia seems to be safe in prevention of pregnancy loss in women with inherited and acquired thrombophilia. Its efficacy should be tested in properly designed clinical trials.

PO 214

Excessive menstrual blood losses can cause severe iron deficient anemia in women with inherited or acquired coagulation disorder for oral anticoagulant treatment

Napolitano M[1], Saccullo G[1], Alberto D[2], Orecchioni A[3], Grandone E[4], Malato A[5], Lucchesi A[6], Mariani G[7] and Siragusa S[8]
[1]University of Palermo; [2]Istituto Superiore di Sanità, Palermo; [3]Central Laboratory, Regional Hospital of L'Aquila, L'Aquila; [4]Ospedale Casa Sollievo della Sofferenza, San Giovanni Rotondo; [5]Ospedale Cervello, Palermo; [6]Istituto Scientifico Romagnolo per lo Studio e la Cura dei Tumori, Meldola; [7]University of Ferrara, Ferrara; [8]University of Palermo, Thrombosis and Hemostasis Center, Palermo, Italy

Background: Excessive menstrual blood losses (EMBL) are a frequent symptom of a inherited bleeding disorder (IBD) but they can also complicate treatment with oral anticoagulants (OAT). EMBL negatively affect the quality of life and can lead to severe iron deficient anemia, sometimes requiring red blood cells transfusion. The quantitative determination of menstrual blood losses can effectively support the management of this frequent complication through an early detection that can help to avoid excessive iron losses and maintain a positive balance of iron homeostasis.
Objective: To quantitatively determine in a prospective evaluation, menstrual blood and iron losses in women with a diagnosis of inherited or acquired coagulation disorder secondary to OAT referring to our Center for iron deficient anemia.
Methods: Alkaline Hematin Method (AHM) was applied for the quantitative determination of menstrual blood losses (MBL) in each enrolled woman. A personal and gynecological history was recorded and all other potential known causes of iron deficiency were excluded in each enrolled woman. Sanitary protection wears used during menses were carefully collected and analyzed in a central laboratory. Menses were studied from 1 cycle to 3 consecutive cycles. A group of healthy women with normal hemoglobin and ferritin levels was enrolled as control. Blood cells count and ferritin serum levels were determined before enrollment and at least 2 weeks after the last menses. EMBL were defined as MBL > 80 mL. Iron losses were determined from the hematin values.
Results: Seventeen women with a known diagnosis of inherited bleeding disorder or under OAT, with a therapeutic INR (range:2–3), were enrolled for iron deficient anemia: von Willebrand's Disease (vWD, $n = 3$), Factor VII deficiency ($n = 6$), OAT for Deep Vein Thrombosis or Pulmonary Embolism ($n = 8$). Mean age at enrollment was 30.2 years (SD:5.19). Mean Hemoglobin levels were: 9.7 g/dL (SD:2.4); mean serum ferritin levels: 5 ng/dL (SD:3.37); mean menses duration was 6 days (SD:2); mean MBL was 95 ml (SD:12.7). Median amount of iron lost was 5.2 mg/cycle. In the control group ($n = 25$), mean age at enrollment was 29.9 years (SD:6.4), mean Hemoglobin levels were: 13.5 g/dL (SD:0.9); mean serum ferritin levels: 36.2 ng/dL (SD:20); mean menses duration was 4.5 days (SD:1); mean MBL was 45 ml (SD:17.2). Median amount of iron lost was 0.8 mg/cycle.
Conclusion: Excessive menstrual blood losses can be the leading cause of moderate to severe iron deficient anemia in women with inherited bleeding disorder or under OAT. The quantitative determination of menstrual blood losses can help to clinically define the problem and take adequate measures to prevent iron deficient anaemia and improve quality of life

PO 215

D-Dimers and pregnancy

Nikoloska I, Neceva V, Apostolovska R, Bojadzieva-Makarovska T, Velkova E and Samonikov-Tosevksa J
Institute of transfusion medicine, Skopje, Macedonia

Background: Elevated D-Dimers (D-D) levels are observed in all diseases and condition with increased coagulation activation especially during pregnancy which is common hypercoagulability state. Some of women have high values of D-D, don't have trombotic problems or problems with pregnancy, but some of them have low values of D-D and have problems with thrombosis or problems with pregnancy. D-D values are very useful tool to prevent thromboembolic complications, such as VTE – DVT or pulmonary embolism during pregnancy.
Aims: To show the values of D-D in pregnant women during trimesters in ITM for first 3 months in 2012 year.
Methods: Two hundred and sixty pregnant women in different months of pregnancy. Quantitative determination of D-D in plasma of pregnant women with Innovace D-D, immunoturbidimeric assay (normal value < 500 ng/mL) for use on BCS (Bechring – Siemens) analyzer.
Results: Two hundred and sixty pregnant women were admitted in Outpatient department in ITM in the first 3 months in 2012 year. The values of D-D show those results: In the first trimester in 34 women values of D-D was until 1.316 ng/mL. In second trimester 107 women had D-D values until 2.369 ng/mL but 50 women in VI th lunar month of pregnancy had higher D-D values instead those in IV th or V th lunar month. In last trimester in 167 women values was until 3.122 ng/mL. All those women have born healthy child.
Summary/Conclusions: Range of D-D not correlates with pregnancy problems. Values of D-D are increasing proportionally during each month of pregnancy, so question is which value of D-D would be upper border to start with prophylaxis therapy. Collaboration between gynecologist and coagulations is most important.

PO 216

Evaluation of protein C activity in pregnant Nigerians

Nwagha TU, Nwagha U, Ibegbulam OG and Ocheni S
University of Nigeria Teaching Hospital, Enugu, Nigeria

Introduction: Thromboembolic phenomenon is under reported among pregnant Nigerians. The paucity of data and hence low index of clinical suspicion among obstetricians and care givers are hugely contributory to this.
Aims and Objectives: This study is aimed at establishing mean levels of protein C activation (PCA) ratio, prothrombin time (PT), activated partial thromboplastin time (APTT) and platelet count in pregnant Nigerians.
Subjects and Method: A prospective study was carried out in a tertiary institution in Enugu State, Nigeria over the 7 months period. Two hundred pregnant women in the 2nd and 3rd trimester and 50 non pregnant female controls were recruited and PCA ratio (coagulometric assay), PT, APTT and platelets count were also determined.
Results: there was a significant difference using ANOVA ($P < 0.0001$) in the mean platelet count for female non pregnant control subjects and the pregnant subjects in the second trimester and third trimester which were $226.34 \pm 69.16 \times 10^9$/L, $186.38 \pm 42.81 \times 10^9$/L and $167.46 \pm 49.63 \times 10^9$/L respectively. The *post hoc* multiple comparison showed that this was as a result the differences between control subjects vs. the pregnant subjects in their 2nd trimester of pregnancy ($P < 0.0001$), the control subjects vs. pregnant subjects in their 3rd trimester ($P < 0.0001$), as well as the 2nd vs. 3rd trimester ($P = 0.004$).
There were also significant difference in The mean PT and APTT for female non pregnant control subjects and Pregnant subjects in the second trimester and third trimester which were for PT,13.17 ± 0.77 s, 12.19 ± 0.84 s and 13.10 ± 2.09 s respectively and APTT 40.09 ± 3.44 s, 36.83 ± 3.61 s and 39.51 ± 4.44 s respectively. However, the *post hoc* multiple comparison showed that this finding was mainly due to the differences in PT and APTT between the control subjects vs. the pregnant subjects in their 2nd trimester of pregnancy and between the 2nd vs. 3rd trimester ($P < 0.0001$), The differences noted between the control subjects vs. pregnant subjects in their 3rd trimester for both PT and APTT were not contributory ($P = 0.960$) and ($P = 0.642$) respectively.
The female non pregnant controls and pregnant subjects in their 2nd and 3rd trimester with PCA ratio ≥ 4 were 20%, 52%and 27% respectively while those with APC sensitivity ratio ≤ 4 were 8%, 38% and 61% respectively. There was a significant difference ($P = 0.000$) in the mean PCA ratio of the non-pregnant controls and the pregnant subjects which were 4.27 ± 0.44, 3.87 ± 0.50 and4.34 ± 0.43 respectively. These changes were also statistically significant ($P < 0.0001$). The *post hoc* multiple comparison showed that these were due to differences between the non-pregnant control subjects vs. pregnant subjects in their 3rd trimester and the pregnant subjects between the 2nd trimester vs.3rd trimester ($P < 0.0001$). However, the differences between non pregnant control subjects vs. the pregnant subjects in their 2nd trimester of pregnancy were not contributory ($P = 0.671$).
Conclusion: There are changes in protein C activity (PCA ratio), PT, APTT and platelet count in our pregnant women. This largely would imply the possibility of thromboembolic disorders in pregnancy and hence the appropriateness of heightened index of clinical suspicion among our obstetricians and care givers.

PO 217

Thrombocytopenia and pregnancy

Tadlaoui D[1], Bendaoud H[2] and Guechi Z[2]
[1]Nafissa Hamoud Hospital, Hussein Dey CHU; [2]Nafissa Hamoud Hospital, Algiers, Algeria

The thrombocytopenia is related to 4–8% of the pregnancies, the rate of platelets is generaly moderate 70 Giga/L and the thrombopenia is insulated occurring especially after the third quarter or sometimes with the first quarter without maternal haemorrhage. It is necessary to differentiate this thrombocytopenia ITP (immune thrombocytopenia Purpura) which is much rarer (1–5 cases out of 10,000 pregnancies) with an important hemorrhagic risk, a foetal or neonatal haemorrhage, since at the time of a ITP, the antibodies anti platelets cross the placenta. The principal objective of our study is to detect on one hand these thrombocytopenia in order to pose a diagnosis as soon as possible of it and to avoid the massive haemorrhage which perhaps fatal, and on the other hand, the search for possible thrombocytopenia could be really a good indicator of pregnancy complications.
We followed 216 pregnant women presenting no characteristic obstétrical, for each one of them a blood numeration'platelets was done, by knowing that they all presented an initial biological assessment (biochemical, hematologic and serologic). At the time of discovered of a thrombocytopenia, a blood smear is then carried out in order to eliminate on the one hand, false thrombocytopenia, and on the other hand, to study the other cellular lines (red and white cells) to check if the cytopenia is insulated or associated (see the quantitative aspect on NFS). At 20 of them, a 9.25% frequency, we especially find a thrombocytopenia in the third quarter, and for three pregnant women only more precociously at the end of the first. Anaemia is present among 182 women (84.25%) during the last quarter (Iron Anaemia deficiency or by mixed deficiency). No hemorrhagic sign was announced, the thrombocytopenia was not symptomatic. The rate of platelets varied between 65 and 110 G/L (Algerian Standards: 120–380 G/L) Among the etiologies, two cases of DIC (disseminated intravascular Coagulation) were diagnosed (Assessment of consumption carried out) three cases of TIP where the rate of platelets fell from 65 to 42 G/L at the end of the pregnancy with caused Caesarean, 1 HELLP syndroma, and 14 of them were purely related to the pregnancy, the rate of platelets returned to normal 10–20 days after the delivery. This preliminary study enabled us to quickly detect the three cases of TIP in order to avoid the hemorrhagic risk at the foetus or the

new-born baby more especially as the maternal rate of the platelets does not reflect that of the new-born baby at all, indeed, for the three cases the rate was lower than 30 G/L and the treatment was very quickly founded, the NFS must be systematic at the new-born baby and the premature. The frequency of the thrombocytopenia at the pregnancy being of 6.48%, the initial anamnesis and assessments must be essential to interpret allthe results obtained.

PO 218

Plasma thrombin generation and circulating nucleosomes in women with early abortions

Tormene D, Ammollo T, Semeraro F, Gjergji M, Camerin M, Visentin S, Nardelli G and Simioni P

University of Padova, Padova, Italy

Background: Miscarriages are distressing complications of pregnancy affecting about 15% of pregnancies, and 2% are recurrent.
Chromosomal abnormalities are considered the leading cause of early abortions, other causes are represented by uterine abnormalities, endocrine disorders, infections, immunological disorders. However, about 50% of recurrent miscarriages is unexplained.
As thrombophilic conditions are associated with an increased risk of obstetric complications we performed a case control study aiming to evaluate the association between early abortions, thrombin generation and levels of circulating nucleosomes, a marker of tissue damage and inflammation with prothrombotic potential.
Materials and Methods: Twenty-six women who were enrolled at the time of early abortion and the same number of healthy women of comparable gestational age were included in the study. The levels of circulating nucleosomes and thrombin generation were measured in the two groups. Quantification of circulating total nucleosomes was determined using a commercially available ELISA kit and nucleosomes were quantified in arbitrary unit (AU). Thrombin generation was determined by calibrated automated thrombinography (CAT).
Results: Plasma thrombin generation was measured in the absence of triggers (recalcification) or in the presence of tissue factor (TF, 5 pM). The thrombin generation was significantly lower in cases with respect to controls under both conditions: in the presence of TF the thrombin peak in cases was 267.7 nM and in controls 321 nM ($P = 0.007$) and the endogenous thrombin potential (ETP) 1286 ± 327.2 nM/min and 1526 ± 270.5 nM/min, respectively ($P = 0.004$).
Circulating levels of nucleosomes were similar in cases (median value 56 ± 22 AU) and controls (median value 62.5 ± 26 AU).
Conclusions:These preliminary results provide evidence that lower levels of thrombin generation are associated with an increased risk of early miscarriages suggesting that a state of hyper-coagulability may favor the implantation of the embryo. Further studies are needed to better understand the role of circulating nucleosomes and thrombin generation in early miscarriages.

PO 219

The features platelet hemostasis in pregnant women with missed abortion

Vasilenko I[1], Gaspsryan S[2], Nalgieva M[2], Lifenko R[2] and Topuzov A[2]

[1]N.I.Pirogov Russian National Research Medical University, Moscow; [2]Stavropol State Medical Academy, Stavropol, Russia

The problem of miscarriage in their social value is one of the leaders in modern obstetrics. In the reproductive loss structure the rate of missed abortion (MA) is 10–20%. Last years much attention in studying of is MA genesis are attended to hemostatic disorders, including genetically determined forms of thrombophilia, hyperhomocysteinemia, antiphospholipid syndrome, etc. Therefore, a detailed studying of the platelet morphofunctional characteristics can improve the diagnosis and treatment of MA.
The features of the morphofunctional state of peripheral blood platelets were analyzed in the I trimester of gestation in 35 pregnant women with physiological, 40 – with MA, as well as in 20 somatically healthy women of reproductive age. Investigations were carried out in the real time using novel information biotechnology based on the apparatus-and-program complex (APC «Bioni», Westtrade LTD, Moscow, Russia) for cellular diagnostics using computed cytomorphometry (module computer laser phase-interference microscopy module «Bioni-CPM») and microelectrophoresis (microelectrophoresis module «Bioni-MEPh»). Dynamics of the morphofunctional parameters of the cellular membranes (electrokinetic parameters of the separate cells and cellular population as a whole, percent of immovable cells, an average fluctuation amplitude, cell distributions in amplitude (histograms), asymmetry, and excess) was estimated as well as the computer platelet images (three dimensions of whole cells and their parts, different cross-sections and histogram) and optic-geometrical parameters of each platelet and its distribution by sizes. At one time standard hemostasis studies of peripheral blood in patients were performed including the platelet number, ADP-induced aggregation. Analysis of coagulation hemostasis was performed by determining the activated partial thromboplastin time (aPTT), prothrombin time (TV), prothrombin index, number of fibrinogen data thromboelastography. Determined the presence of antiphospholipid antibodies (aPL), lupus anticoagulant (LA).
The circulating platelet multiplicity reflects cell distinctions in size, density, metabolic, functional, biochemical features and the level of megakaryocyte polymorphism. When MA revealed marked heterogeneity of platelet hemostasis: reduced percentage of resting platelets (49% vs. 56% in physiological pregnancy), increased content of activated cells (32% and 14% vs. 28% and 11%, respectively), the average in the population value of the diameter, perimeter, area and volume of platelets increased by 19.2%, 15.9%, 39.1% and 44.4%, respectively. Apparently, this is due to the processes of conversion of the cell hemostasis towards activation and implementation of hypercoagulability. The subpopulation of large platelets (with diameter > 5 microns) were isolated and characterized. Outside of pregnancy the macroform content does not exceed 2%, in physiological pregnancy (I term) – 4%, MA – increases to 7%. All patients with MA were followed up 7–10 days after emptying the uterus against the background of antiplatelet and anticoagulant therapy. The effectiveness of treatment was evaluated by the activation status of the restoration and normalization of morphometric parameters of circulating platelets.
There were significant correlation relationship between the platelet morphometric parameters, different morphological cell types, and the most important indicators agregatogramms. On the basis on these results, a system of objective and informative criteria for the timely MA diagnosis and the adequacy of pathogenetic therapy.

PO 220

The clinical outcome of 103 pediatric ITP patients in one center

Bay A and Karaoglu O

Gaziantep University, Gaziantep, Turkey

Background: Immune thrombocytopenic purpura (ITP) is a common disease in children that can be seen in two clinical forms as acute and chronic.
Aims: In our study, clinical course and treatment responses of patients with childhood ITP were evaluated in terms of determining causes of disease and the factors affect on chronicity.
Methods: The files of 103 patients followed as ITP and sufficient information can be accessed between march 2006 and February 2011 at Gaziantep University Faculty of Medicine, Department of Pediatric Hematology were investigated for history, clinical examination, laboratory findings, clinical course and treatment responses.

Results: Average age at diagnosis was 73.0 ± 50.7 months and female/male ratio was 1.1. Thirty-three percent of the patients had history of previous infection and 3.9% had history of vaccination. Bruising (75.7%) and epistaxis (35.9%) were most common compliants at admission. Most of the patients were admitted in spring (29.1%) and summer (27.2%). In our ITP patients 33.3% had previous viral infection, 20.6% had antinuclear antibody (ANA) positivity, 29% had antithyroglobulin antibody positivity. At the admittion 50.5% of the patients were diagnosed as acute ITP and 49.5% were diagnosed as chronic ITP. The age of diagnosis > 10 years, admission platelet count > 10,000/mm^3, and those with insidious onset, chronity was significantly higher than those without a history of previous infection ($P = 0.009$, $P = 0.001$, and $P = 0.003$ respectively). Asthe preferred initial treatment with intravenous immunoglobulin (IVIG) and steroid there was no difference in terms of the treatment response and relaps rate ($P = 0.097$, $P = 0.62$ respectively). Between follow up without treatment, IVIG, and steroid treatments there was no difference in terms of chronicity ($P = 0.33$).
Conclussion: In children, ITP can be seen after previous infection or vaccination and may be associated with underlying autoimmun disease. Although the prognose is variable, age at diagnosis, platelet count at admission, and previous history of infection are risk factors for chronicity.

PO 221

The serum TPO levels, not a good biomark in children immune thrombocytopenia

Chen Z, Ma JY, Jiang J, Jin L, Zhang L, Yang J and Wu R
Beijing Children's Hospital, Beijing, China

Objective: To explore the relationship between serum TPO levels and the prognosis of children Immune Thrombocytopenia (ITP) during their onset period.
Method: The children (< 14 years) with new-diagnosis ITP were included in this study in Hematology Center ward of Beijing Children's Hospital from April 2012 to September 2012. The serum thrombopoietin (TPO) levels were tested in all patients. All of the children were followed in the 3rd month and were divided to two groups: Remission group (platelet count > 100×10^9/L) and Non-remission group platelet count < 100×10^9/L according to the platelet count. Several clinical data of the children with ITP were collected included: the first platelet count, megakaryocytes count of bone marrow for the ITP diagnosis, response to treatment measure, platelet count in the 3rd month followed period. And the relationship between these clinical data and serum TPO levels were analysed.
Result: There were 33 children with new-diagnosis ITP were included in this study. Age: from 2 months to 12 years old, median age is 3.0 years old. Six cases in non-remission group and other 27 cases in remission group. Correlation analysis showed no significant correlation between TPO levels and platelet count before therapy ($P = 0.775$,$r = -0.051$) and megakaryocyes count of bone marrow ($P = 0.773$,$r = -0.051$). similarly, no significant correlation were founded between TPO levels and response of treatment ($P = 0.907$, $r = -0.021$). The TPO levels were no significant difference between non-remission group and remission group ($P = 0.456$).
Conclusion: There is no significant correlation bewteen serum TPO levels and several clinical data of Children ITP. The TPO levels can't be used as a biomark for evaluating the prognosis of children ITP.

PO 222

Safety and efficacy of laparoscopic splenectomy in children with chronic immune thrombocytopenic purpura

Evstafyeva I[1], Poddubnyi I[2], Tolstov K[2], Donyush D[1], Svirin P[1] and Vdovin V[1]
[1]Izmailovskaya Children Hospital; [2]Moscow State University of Medicine and Dentistry, Moscow, Russia

Background: Prevalence of Immune thrombocytopenic purpura (ITP) in Russian children range 5.5–6.5 in 100,000. Fifteen percent of them suffer from chronic ITP with excessive bleeding and poore quality of life. Treatment mode for this group is splenectomy.
Aims: To evaluate safety and efficacy of laparoscopic splenectomy (LS) in children with chronic ITP.
Methods: During the period 2000–2012 we observed 61 children with chronic ITP, who had excessive impending bleedings (35 – epistaxis, 20 – menorrhagia, 7 – kidney bleedings, 4 – intestinal bleedings, 6 – gum bleedings, 7 – eye bleedings, 2 – cerebrovascular accidents, 1 – hemothorax). Pre-operative conservative treatment in all patients included intravenous immunoglobulin (IVIG), steroids, interferon-alpha, anti-D-Rh immunoglobulin, danazol with no sufficient effect. The age of the patients varied from 2 to 17 years. The mean disease duration was 51.1 months. Laparoscopic splenectomy was performed in all patients. Three trocars – two 5 mm and 10 mm – were used in all cases; Ligasure instruments were employed for dissection and vessels ligation and transection (including the vascular pedicle).
Results: Mean platelet count during the surgery was 110.3 × 10 (9)/L (range 12–383 × 10(9)/L). Mean surgery time was 65 min (range 30–195 min). There were no indications for conversion. Five children required red cells transfusion in the early postoperative period, 29 – had reactive postoperative pancreatitis. No fatal complications occurred. There were no relaparoscopies or relaparotomies in our series of 61 patients. After LS 35 (57.4%) children have stable normal platelet count without bleedings; 26 (42.6%) children after LS need additional drug therapy- danazol, IVIG, steroids. After surgery and additional drug treatment nine children (14.7%) still have severe thrombocytopenia with episodes of bleeding.
Conclusion: LS in combination with conservative therapy was effective in 85.3% of actively bleeding ITP children after unsuccessful nonsurgical therapy.

PO 223

Comparison of length of stay for inpatients with immune thrombocytopenia treated with anti-Rh(D) vs. those treated with intravenous immunoglobulin or steroids

Melinscak H[1], Shapira I[2], Grossbard ML[1] and Varma M[1]
[1]St Luke's Roosevelt Hospital; [2]Beth Israel Medical Centre, New York, NY, USA

Background: Anti-Rh(D) is an effective treatment for immune thrombocytopenia [ITP]. It has a more rapid onset of action (1 day) vis a vis glucocorticoids (3 days) and intravenous immunoglobulin [IVIG] (4 days). A direct comparison of length of stay [LOS] for adult inpatients receiving these therapies has hitherto not been performed.
Aims: To determine whether anti-Rh(D) therapy for ITP results in shorter mean LOS compared to treatment with glucocorticoids or IVIG.
Methods: With institutional review board approval, a retrospective chart review was conducted to assess length of stay in relation to treatments proffered for ITP. The defining diagnosis of ITP [coded 287.31] was rendered from the computerised record at St. Luke's-Roosevelt Hospital Center. In a period spanning 01SEP2005 through 29FEB2012, 303 admissions were identified, of which 78 were just for

active ITP, and in which ITP-related complications or other co-morbidities did not impact on LOS. Single agent therapy – glucocorticoids, anti-Rh(D), or IVIG – was administered in 50 of the 78 admissions; combination therapy was given in the remaining 28. LOS was extracted from the medical record. An average LOS was tabulated for each treatment group. Age and gender were also recorded. An apriori one-way ANOVA calculation was used to compare LOS among patients treated with prednisone, dexamethasone, or IVIG. The student's *t*-test was used to compare LOS between patients treated with anti-Rh(D) vs. the group of patients treated with prednisone, dexamethasone, or IVIG (http://www.physics.csbsju.edu/stats/).

Results: There were 45 adult and 5 pediatric admissions. The median age was 43 years, range 3–78 years. The male:female ratio was 1.1:1. Mean LOS (days) was similar for patients treated with prednisone ($n = 7$) 2.714 [95% CI 1.841–3.588], dexamethasone ($n = 7$) 3.000 [95% CI 2.127–3.873], or IVIG ($n = 10$) 2.500 [95% CI 1.769 thru 3.231], $P = 0.66$. Mean LOS was shorter for patients treated with anti-Rh(D) ($n = 26$) 1.888 [95% CI 1.383 thru 2.386] in comparison with the group of patients treated with prednisone, dexamethasone, or IVIG ($n = 24$) 2.71 [95% CI 2.186 thru 3.230], $P = 0.027$. There were no complications noted in the treatment arms.

Summary/Conclusions: LOS is 1 day shorter for ITP patients treated with anti-Rh(D) vs. those treated with glucocorticoids or IVIG. According to the findings of this study, anti-Rh(D) is a rapidly effective, well-tolerated therapy for ITP.

PO 224

Successful management of ITP during pregnancy: weekly IVIg is an option

Villaca PR, Okazaki E, Zeinad-Valim AK, Chamone DAF and D'Amico EA

Hospital das Clínicas – University of Sao Paulo, Sao Paulo, Brazil

Background: Primary ITP is an autoimmune disorder characterized by isolated thrombocytopenia (peripheral blood platelet count $< 100 \times 10^9$/L) in the absence of other causes or disorders that may be associated with thrombocytopenia. Pregnancy does not increase the risk of developing ITP nor does it exacerbate preexisting ITP, although anecdotal reports of exacerbation of ITP during pregnancy with improvement after delivery. Treatment is largely based on the risk of maternal hemorrhage. Studies have shown that pregnancy in women with ITP can proceed safely with low hemorrhagic risk, with around 1/3 of patients requiring intervention. Throughout the first 2 trimesters a platelet count at 20 to 30×10^9/L or higher do not routinely require treatment, unless the patient is symptomatic or to produce an increase in platelet count to a level considered safe for procedures. They should be monitored more closely as delivery approaches. Corticosteroids are the first line of therapy in pregnant women; intravenous immune globulin (IVIg) is commonly used in steroid resistant patients. Other treatments such as intravenously administered anti-D (IV anti-D) and splenectomy during pregnancy have been reported. The mode of delivery is determined by obstetrical considerations.

Case report: A 20-year-old woman was admitted to the hospital during week 20 of her first pregnancy because of thrombocytopenia (3×10^9/L) without bleeding. She had no history of infection or drug intake. A subclinical hypothyroidism was diagnosed. Laboratory studies revealed a hemoglobin of 11.7 g/dL, WBC counts $12{,}300 \times 10^9$/L (normal differential), and normal coagulation and serological tests. She was started on oral doses of 60 mg of prednisone daily and IVIg (1 g/Kg/day for 2 days) with a complete response. Despite being maintained with steroids, there was a significant drop in platelet count after 14 days. At this time she presented with petechiae on the trunk and limbs, and she was noted to be hypertensive. IVIg was administered again and a single weekly IVIg (400 mg/Kg) infusion was given, which provided a normal platelet count. In the absence of any response and because of hypertension, steroid was tapered to 30 mg. Cesarean section was performed and she gave birth to a female infant with a normal platelet count.

Summary: Due to the paucity of RCTs, recommendations for the diagnosis and management of ITP in pregnancy are mainly based on clinical experience and expert consensus. First-line treatment of ITP in pregnancy include corticosteroids, IVIg, IV anti-D and splenectomy. There are no comparative trials of corticosteroids and IVIg in pregnant women; however, response rates are similar to those in non-pregnant patients. For the management of maternal ITP patients failing firstline treatment, azathioprine, cyclosporin A, splenectomy may be some options to be used before delivery. In our patient, a single weekly IVIg infusion was sufficient to prevent hemorrhage and provide an adequate platelet count for delivery. IGIV therapy offers a therapeutic modality in managing the difficult patients with ITP throughout their pregnancy.

PO 225

CXCR4 gene variation is associated with minimal platelet count of childhood primary immune thrombocytopenia

Wang J-D[1], Fan-Chen K[2], Chi-Ren T[3] and Te-Kau C[1]

[1]Taichung Veterns General Hospital, Taichung; [2]Changhua Show-Chwan Memorial Hospital, Changhua; [3]Taichung Veterans General Hospital, Taichung, Taiwan

Background/Aim: Primary immune thrombocytopenia (ITP) of childhood is an autoimmune disease characterized by abnormally increased destruction of platelets and decreased megakaryopoiesis. Chemokine receptor, CXCR4 is involved in the migration, homing, mobilization, proliferation and survival of hematopoietic stem cells. In addition, CXCR4 is shown to have an impact on the survival of platelets derived from ITP patients.

Methods: Two single nucleotide polymorphisms (SNPs) of the CXCR4 gene (rs2228014 and rs2471859) were assessed in 100 children with ITP and 126 healthy controls. The genotypes were analyzed by tetra ARMS polymerase chain reaction and confirmed by direct sequencing.

Results: Compared with controls, the rs2228014 and rs2471859 genotypes were not different in ITP patients ($P = 0.225$ and 0.759, respectively). Further analysis of the relationship between *CXR* polymorphisms and clinical features also showed that the rs2228014 and rs2471859 genotypes were not associated with protection from chronicity and steroid-dependence in ITP patients. However, the minimal platelet count were significantly decreased in patients with rs266085 genotype C/C ($P = 0.03$).

Conclusion: The findings of this study suggest that *CXR* gene variation may be associated with the minimal platelet count of childhood ITP.

PO 226

Decreased interlukin-7 in peripheral blood is due to the negative feedback of apoptosis-resistance and over-expression of pro-inflammatory cytokines of lymphocytes in primary immune thrombocytopenia

Zhang D, Li H, Zhang X, Liu X, Xue F and Yang R

Institute of Hematology & Blood Diseases Hospital, Tianjin, China

Background: Primary immune thrombocytopenia (ITP) is an autoimmune disease with many immune dysfunctions, including over-proliferation and apoptosis resistance of auto-reactive lymphocytes. As a critical cytokine for development and survival of lymphocytes, whether interlukin-7(IL-7) is involved in ITP remains unclear.

Aims: This study aimed to determine the effects of IL-7 on the cytokine production and survival of peripheral blood mononuclear cells (PBMCs) and bone marrow mononuclear cells of (BMNCs) of ITP.

Methods: The levels of IL-7 in PB and BM serum and the production of IFN-γ, tumor necrosis factor (TNF)-α, and IL-10 were measured by ELISA. Besides, flow cytometric analysis of cell apoptosis was performed by staining with annexinV-FITC/Propidium Iodide (PI). The proliferation rate of PBMCs was examined by BrdU incorporation method.
Results: The result showed that the plasma IL-7 levels in peripheral blood (PB) from ITP patients were lower than that of the normal controls, and it had correlation with therapy and platelet counts, but the levels of IL-7 did not change in bone marrow (BM) of ITP patients compared with that of normal controls. The results also showed that IL-7 promoted the proliferation of lymphocytes both in PB and BM. Additionally, we also found that the exogenous IL-7 up-regulated the secretion of interferon-γ, tumor necrosis factor-α as well as IL-10.
Conclusion: These findings suggest that decreased IL-7 in PB is a consequence of the negative feedback of apoptosis-resistance and overexpression of pro-inflammatory cytokines of lymphocytes in ITP patients.
Hui Yuan Li and Dong Lei Zhang contributed equally to this study.

PO 227

Experience in treatment with alpha interferon in children with hemangioma in Srinagarind Hospital

Komvilaisak P, Jetsrisuparb A, Wiangnon S and Choksantisook K
Srinagarind Hospital, Khon Kaen, Thailand

Background: Hemangioma, most common benign vascular tumor, has natural history of proliferation in the first year of life followed by spontaneous resolution. The treatment is not universal standard with indication as following: impaired organ function and Kasabach Merritt syndrome (KMS). Alpha-interferon inhibits angiogenesis, endothelial cell migration and proliferation.
Objective: To evaluate the outcome of alpha-interferon for the treatment of hemangioma.
Methods: We recruited 35 patients with hemangioma receiving alpha-interferon followed at hemangioma clinic between January 2001- January 2011.The patients' data including sex, age, type and location of hemangioma, indication, duration, outcome and complications of treatment were reviewed.
Design: Retrospective descriptive study.
Measurements: We evaluate of the outcomes including improvement of organ function, resolution of Kasabach Merritt syndrome (KMS) and decrease hemangioma size.
Results: the number of patients was 35 patients (female = 21, male = 14) with mean age 3.2 months (range 5 days-15 months), loss follow up in five patients. Hemangioma was divided into cavernous (9), capillary (10), mixed (7). Location of hemangioma includes head and neck (21), extremities (7), mediastinum (3), intraosseous (1), liver (2), larynx and epiglottis (2), and scrotum (1). Average age of treatment was 4.7 months (range 5 days-18 months). Duration of response in 29 patients was 4.7 months (range 1–6 months). Indications of treatment included KMS (1), KMS with impaired organ functions (2), impaired organ functions (30), infection (2), intracranial (1). Eleven patients were decrease in size of mass > 50%, 14 patients were decrease in size < 50% but 23 patients (82.1%) were improved organ function and resolution of KMS. Complications of treatment were elevation of liver enzymes (3), and fever (6).
Conclusions: The use of alpha-interferon was well response to improve organ function and decrease hemangioma size. Due to spastic diplegia, serious complication of alpha-interferon from previous case report studies, the consideration of this treatment should be discussed with parent in light of pro and cons.

PO 228

APC and PAR-antagonists' protective effects on inflammated mast cells and mast cells co-cultivated with rat neurons

Erukhimovich A[1], Gorbacheva L[1], Bespalova Z[2], Pinelis V[3], Strukova S[1] and Reiser G[4]
[1]Lomonosov Moscow State University; [2]Institute of Experimental Cardiology; [3]Centre of Children Health, RAMS, Moscow, Russia; [4]Otto-von-Guericke University, Institute of Neurobiochemistry, Magdeburg, Germany

Backgrounds: Serine proteinases of blood coagulation system – thrombin and APC – are signal molecules that regulate cell functions via protease-activated receptors (PARs). PAR activation with thrombin results into transcription factors activation, increase of inflammatory mediators, expression of adhesive molecules on cells' surface [Angiolillo D.J., et al., 2010]. But APC through the same receptor with thrombin helps to stabilize cells and suppress inflammation [Griffin et al., 2007]. Mast cells are rich with PARs and so they contribute to connection between coagulation and inflammation. Activated mast cells secrete vasoactive and inflammatory factors, growth factors, and cytokines. It was suggested that mast cells can promote blood-brain barrier (BBB) damage. So stabilization of BBB after acute stroke via mast cells regulation may become a new pharmacological target [P.J. Lindsberg, et al., 2010]. It was shown previously that APC and iPAR 1-III can significantly decrease histamine, IL 1b and IL 6 release from peritoneal rat mast cells [Rusanova A. et al., 2009, Strukova S. et al. 2011]. But there are very few data APC and PAR-antagonists effects on TNF release from mast cells during acute inflammation and neuron survival at co-cultivation with inflammatory mast cells after APC and PAR-antagonists. Therefore it constitutes the aim of the present study.
Aims: To estimate secretory activity of mast cells in experimental peritonitis and APC/PAR-antagonists influence on it. To study interaction between mast cells and hippocampal neurons in co-culture.
Methods: Mast cells were isolated from rat peritoneal cavity and purified by centrifugation on Ficoll gradient. Histamine secretion was measured by spectrofluorescent methods, TNF secretion was measured by ELISA. Hippocampal neurons were isolated from newborn rat cubs and cultivated for 10 DIV (Gorbacheva et al., 2009). Mast cells were pre-incubated with APC or PAR-antagonists for 15 min and then co-cultivated for 1DIV with hippocampal neurons. To estimate the contents of co-cultures immunostaining with mast cells tryptase and synaptotagmin was performed. Neuron survival was estimated by morphological staining with SYTO13, Hoechst and Ethidium Bromide. Statistical analysis: non-parametric Mann-Whitney criterion. All the studies that involve experimental animals were performed according to ethic protocol approved by Lomonosov MSU.
Results: In short times of *in vivo* model (intraperitoneal injection of Thioglycolate broth) APC effect on TNFα release from mast cells resulted into 76% decrease of TNFα amount detected in mast cells supernatant. It was also shown that APC (1 mkM) pre-incubated with mast cells increased neuron survival by 12% compared to control group without mast cells and by 32% compared to co-cultures with untreated mast cells. The results also indicate that iPAR's influence on cell survival was more effective in tested concentrations of 2.5 mkM. Total cell survival was increased for 40% and level of apoptosis and necrosis was significantly suppressed.
Conclusions: The results show that APC and iPAR 1-III may be considered as effective cytoprotectors in our research model. If APC and iPAR can possibly modulate and stabilize mast cells that may be a background for investigation of mast cell-nerve interaction and cross-talk in different models.

PO 229

Splitomicin inhibits fMLP-induced superoxide anion production in human neutrophils by activate cAMP/PKA signaling inhibition of ERK pathway

Liao HR[1], Liu FC[2], Liou J-T[2], Day YJ[2] and Yu HP[2]

[1]Chang Gung University; [2]Department of Anesthesiology, Chang Gung Memorial Hospital, Tao-Yuan, Taiwan

Splitomicin, is a cell-permeable lactone derived from naphthol and known to be a potent selective inhibitor of Sir2 (silent information regulator 2). Previous studies have demonstrated that naphtholic compounds pos- sess an inhibitory effect on neutrophils. Here, we present our investigation on the inhibitory effects of splitomicin in human neutrophils. The primary goal of our study was to locate a possible candidate on inflam- matory reactions and to hopefully develop a novel anti-inflammatory therapy. Neutrophils were prepared following standard procedures. Neutrophils induced by either fMLP (1 μM) or PMA (100 nM) were observed using a flow cytometer and the intracellular production of superoxide anions was investigated at different splitomicin concentrations. The cytosolic Ca++ influx concentration was measured using a fluorescence spec- trophotometer, and Mac-1 expression was detected with a flow cytometer. The MAP kinases were measured using western blotting. Our results showed that splitomicin inhibited superoxide anion production by fMLP (1 μM) and NaF (20 mM) in a concentration-dependent manner (37.5–450 μM). Splitomicin (300 and 450 μM) also suppressed fMLP-induced intracellular calcium ion mobilization and extracellular-signal regu- lated kinase (ERK) phosphorylation. Moreover, splitomicin could inhibit fMLP-induced Mac-1 expression and increase cAMP levels in human neutrophils. Our data demonstrated that splitomicin exhibits a noticeable inhibitory effect on superoxide anion production in human neutrophils. This negative effect was well- correlated with increased cAMP levels via PKA activity and the subsequent inhibition of ERK (p42/p44) phos- phorylation to decrease superoxide anion production.

PO 230

Prospective study of inflammatory biomarkers in patients undergoing peritoneal dialysis

Rios DRA[1], Velloso MSS[1], Lima SMA[1], Turani SAD[1], Rodrigues LSM[1], Pinheiro MB[1], Dusse LMS[2], Sabino AP[2], Gomes KB[2] and Pinto SW[3]

[1]Federal University of Sao Joao del-Rei, Divinópolis; [2]Federal University of Minas Gerais, Belo Horizonte; [3]Hospital Sao Joao de Deus, Divinópolis, Brazil

Background: Peritoneal dialysis (PD) is a kidney replacement therapy for patients in the end stage renal disease (ESRD). The PD has long-term complications, including inflammation, fibrosis and neoangiogenesis, which make this therapy ineffective for proper removal of solutes.
Aims: The aim of this study was to evaluate inflammation biomarkers in patients undergoing PD and to investigate the association with peritoneal solute transport rate (PSTR).
Methods: Forty-five patients who were under PD therapy for more than 6 months in the Nephrology Center of Hospital Sao Joao de Deus – Brazil, were eligible for this longitudinal study. IL-2, IL-4, IL-6, IL-10, IFN-γ, TNF-α plasma levels were measured, at baseline and after 6 months on PD, by flow cytometry (BD-FACSFortessa), using BD Cytometric Bead Array (CBA) Human Th1/Th2/Th17 Cytokine kit. PSTR of small solutes was evaluated using the dialysate-to-plasma ratio (D/P) of creatinine after a 4-h dwell. The Ethics Committee of the Hospital Sao Joao de Deus approved this study and written informed consent was obtained from all subjects. Statistical analysis was performed using SigmaStat 2.03 program and ANOVA test.
Results: At baseline 12 patients were classified as low-transporters, 25 as low-average transporter and 8 as high-average transporters. There was not difference between the respectively groups with regard to IL-2 (3.0 vs. 3.1 vs. 2.6 pg/mL), IL-4 (1.8 vs. 2.2 vs. 1.6 pg/mL), IL-6 (8.3 vs. 7.8 vs. 5.9 pg/mL), IL-10 (2.2 vs. 2.9 vs. 2.2 pg/mL), IL-17A (5.0 vs. 7.3 vs. 5.1 pg/mL), TNF-α (2.0 vs. 2.5 vs. 2.2 pg/mL) and INF-γ (3.2 vs. 3.5 vs. 2.8 pg/mL) plasma levels. Of the 45 patients, 12 (26.6%) were increased of the PSTR after 6 months follow-up. However, no significant changes were observed for cytokines levels during this time.
Summary/Conclusions: No association between inflammation markers and the PSTR in PD patients after 6 months follow-up was observed. Moreover, further studies with a larger number of patients need to be developed to better understand the pathogenesis of peritoneal dysfunction.
Supported by FAPEMIG, CNPq and UFSJ – BRAZIL.

PO 231

Role of protein S in murine model of allergic asthma

Takagi T[1], Onishi M[1], Chelakkot-Govindalayathil A[1], Hosoki K[1], Tetsu K[1], D'Alessandro-Gabazza CN[1], Morser J[2], Taguchi O[1] and Gabazza EC[1]

[1]Mie University Graduate School of Medicine, Tsu, Mie, Japan; [2]Stanford University Graduate School of Medicine, Stanford, CA, USA

Background: Protein S may exert an anticoagulant activity by enhancing the anticoagulant activity of activated protein C and/or by directly inhibiting the prothrombinase complex. Protein S itself may also directly regulate inflammatory responses and apoptosis. Recent studies have suggested that coagulation and anti-coagulation factors are associated with asthma, but the relationship between asthma and protein S is unclear.
Objective: To evaluate the effect of protein S in allergic bronchial asthma. On this purpose, we compared the development of bronchial asthma in wild type and human protein S transgenic mice.
Methods: Bronchial asthma was induced by sensitization and challenge with ovalbumin (OVA). Mice treated with saline were used as control. The effect of inhaled rhTM was assessedby administering it prior to OVA exposure. Airway inflammation was evaluated by measuring the number of inflammatory cells and the levels of cytokines in bronchoalveolar lavage fluid (BALF). Airway hyperresponsiveness was measured using a plethysmograph.
Results: Airway hyperresponsiveness was significantly decreased in protein S transgenic mice compared with their wild type counterparts. The number of eosinophils in BALF was decreased in protein S transgenic mice compared with their wild type counterparts.
Conclusions: These results suggest that protein S inhibits the development of bronchial asthma.

PO 232

Protective effect of thrombomodulin in murine asthma is dose dependent

Takagi T[1], Onishi M[1], Chelakkot-Govindalayathil A[1], Toda M[1], Tetsu K[1], D'Alessandro-Gabazza CN[1], Morser J[2], Taguchi O[1] and Gabazza EC[1]

[1]Mie University Graduate School of Medicine, Tsu, Mie, Japan; [2]Stanford University Graduate School of Medicine, Stanford, CA, USA

Background: Thrombomodulin (TM), the thrombin receptor on the endothelial cell surface, plays an important role in coagulation and inflammation by inactivating thrombin and activating protein C. Previously we reported that recombinant human TM (rhTM) is protective against murine asthma. However, the effect of different concentrations of rhTM on asthmatic inflammation remains unclear.

Objective: To evaluate the dose-dependent effect of inhaled rhTM on airway inflammation and hyperresponsiveness in a murine asthma model.
Methods: Bronchial asthma was induced by sensitization and challenge with ovalbumin (OVA). Mice treated with saline were used as control. The effect of inhaled low dose to high dose rhTM was assessedby administering it prior to OVA exposure. Airway inflammation was evaluated by measuring the number of inflammatory cells and the levels of cytokines in bronchoalveolar lavage fluid (BALF). Airway hyperresponsiveness was measured using a plethysmograph. Particle size distribution of each different rhTM was measured by Spraytec.
Results: The number of eosinophils in BALF and airway hyperresponsiveness was decreased by rhTM in a dose-dependent manner compared to saline treated mice. rhTM concentration of 3.75 μg/ml was associated with the lowest number of BALF eosinophils and airway hyperresponsiveness, and with the smallest particle size.
Conclusion: These results suggest that the effect of rhTM in murine asthma is dose- and particle size-dependent.

PO 233

The role of ETX in the pathogenesis of vascular complications of diabetes

Wakabayashi N, Kimura M, Kanno Y, Kawashita E and Matsuno H
Doshisha Women's Collage of Liberal Arts, Kyo-tanabe, Japan

Background: Vascular complications of diabetes can be largely classified into macroangiopathy such as cardiovascular disease, stroke, and peripheral artery disease, and microangiopathy such as diabetic nephropathy. Preventing the complications of these vessels can significantly improve on QOL. However, the progression of vascular complications mechanism remains unclear.
Endotoxin (ETX) is a lipopolysaccharide (LPS) in the gram-negative bacteria of the outer membrane of the cell wall, and is recognized as a causative agent of lethal shock, high fever, DIC, etc. ETX contributes to acute and chronic inflammations, and triggers the innate immune response characterized by cytokine release and immune system activation. It was known that ETX induce reduce the dysfunction of the kidney.
Aim: The aim of this study was to clarify the role of ETX in vascular complications of diabetes.
Method: We obtained individual informed consent in the Traditional Outpatient Department for Diabetes, Internal Medicine, Shiga University of Medical Science from 2005 to 2011 upon obtaining approval from the ethics committee of the university, and measured the amounts of ETX in the blood (343 patients).The study protocol is in accordance with the Declaration of Helsinki.
Insulin resistance model mice by the ingestion of 70% glucose solution for 4 weeks were used in this study, insulin resistance in mice was confirmed by Oral Glucose Tolerance Test (OGTT). We measured the blood flow in the tail of mice by using the Doppler blood flow meter, and then. We also examined the amount of ETX in the blood and kidney.
Result: We found that ETX was detected in the blood of 148 patients with type 2 diabetes, and the patients who are detected ETX was also significantly increased the level of urine albumin compared with undetected patients. ETX was detected in the blood and kidney of insulin resistance model mice. We also found that the blood flow of the insulin resistance model mice was significantly reduced compared with controls.
Conclusion: We found that ETX was detected in blood of patients in type 2 diabetes, the renal function in the patients was significantly reduce. We also found that ETX was detected in blood and kidney of insulin resistance model mice, the function of the blood vessel was reduced. These data suggest that ETX may plays a pivotal role in the pathogenesis of vascular complications of diabetes.

PO 234

Venous thrombosis and the incidence of factor V Leiden and factor II A20210 mutation in the cardiac pacing patients

Domagala TB[1], Lelakowski J[2], Janczura M[2], Dziedzina S[1], Iwaniec T[1], Rydlewska A[2] and Musial J[1]
[1]*Jagiellonian University School of Medicine, Krakow, Poland;* [2]*The John Paul II Hospital, Krakow, Krakow, Poland*

Background: The pathogenesis of venous thrombosis (VT) is multi-factorial, involving the acquired and genetic factors. Additionally to the predisposing factors (e.g. pacemaker implantation), genetic predisposition due to molecular abnormalities of the coagulation pathway components have been encountered in the subjects with thromboembolic disease. In the patients of European ancestry, common mutations within the coagulation factor V (FV Leiden) gene and the factor II (G20210A prothrombin mutation) gene have been demonstrated to account for a large number of thromboembolism cases. There is a scarcity of studies focused on the contribution of genetic risk factors to VT (i.e. FV Leiden and G20210A prothrombin mutation) in the cardiac pacing patients.
Aim: To assess whether FV Leiden and G20210A prothrombin mutation are associated with venous thrombosis in the cardiac pacing patients.
Methods: The study group comprised 95 subjects (38 females, mean age 71 $\pm$ 7.58 years) with a cardiac pacemaker. Cardiac pacemakers were implanted due to SSS, AVB (II, III gr.), atrial fibrillation cum brady-arrhythmiae, respectively. All subjects were subsequently followed up for 18 months, whereupon in 10 subjects VT developed. Subjects were divided according to the non-occurrence (Group A; $n = 85$; mean age 71.2 $\pm$ 7.6 years) or occurrence (Group B; $n = 10$; mean age 72.6 $\pm$ 7.2 years) of VT in the post-implantation period, respectively. A transthoracic echocardiogram (TTE) and a venous ultrasound examination were performed.
Screening for FV Leiden and the G20210A prothrombin mutation were carried out by standard methods. Also the levels of D-dimers, fibrinogen, tissue factor (TF), factor VII, plasminogen activator inhibitor-1 (PAI-1), interleukin-6 (IL-6) and hsCRP) were determined before and at the 7th day, within 6 and 12 months after pacemaker implantation, respectively.
Results: The two groups did not differ with respect to the pacing mode. The symptoms of VT occurred in 10 subjects in Group B at a mean of 13.06 months (7–17 months), i.e. in 11.76% of the entire study population. The subclavian and brachiocephalic veins on the pacemaker side were occluded. Three subjects (20.0%) in Group A and six subjects (7.0%) in Group B were the carriers of FV Leiden ($P = 0.01$), whereas 3 (3.5%) subjects in Group A had the G20210A prothrombin mutation.
Initially, the plasma levels of prothrombotic (D-dimers, fibrinogen, TF, factor VII, PAI-1) and proinflammatory (IL-6, hsCRP) markers were appreciably higher in Group B than in Group A ($P < 0.001$). In all study subjects the values continued to rise until the 7th day after pacemaker implantation. Within 6 and 12 months after the procedure the trend towards increasing the plasma levels of these markers was observed in Group B only. In Group A the levels returned to normal.
Conclusion: It is highly recommendable that all cardiac pacing patients be screened for FV Leiden and G20210A prothrombin mutation. Coexistence of FV Leiden with the acquired VT risk factors increases the risk of thrombosis after pacemaker implantation.

PO 235

Impact of inherited thrombophilia on the risk of recurrence venous thromboembolism (VTE) in Georgian population

Makhaldiani L[1], Pirtskhelani N[2], Kochiashvili N[2], Pargalava N[3], Gaprindashvili E[1] and Kartvelishvili K[2]

[1]Institute of Hematology and Transfusiology; [2]National Forensics Bureau; [3]Georgian Centre of Angiology and Vascular Surgery, Tbilisi, Georgia

Background: Factor V Leiden (1691G/A) and prothrombin gene mutations (20210G/A) are the most common genetic markers that predispose to a first episode of venous thromboembolism (VTE). However, whether the presence of these mutations confer an increased risk of recurrent venous thromboembolism is controversial.
Methods: A total of 70 patients with venous thromboembolism were genotyped by PCR analysis for the prothrombin gene (PTH) mutation and factor V Leiden (FVL) and were followed prospectively for recurrent VTE.
Aim: The aim of the present study is to estimate the impact of inherited thrombophilia on the risk of recurrence venous thromboembolism (VTE) onset in Georgian population.
Results: A total of 26 patients (37%) suffered recurrent VTE, while the rest of the patients 44 (63%) had the first episode of venous thromboembolism. In 20 patients out of 70 were found the genetic markers of inherited thrombophilia. In 10 patients (38%) out of 26 with recurrent venous thromboembolism were detected mutations that predispose to inherited thrombothilia, while in 44 patients with first episode of venous thromboembolism, mutations were identified in only 23% of cases. Thus, presence of mutations in patients with inherited thrombophilia were associated with increased risk of recurrent VTE. In these data, the recurrence rates were higher among those with the factor V Leiden (8 patients with reccurent VTE had factor V Leiden and 2 patients had both, factor V Leiden and prothrombin gene mutations. The results also showed the presence of double heterozygous of FVL and PTH mutations in the group of patients with recurrent VTE.
Conclusions: In a prospective evaluation of 70 patients, the presence of inherited thrombophilia was associated with a significantly increased risk of recurrent VTE, particularly among those with factor V Leiden mutation. Differently from other populations the role of mutations responsible for development of inherited thrombophilia in the pathogenesis of recurrent VTE has not been yet studied in Georgian population. The preliminary studies of mutations indicate that the investigated mutations significantly increase the risk of onset of recurrence venous thromboembolism (VTE) in Georgian population. The future investigations in this area would be especially important.

PO 236

Familial screening in the case of Budd-Chiari syndrome with multiple thrombi due to Arg42Ser mutation in the protein C gene

Muratsu J[1], Morishima A[1], Kukida M[1], Tanaka A[1], Fan X[2], Miyata T[3] and Sakaguchi K[1]

[1]Sumitomo Hospital, Osaka, Japan; [2]National Cerebral and Cardiovascular Center; [3]National Cerebral and Cardiovascular Center, 5-7-1, Fujishirodai, Suita, Osaka, Japan

Background: Protein C is the precursor of a vitamin K-dependent serine protease that plays an important role in the regulation of blood coagulation. Heterozygous protein C deficiency is inherited in an autosomal dominant fashion, and hereditary deficiency in this protein is associated with a high risk of thrombotic disease. Patients with protein C deficiency are at increased risk of recurrent venous thrombo-embolic events. A C-to-A substitution at nucleotide number 1387 within exon III of the protein C gene (*PROC*) is designated protein C Osaka 10. A c.125C>A change was identified in the proband and encodes an Arg42-Ser mutation. Arg42 is located at the cleavage site recognized by the enzyme that normally processes protein C to its active form. On the other hand, the frequency of heterozygous protein C deficiency may be as high as 1/200 to 1/500 in healthy adults; however, those affected do not exhibit thrombotic manifestations. Thus, the contribution of protein C deficiency to thrombogenicity remains to be determined.
Aim: We investigated the contribution of Arg42Ser mutation to thrombogenicity. We analyzed difference between the patients complicated thrombosis and no thrombosis with the same *PROC* mutation.
Methods: A 34-year-old Japanese female was admitted to our hospital for Budd-Chiari syndrome with multiple venous thrombi caused by an Arg42Ser mutation in *PROC*. We investigated genetic analysis of family members and analyzed their character.
Result: An Arg42Ser mutation in *PROC* was also identified in the patient's father and younger brother, whereas the sequence of her mother's DNA in this region was found to be wild-type. The levels of total cholesterol and LDL cholesterol in our patient were higher than those of her younger brother and father. Idiopathic high levels of hepatic enzymes were detected in our patient's younger brother as well as her father, both of whom exhibited hypertriglyceridaemia.
Summary/Conclusions: Our present study reveals that the patient's brother or father did not experience thrombotic events, even though they harbored the same Arg42Ser mutation in *PROC* with a concomittant decrease in protein C activity. We suggest two hypotheses to account for the absence of detectable thrombosis in our patient's family members, despite these individuals harboring the same mutation as our patient with a concomittant decrease in protein C activity. The first hypothesis maintains that elevated levels of total cholesterol may be a risk factor for venous thromboembolism (VTE). Moreover, in this case, we noted no recurrence of thrombosis after statins were administered to our patient for 18 months. Our second hypothesis maintains that levels of protein C activity were elevated by physiological increases in the levels of triglycerides and hepatic enzymes, findings consistent with a report that protein C activity is relatively high in patients with hypertriglyceridaemia.

PO 237

Protein C deficiency: a case study

Timova T, Kocovska E, Stambolieva D, Malinova T, Maninska L, Gorgevska V, Ortakovska S and Vitlarova J

Institute of transfusion medicine of R.Macedonia, Strumica, Macedonia

Background: The inherited thrombophilias are a heterogeneous group of genetic disorders associated with an elevated risk of venous thromboembolism (VTE). Causes of inherited thrombophilia include the factor V Leiden mutation, the protrombin gene mutation, dysfibrinogenemia, and deficiencies of protein C, protein S, and antithrombin III. The function of protein C is to inactivate factor Va and factor VIIIa.
Aims: Protein C deficiency by plasma level alone is found in 1 in 200 to 1 in 500 persons in the general population. However, many affected individuals remain asymptomatic throughout life. Protein C deficiency is present in approximately 2–5% of patients presenting with VTE. This case report has demonstrated an increased risk of multiple venous thromboembolic disease in patients with protein C deficiency.
A case study: A 55-year-old woman got pain in the left hypohondrium accompanied by fever. She was hospitalized and during her stay in the hospital she started complaining about pain in her left lower leg.
Results: A CT of the abdomen and thorax was performed and it showed the following findings: a) The scanned part of the chest shows a small pleural effusion on the left side, with small plate-like atelectasis; b) On the level of mediastinum trunkus pulmonalis with defects in filling the lobar and segmental parts which points to pulmonary thromboemboly; c) Abdominal aorta with defects in filling (possible thrombosis) in the length of 5.4–1.8 sm proximally from trunkus celia-

cus; d) Liver, gallbladder and pancreas with normal findings; e) Spleen with diffuse hypodense zones with different sizes which do not show colouring after application of i.v. contrast and point to infarct zones; f) The other organs in the small pelvis are KT regular. A colour Doppler sonographic screening of the circulation of the lower extremities showed DVT of the left lower leg. EKG and Ehocardiogpraphy of the heart with normal findings. Laboratory tests (coagulatory and biochemical) with the following findings: lightly increased cholesterol 5.45 (3.50–5.20), LDH 660 (208–378), D-Dimeri positive (3200 ng/ml), PT, aPTT and TT point to hypercoagulation condition. Diagnosis: DVT of the lower leg, Pulmonary thremboemboly, Thrombosis of the abdominal aorta, Infarct of the spleen. The therapy was as follows: LMWH (Low Molecular Weight Heparin) in therapeutic doses together with oral anticoagulant therapy for 10 days until achieving a therapeutic INR (target 2.5; range 2.0–3.0) as well as acetylsalicylic acid of 100 mg per day. The control tests performed after 1 month show slight regression in relation to the previous CT findings. Further tests for exclusion of neoplastic processes were carried out as well as genetic tests for hereditary thrombophilia. A heterozygous deficit of Protein C was determined.

Conclusion: The risk of VTE increases with age and among heterozygotes thrombosis is unusual before age 20 years. Treatment of a patient with protein C deficiency depends upon the individual patient's risk of thromboembolic disease. Patients that have had multiple thromboembolic episodes or are at high risk of further episodes may be considered for long-term oral anticoagulation therapy.

PO 239

Platelets function as enhancers of the dendritic cell-mediated allergic response

Ito T, Nakanishi T, Inaba M and Nomura S

Kansai Medical University, Moriguchi, Japan

Dendritic cells (DCs) are widely distributed in the body to enhance the innate immune response by cytokine production through antigen recognition and initiate acquired immunity by priming naïve $CD4^+$ T cells. Thus, DCs are the master cells in activating immune responses. Recently, it has been demonstrated that the interaction between thymic stromal lymphopoietin (TSLP) and human DCs plays an essential role in evoking inflammatory Th2 responses in allergy through expression of CCL17 by DCs, which recruits memory Th2 cells to the skin.

Meanwhile, platelets represent an important linkage between inflammation, thrombosis, and atherosclerosis. Platelets express many immune mediators such as cytokines and TNF superfamilies. However, few researchers have suggested that platelets have the ability to modulate DC-mediated immune responses.

We newly demonstrated that TRAP (thrombin receptor agonist peptide)-activated platelets expressed RANKL that is a molecule expressed on activated T lymphocytes working to maintain survival and maturation of DCs. The activated platelets promoted CD86 expression on DCs through the RANKL. We further clarified that the activated platelets enhanced the production of CCL17 induced by the DC stimulated with TSLP. Thus, platelets have the ability to enhance the DC-mediated Th2 response and may contribute to the allergic inflammation. In conclusion, our study may provide new insights of platelet function into the possible mechanism of allergic response that stems from DCs.

PO 240

Modern approach for the detection of pulmonary embolism and our results of it surgical cure

Medvedev AP[1], Nemirova SV[1], Melnikov NY[1], Pichugin V[1] and Bokarev IN[2]

[1]Nizhny Novgorod State Medical Academy, Nizhny Novgorod; [2]I.M. Sechenov First Moscow State Medical University [MSMU], Moscow, Russia, Moscow, Russia

Background: More than 6 500,000 people worldwide died from pulmonary embolism every year. According M.Verstaete 65% of Pulmonary Embolism were not diagnosed.

We propose to begin to think about the possibility of PE at the early stage as the patients is admitted to ICU of the Hospital and according with the ECG, and cardiac enzimes to do the PA blood pressure at once. If it increased to do. KT with contrasting.

The aim of our study was to develop indications to pulmonary embolectomy and to evaluate results of surgical treatment of PE.

Material and Methods: From January 2007 to September 2012, 239 patients with suspicion on massive PE were sent to our hospital. Diagnosis of PE was confirmed in 175 patients.

Intravenous infusion of thrombolytic agents under dynamic ultrasound control in combination with symptomatic intensive therapy was used in patients with moderately expressed signs of an overload or dysfunction of the right ventricle, pulmonary artery pressure below 50 mm Hg, and absence of intracardiac (thrombus) pathology. Indications to pulmonary embolectomy was: PE of high risk with the right ventricle dysfunction and PAP more than 50 mm Hg, the presence of absolute contraindications to thrombolytic therapy or its inefficiency, the presence of intra cardiac blood clot, and also the central or mixed localization of blood clots in pulmonary artery.

Methods: Seventy-seven patients with acute massive PE were operated. Disease duration from the moment of the first clinically significant episode of PE was in average 5.3 ± 1.7 days. Operation in all these cases was emergent. Hospital mortality rate was 5.19%. The condition of 73 patients was satisfactory, breathing rate at rest was 16–18 in a min, pressure in PA decreased to 23.8 ± 7.0 mm Hg. The choice of a method of an open embolectomy depends on localization of thromboemboli in the pulmonary artery tree and the right heart, and also on presence of accompanying intra cardiac pathology.

We consider justified embolectomy without cardiopulmonary bypass in general surgery hospitals in case of the isolated unilateral embolic defeat of large pulmonary arteries. We give preference to operation with artificial blood circulation in specialized departments of cardiovascular surgery in case of bilateral defeat. It should be noted that thrombolytic therapy before operation isn't contraindication to surgical treatment. Conclusion. Thrombolytic therapy demands constant monitoring of the patient condition, thus the echocardiography is highly informative, safe and available method of the research, allowing to define further tactics of maintaining patients with PE and to define indications to surgery. Surgical treatment of PE is 'a method of the second line', applied in case of impossibility or an inefficiency of thrombolytic therapy.

PO 241

Treatment of occluded stented segments in the venous system by ultrasound accelerated catheter directed thrombolysis

Strijkers HW, De Wolf MA, Arnoldussen CWKP, De Graaf R, Ten Cate-Hoek AJ and Wittens CHA

MUMC+, Maastricht, The Netherlands

Introduction: Stent placement in the venous system is an increasingly used treatment modality in chronic venous obstruction as well as additional treatment after thrombolytic therapy in iliofemoral DVT. Reocclusion of the recanalized venous tract in these patients is the most

important complication and manifests as a rethrombosis of the stented segments in up to 51% of cases. Reocclusion mostly occurs within the first 6 months after stent placement. We report on our experience in treating in-stent (re) thrombosis with ultra-sound accelerated catheter directed thrombolysis in patients referred to our tertiary center.
Methods: Retrospective analysis of patients treated for venous stent occlusion, after PTA and stent placement for either chronic venous occlusive disease or persistent vein compression in patients with acute DVT. Duration of the occlusion and suspected clot age were assessed using patient complaints and typical findings on duplex ultrasonography (DUS). DUS and venography were used to assess patency of the venous tract and to determine the cause of reocclusion. Acute treatment of occlusion consisted of ultrasound accelerated catheter directed thrombolysis. Additional procedures included: PTA, stent placement, and creation of an arteriovenous-fistula.
Results: We identified 12 patients from our database who were treated between January 2009 and October 2012. Mean age was 38 (16–54), and 50% were male. In four patients May-Thurner syndrome was found. Four presented with C1 disease, 1 with C2, 3 with C3, 2 with C4 and 1 with C5. Indications for stenting were; treatment of underlying obstruction after initial thrombolysis in acute DVT in five patients and treatment of chronic venous obstructive disease in seven patients. Technical success was achieved in 67% of patients. Complications during the intervention were; minor bleeding complications in two patients, positive blood cultures for staphylococcus aureus in one and a heparin-induced thrombocytopenia in one. Patency rate was 67%, as all successfully treated segments remained patent, during a mean follow-up of 10 months (1–24). Additional treatments were; restenting in four patients and creation of an arteriovenous fistula in three patients.
Conclusion: Treatment with catheter directed thrombolysis of thrombosed stent tracts is feasible and safe, in this population with complex secondary venous disease. Adequate treatment of these underlying causes of rethrombosis after stenting yields excellent patency rates.

PO 242

Polyphosphatehosphate is an haemostatic agent *in vivo*

Larsson M, Labberton L, Österholm Corbascio C, Nickel KF and Renné T

Karolinska Institutet, Stockholm, Sweden

Background: Polyphosphate is an inorganic polymer of linear linked phosphate units that is abundantly found in nature and used in technical processes. Polyphosphate are procoagulant mediators in plasma.
Aims: Here, we analyzed synthetic polyphosphate of 70 phosphate units of as hemostatic agent in clinical relevant bleeding models in swine.
Methods and Results: Polyphosphate efficiently initiated real time thrombin formation in a factor XII-dependent manner in plasma. Topical applied polyphosphate terminated bleeding from liver and spleen wounds similarly to fibrin sealant or factor XII activator Kaolin and largely reduced blood loss, whereas tri-phosphate was inactive. Electron microscopy, histology and immunohistochemistry revealed that polyphosphate triggered fibrin meshwork formation and improved fibrin fiber structure at the wound site. Polyphosphate-triggered inflammatory leukocyte recruitment, edema and vessel activation was minor. Polyphosphate was degraded to inactive fragments with a half-life of 2 h by plasma-borne phosphatases.
Summary/Conclusion: The data identify polyphosphate as an inexpensive hemostatic agent with broad therapeutic implications.

PO 243

Hemorrhagic diathesis in patient with multiple myeloma – case report

Lisá L, Plamenová I, Hollý P, Sokol J, Staško J and Kubisz P

Jessenius Medical Faculty Comenius University, Martin, Slovakia, Martin, Slovakia

Background: Myeloma cells usually produce the monoclonal immunoglobulin (M-Ig; paraprotein) that interferres with platelets and causes thrombocytopathy. On other hand it acts in the coagulation cascade, prolongs the basic coagulation tests and clinically leads to the complex disorder of hemostasis associated with the very high risk of bleeding.
Case-report: Authors describe a case of 62-years old patient with mutiple myeloma and hemorrhagic diathesis. In the significant hyperproteinemia and paraproteinemia were found in the laboratory tests (the total serum proteins 122 g/L). Because of abnormal level of M-Ig that interferred with the coagulation factors prolonged standard coagulation tests were detected – slightly prolonged prothrombine time (PT; 70% INR; 1.17), more prolonged activated partial thromboplastine time (APTT; 40.1 s) and not measurable thrombine time (TT; more than 3 min). In full blood count severe thrombocytopenia was found. These laboratory findings were clinically manifested as an extensive hematomas in axillar and thoracic regions, with the size of 22 × 8 cm on the left, and 14.5 × 6 cm on the right. The patient underwent the standard treatment to stop bleeding (hemostyptics, transfusions of thrombocytes concentrates, fibrinogen), except transfusion of fresh frozen plasma which was contraindicated due to severe hyperproteinemia. In spite of this treatment and repeated transfusions of erythrocytes concentrates signs of circulatory instability became evident. Surgical hemostasis was repeatedly contraindicated by vascular surgeon due to severe thrombocytopenia and coagulopathy. Therefore the recombinant activated factor VII (rFVIIa) was used. Effect of this factor – shortening the standard coagulation times except of the thrombine time – was obvious after first intake of rFVIIa. Several doses of the rFVIIa were needed. In spite of normalized laboratory findings the control computer tomography of chest revealed progression of the bleeding. On other hand the clinical performance status of patient was improved and lower need of the transfusion treatment was detected. The treatment with rFVIIa continued till stabilization of patient (the total dose 45 mg of rFVIIa).
Conclusion: None of the standard coagulation tests may monitor the effect of the rFVIIa treatment and hemostasis status *in vivo*. The standard coagulation tests were not helpful in the management of the massive or life-threatening bleeding in patient with the multiple myeloma.

PO 244

The effect of adenosine/lidocaine/Mg2+ on correcting coagulopathy following traumatic hemorrhagic shock

Pecheniuk NM[1], Letson HL[2], French S[1] and Dobson GP[2]

[1]*Queensland University of Technology, Kelvin Grove, Brisbane;* [2]*James Cook University, Townsville, Australia*

Background: Previous studies have shown that the use of Adenocaine® (adenosine and lidocaine) and Mg^{2+} can rescue and stabilize the heart during hypotensive resuscitation and provide a full correction of coagulopathy (reversal of aPTTand PT) in a severe hemorrhage rat model.
Aims: To shed light upon the potential mechanisms of action of adenocaine®/Mg^{2+} on the reversal of coagulopathy as observed in our hemorrhagic shock rat model, we have investigated if adenosine, lidocaine and magnesium has an effect on *in vitro* coagulation in human plasma.
Methods: APTT and PT clotting times in human pooled normal plasma were examined at doses, up to 5 mM each, of adenosine, lidocaine and magnesium and combinations thereof.
Results: APTT clotting times in human pooled normal plasma were significantly shortened upon increasing concentration of lidocaine 0–5 mM ($P = 0.029$) and $MgSO_4$ ($P < 0.0001$). Dose analysis of adenosine (0–5 mM) showed no difference in APTT. No significant

differences in PT clotting times were observed with adenosine, lidocaine or magnesium sulphate (0–5 mM) in human normal pooled plasma. The combined use of adenosine:lidocaine:magnesium (1:3:2.5 mM) decreased the APTT and PT clotting times by an average of 4 and 2 s, respectively. The doses tested here are approximately 30 times higher than what would be present in the circulation of our rat hemorrhagic shock model after bolus infusion of the Adenocaine®/Mg^{2+}, for which our previous studies indicated correction of APTT and PT clotting times. These differences observed between our present and previous studies may be attributable to variations between the *in vitro* and *ex vivo* analysis and between the two species.

Summary: Our previous investigations concluded that Adenocaine®/Mg^{2+} has coagulation restorative properties in addition to being able to rescue and stabilize the heart. The present findings suggest that the correction of APTT and PT clotting times observed in the rat are either not due to the effect of increasing adenosine, lidocaine or magnesium alone or in combination, relying other physiological factors operating during traumatic hemorrhagic shock, or are not necessarily transferrable to the human situation. The mechanisms of this resuscitation regime on coagulation parameters warrant further investigation.

PO 245

Fibrinogen therapy of severe bleeding based on whole blood rotational thromboelastometry

Spiezia L, Maggiolo S, Campello E, Bon M, Pelizzaro E and Simioni P

University of Padova, Padova, Italy

Background: Fibrinogen is an under-recognized coagulation factor critical for producing effective clot in surgical patients. Moreover, fibrinogen plasma levels are reported to be predictive of perioperative bleeding. Although, the normal fibrinogen plasma levels are between 200 and 400 mg/dL, the target fibrinogen level in a bleeding patient is not known. Most transfusion algorithms recommend supportive therapy with fibrinogen when plasma levels are less than 100 mg/dL. In this situation, fibrinogen concentrates is a better option than fresh frozen plasma or cryoprecipitate to restore adequate fibrinogen plasma levels. Perioperative monitoring of blood coagulation is critical to better understand causes of hemorrhage, to guide hemostatic therapies, and to predict the risk of bleeding during the consecutive anesthetic or surgical procedures. Point-of-care coagulation monitoring devices assessing the viscoelastic properties of whole blood (i.e. rotation thromboelastometry), may overcome several limitations of routine coagulation tests in the perioperative setting.

Aim: The aim of this retrospective study was to evaluate in a cohort of adults with severe bleedings, treated with fibrinogen concentrates, the effects in terms of red blood cells (RBC), plasma, platelets and fibrinogen administration, 30 days mortality and recovery time in intensive care units, if the indication to treatment with fibrinogen was based on thromboelastometry or on the fibrinogen plasma level.

Methods: We retrospectively evaluated 81 consecutive patients with acute severe bleeding, which had necessitated supportive therapy with fibrinogen concentrate. In 40 patients (cases) fibrinogen was administered according to thromboelastometric profile (ROTEM®) and 42 (controls) the administration of fibrinogen was based on the determination of plasmatic fibrinogen according to the test of Clauss.

Methods: We observed a consumption of RBC (14 ± 8 vs. 12 ± 8 U), plasma (12 ± 8 vs. 9 ± 6 bags) and platelets (1 ± 2 vs. 1 ± 1 bags) similar (P = ns) in cases and in controls. The average amount of administered fibrinogen was significantly higher in patients monitored with ROTEM® compared to the control group (6 ± 3 vs. 4 ± 3 g, $P < 0.05$). In cases we observed a lower 30 day mortality than in the control group (28% vs. 37%) and a lower recovery time in intensive care units (12 ± 10 vs. 17 ± 15 days). These differences have not proved statistically significant.

Conclusions: The data of our study, although preliminary, indicate that the amount of fibrinogen administered according to the results of thromboelastometry was higher than that given by the value of the plasma fibrinogen obtained by the Clauss method. This difference could improve patient outcome in terms of 30 days mortality and recovery time in intensive care units. Prospective and larger studies are needed to confirm the results of our study.

PO 246

BDNF acts as an autocrine cell proliferation factor in TPO stimulated megakaryocytic cell line

Tamura S[1], Moriyama T[1], Matsuno K[1], Suzuki-Inoue K[2] and Ozaki Y[2]

[1]Hokkaido Univesity, Sapporo; [2]University of Yamanashi, Chuo, Japan

Background: While human platelets contain brain-derived neurotrophic factor (BDNF) and release it upon activation, a previous report on MEG-01, a megakaryocytic cell line, found no trace of BDNF production, and the pathophysiological function of platelet BDNF has remained elusive.

Aims: We sought to investigate whether MEG-01 can produce BDNF under various conditions. Furthermore, to examine the pathophysiological function of BDNF on megakaryocytic lineages, we evaluated the effect of BDNF on proliferation and polyploidization of MEG-01.

Methods: MEG-01 cultured with or without thrombopoietin (TPO) was subjected to western blot analysis to detect BDNF in MEG-01. Proliferation of MEG-01 stimulated with TPO, BDNF, or the combination of TPO and BDNF was accessed in the presence or absence of BDNF neutralizing antibody. Polyploidization assay was performed by measuring DNA contents of MEG-01 cultured with TPO and/or BDNF using flow cytometry with propidium iodide staining.

Results: Western blot analysis revealed no BDNF signal in MEG-01 in the absence of TPO, whereas BDNF production was clearly detected in MEG-01 stimulated with TPO. In proliferation assay, TPO added to the cell culture increased the cell number, and BDNF alone also accelerated MEG-01 proliferation. The combination of TPO and BDNF further accelerated MEG-01 proliferation. A BDNF-neutralizing antibody significantly suppressed cell proliferation of MEG-01 stimulated with TPO, suggesting that BDNF serves as an autocrine proliferation factor. On the other hands, BDNF did not positively affect the ploidy of MEG-01.

Conclusions: In this study, we demonstrate that MEG-01 produces BDNF in the presence of TPO and that it serves to potentiate cell proliferation without changing its ploidy. Our *in vitro* findings suggest that BDNF regulates MEG-01 proliferation in an autocrine manner, and that BDNF may be a physiological autocrine regulator of megakaryocytic progenitors, constituting a family of megakaryocyte-colony stimulating factors (MEG-CSF).

PO 247

Comparison of platelet microparticles quantification between patients with Alzheimer disease and individuals without cognitive impairment

Gonçalves GS[1], Campos MF[2], Duarte RCF[1], Martins-Filho OA[2], Caixeta L[1], Dusse LMS[1], Silveira JN[1] and Carvalho MG[1]

[1]Federal University of Minas Gerais; [2]Centro de Pesquisas René Rachou – Fiocruz, Belo Horizonte, Brazil

Introduction: Microparticles (MP) are small membrane fragments that are released during cell activation and apoptosis. Once MP are formed, they can move carrying membrane proteins from their cell of origin. The most common MP are derived from platelets. Increased number of platelets MP has been observed in patients who have an increased platelet activation as in Alzheimer disease (AD). Considering that senil plaques in the brain are formed by β amyloid and that

platelets are the main source of the amyloid precursor protein (APP) in the blood of humans, it can be assumed that platelet activation in patients with AD may contribute to the pathogenesis of this disease. This study describes the initial attempts made in characterizing the phenotype of PMP in AD.

Objective: To investigate whether levels of platelet microparticles (PMP) in the blood of patients with Alzheimer's disease (AD) are increased comparing to individuals without cognitive impairment (controls).

Methods: The study was approved by the ethics committee at the Federal University of Minas Gerais (UFMG), Brazil, and blood samples of the participants were collected after informed consent by themselves or relatives. PMP were determined in plasma from 118 subjects with similar age and socioeconomic status (AD, $n = 59$ and controls, $n = 59$), selected in the University Hospital at the UFMG, by flow cytometric technique using Annexin V (capable of recognizing phosphatidylserine present on the surface of PMP). Furthermore, it is also used PE fluorochrome for labeling of monoclonal antibodies against CD41a platelet surface. PMP isolated from plasma were then analised according to the size and granularity.

Results: No significant difference in the values of PMP (%) between the control group (27.6%) and DA (28.3%) was found. The lack of significant difference between the two groups might be partially attributed to the lifestyle changes of patients with Alzheimer disease, namely diet controlled by family members and caregivers. The use of medications that decrease platelet activation by these patients may also have a role. However, the lack of platelet profile data before installing the DA preclude any inference about the possible correlation between the plasma level of PMP and development of this devastating disease.

Conclusion: PMP levels in plasma samples were not different between control and Alzheimer disease groups, with considerable results overlapping in both groups.

Supported by CNPq, CAPES and FAPEMIG – BRAZIL.

PO 248

Identification and isolation methodologies for blood microparticles

Saunder X[1], Monagle P[2] and Ignjatovic V[1]

[1]Murdoch Childrens Research Institute; [2]The University of Melbourne, Parkville, Australia

Background: Blood microparticles have been shown to be involved in a number of disease processes such as inflammation, vascular injury, angiogenesis and thrombosis. There have been extensive studies conducted into the quantification and characterization of microparticles and their association with certain disease processes. However, the methods used to study microparticles have lacked standardization, and the optimal protocols remain unclear, making it difficult to compare results across different studies.

Aim: To review published methods used for isolation and characterisation of microparticles in human blood.

Methods: The PubMed database was searched using the search terms: microparticles, endothelial, method, protocols, blood, platelet, isolation for the 5 year period of 2008–2012.

Results: Blood samples are typically collected in the atraumatic fashion with a large needle (19G or 21G), to reduce stress and endothelial reaction. In order to avoid contamination the first 3 ml is usually discarded, while the remainder is collected in a vacutainer containing citrate (0.105–0.129 M). Centrifugation parameters tend to have the most variation in the overall testing for microparticles. Strategies ranged from a two step centrifugation process to detecting microparticles directly from the platelet poor plasma, the rationale behind the different approaches included whether to run the risk of losing microparticles through centrifugation. Storage of the microparticles following centrifugation was achieved by a variety of freezing processes as this step was shown not to affect the microparticle count. The most frequently used are snap freezing in liquid nitrogen as well as freezing samples at -80 °C.

Detection of microparticles is accomplished by utilizing the expression of antigens on the surface of the various forms of microparticle, i.e. endothelial-derived (EMP), platelet-derived (PMP), leukocyte-derived (LMP) and exposing them to their complementary antibody. PMPs are detected mainly by CD31, CD41 and CD42 antibodies; LMPs are detected by the CD45 antibody; EMPs are detected by CD144, CD62E, CD146, CD54, CD31, CD105 and vWF antibodies. As PMPs and EMPs are both detected by CD31, this can be exploited to identify EMP in platelet free plasma by using CD31 +/CD41- marker.

Conclusion: There are multiple protocols utilized for microparticle isolation and characterisation. Standardisation is crucial in studying these important cellular elements, if we are going to be able to compare results of various studies.

PO 249

Prothrombotic microparticles concentration after percutaneous coronary intervention and stent implantation

Zawilska KM[1] and Wachowiak J[2]

[1]J.Strus Hospital; [2]Regional Hospital, Poznan, Poland

Background: Platelet activation accompanying numerous diseases as well as medical procedures can result in thrombotic complications. Microparticles (MP) are shedded upon platelet activation, and may be used to assess platelet function.

Aims: To measure MP concentration in the plasma of patients (pts) with coronary artery disease (CAD) taking aspirin and clopidogrel, before as well as after elective percutaneous coronary intervention (PCI) with or without stent implantation.

Methods: One hundred and thirty pts (76 men, 54 women) with CAD. During elective PCI stent implantation (bare-metal stent or drug-eluting stent) has been performed in 35 pts. MP concentration was measured using ZYMOPHEN MP-Activity test of HYPHEN BioMed Research Company before, 24 h and 1 month after PCI. In the control group there were 26 healthy blood donors not taking antiplatelet drugs.

Results: The influence of PCI and stent implantation on the generation of prothrombotic microparticles (MP) has been presented in tables 1 and 2. (M-men; W-women; MPc – microparticles concentration, VC-variation coefficient).

Table 1: MP concentration in plasma (nM) in patients subjected to percutaneous coronary intervention.

Table 2: Variation of MP concentration in plasma in patients subjected to percutaneous coronary intervention.

The mean microparticles concentration in the control group was 4.2 ± 2.3 nM.

Conclusions: Microparticle concentration in patients with coronary artery disease was higher than in the control group. In women it increased after coronary angiography, and in men after stent implantation. The average results did not exceed the values regarded as normal, 20% of results were > 10 nM, considered as the cut-off value for pathological results.

PO 250

Anticoagulant activity of sulfated polysaccharides from the green seaweed Cladophora falklandica

Arata P[1], Ciancia M[1], Kordich L[2] and Quintana I[2]

[1]Facultad de Agronomía, Universidad de Buenos Aires; [2]Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Buenos Aires, Argentina

Background: Some sulfated polysaccharides were found to have anticoagulant properties. Seaweeds from the Cladophorales synthesize sulfated xyloarabinogalactans. Aqueous extracts from *C. falklandica* showed as major constituents galactose and arabinose, and high percentage of sulfate. Taking into account the increasing interest in the

development of new antithrombotic agents, these polysaccharides deserve to be investigated as potential anticoagulants.
Aims: To evaluate the anticoagulant activity of the water extracts of *C. falklandica*.
Methods: The room-temperature water extracts (CX1-CX3) were evaluated. Determinations of prothrombin time (PT), activated partial thromboplastin time (APTT) and thrombin time (TT) were assayed according to established methods. Normal platelet depleted citrated plasma (900 μL) was mixed with 100 μL of each polysaccharide extracts, in different concentrations, and incubated for 1 min at 37 °C. Saline solution was used as control. TT-like assays were also performed with purified fibrinogen (3 mg/mL) instead of plasma. Results were expressed as ratios obtained by dividing the clotting time achieved with the extract by the time achieved with the control. In order to performed fibrinformation studies, clots were generated by adding thrombin (0.05 IU/mL) and calcium chloride (20 mM) to the preincubated plasma. The kinetics was evaluated measuring optical density (OD) at 405 nm every one min up to constant values. Assays were carried out in polystyrene strips, in the presence of different concentrations of CX2 (10–100 μg/mL) or saline solution as control. The sigmoid curves obtained (OD vs. time) were characterized by three parameters: lag phase, maximum velocity achieved and final network OD. All assays were performed in quadruplicate.
Results: The second room temperature water extract (CX2), comprises arabinose as the major component (60.6%), galactose (23.5%) and xylose (10.5%), with a high percentage of sulfate, with a molar ratio carbohydrate: SO_3 of 1:0.7. CX2 was the most active one in coagulation tests. This fraction significantly prolonged PT, APTT and TT, in concentration dependent manner; for CX2 solution (100 μg/mL) the ratios were 1.8, 5.2, and 4.1, respectively. For the TT-like assays the ratio was 2.7, for the same concentration of CX2. The kinetics analysis of fibrinformation with CX2 showed statistically significant differences vs. control in lag phase (0.5 ± 0.0 min vs. 6.0 ± 0.0 min, $P < 0.001$), Vmax (408.5 ± 30.4 min vs. 212 ± 23.8 min, $P < 0.001$) and in the final network OD (0.709 ± 0.002 vs. 0.801 ± 0.011, $P < 0.001$).
Conclusions: The second water extract of *C.falklandika* showed anticoagulant activity by global coagulation tests with normal plasma; therefore CX2 could potentiate thrombin inhibition by antithrombin and/or heparin cofactor II. Besides, TT-like assays with purified fibrinogen suggest that, at least one of the mechanisms involved would be direct thrombin inhibition. By other hand, a probable procoagulant effect was shown by fibrinformation kinetics. In other to understand these findings further studies are currently undertaken.

PO 251

Purification method thrombin-like enzyme and fibrinogenolytic enzyme from Agkistrodon blomhoffi ussuriensis snake venom

Buyanbadrakh B[1], Dashnyam P[2] and Byambasuren S[3]
[1]*Health Science University of Mongolia;* [2]*Mongolian Academy of Science;* [3]*Alsglobal LLC, Ulaanbaatar, Mongolia*

Background: Snake venoms contain a variety of proteolytic enzymes affecting the host coagulation process. Snake venom fibrinogenolytic enzymes act on fibrinogen, leading to defibrinogenation of blood and a consequent decrease in blood viscosity. And thrombin-like enzymes are responsible for *in vitro* blood-clotting activity present in several snake venoms is a protease which resembles at least in part thrombin, a multifunctional protease that plays a key role in coagulation.
Aims: The purpose of this study was purification of fibrinogenolytic and thrombin-like enzymes (TLE) from snake venom.
Methods: The crude venom of *Agkistrodon blomhoffii ussuriensis* was used as a raw material for obtaining of fibrinogelytic enzyme and TLE. The venom separation was started with affinity chromatography on Blue Sepharose FF and followed by Phenyl Sepharose HP, Source 15S for fibrinogelytic and Sephadex G25 SF for TLE. The TLE activity was monitored by detection of the clot formation on coagulometer and fibrinogenolytic activity was determined by enzyme electrophoresis.
Result: The TLE was a single chain glycoprotein with 27 kDa molecular weight and fibrinogenolytic enzyme was a heterodimer protein that includes two polypeptides with 36 kDa molecular weight. Purified TLE cut from fibrinogen molecule only fibrinopeptide A and that allows make it to class α-specific TLE. Fibrinogenolytic enzyme was cleaved on β-chain quicker than α-chain and slower than on γ-chain.
Conclusion: *Agkistrodon blomhoffii ussuriensis* snake venom contains 36 kDa fibrinogenolytic enzyme that can be purified by affinity and 2 more ion exchange chromatography and 27 kDa TLE that can be purified by same affinity and size exclusion chromatography.

PO 252

Alterations in natural coagulation inhibitors in acute leukemias

Galar M, Szumowska A, Kostur A, Bolkun L and Kloczko J
Medical University of Bialystok, Bialystok, Poland

Background: Inherent inhibitors of coagulation carefully control the blood clotting system *in vivo* and ensure that blood propagation does not lead to occlusion of the vasculature. TM/protein C/protein S pathway is important in modulating coagulation. Acute leukemia development is accompanied by various abnormalities of hemostasis with nearly all patients demonstrating subclinical activation of coagulation. Our previous study revealed a low plasma concentrations of anticoagulation proteins at the moment of diagnosis of acute leukemia.
Aim: The aim of this study was to estimate the concentrations of selected endogenous anticoagulation proteins in patients with acute leukemia receiving chemotherapy.
Methods: Blood samples were obtained from 20 adult patients with acute leukemia (AML-13; ALL-7) at the following time intervals: before treatment (0) and on the 7th (1), 14th (2) and 21st (3) day of chemotherapy. The patients were followed-up in the Department of Hematology, University Hospital in Bialystok. They were not under the oral anticoagulant treatment and had normal liver function. Control samples were obtained from 20 healthy subjects, age- and sex-matched. Plasma concentrations of protein C (PC), total protein S (PS), soluble thrombomodulin (sTM) and soluble endothelial protein C receptor (sEPCR) were measured by ELISA method, using commercial tests. The patients with AML and ALL underwent the induction regimens according to generally applicable standards.
Results: The low concentrations of PC, found in ALL patients at diagnosis (76.1 ± 26.9%), were elevated on the 7th (109.9 ± 28.2%) and 14th (100.8 ± 31.3%) day of the treatment, then became reduced at 21st day to approximately normal value (89.1 ± 27.3%). In patients with AML the concentration of PC remained low during all the time of treatment (0–63.0 ± 20.8%; 1–62.1 ± 17.2%; 2–57.4 ± 14.3%; 3–50.3 ± 17.2%). There were no differences in the levels of total PS in both groups of leukemia during the treatment. The concentrations of sEPCR which were low at diagnosis of acute leukemia, were rapidly reduced on the 7th day and remained downregulated thereafter (AML: 0–82.8 ± 57.1; 1–46.0 ± 10.3; 2–44.9 ± 10.6; 3–36.5 ± 10.5 ng/ml; ALL: 0–79.7 ± 34.7; 1–44.3 ± 15.9; 2–47.3 ± 31.4; 3–44.9 ± 25.7 ng/ml). The study revealed that sTM concentrations, which were elevated in acute leukemia at the diagnosis (AML; 72.2 ± 101.7; ALL: 140.6 ± 199.3 ng/ml), were reduced at 7th and 14th (AML: 1–64.1 ± 32.5; 2–64.3 ± 38.0; ALL: 1–71.1 ± 25.2; 2–66.6 ± 19.8 ng/ml) day of treatment in order to reach very high values at the 21st day (AML: 124.5 ± 139.4; ALL: 120.7 ± 159.8 ng/ml).
Conclusions: Alterations in the concentrations of the physiological inhibitors of blood coagulation may result from different pathogenesis of acute leukemias as well as of different treatment of AML and ALL. This study indicates that basal coagulation system markers (PC, PS, sTM, sEPCR) may be helpful in monitoring patients presenting a disorder of this anticoagulant pathway, especially during treatment of acute leukemia. Nevertheless, some limitation of this study is a small number of enrolled patients.

PO 253

Venous thromboembolism prophylaxis with rivaroxaban subsequent to enoxaparin in major orthopaedic surgery

Altintas F[1], Ulucay C[1], Ozler T[1], Kilincoglu V[2], Guzelbey T[1] and Aksu BC[3]

[1]Yeditepe university, Istanbul; [2]Medical park hospital, Gaziantep; [3]Yediyepe university, Istanbul, Turkey

Background: Venous tromboembolism is an important complication for which precautions should be taken after major orthopaedic surgery (elective hip and knee replacement, hip fracture).

Aim: Short and long period pharmacoprophylaxis are suggested for the prevention of venous thromboembolism in all guidelines following major orthopaedic surgery. In this study, we evaluated the efficiency of new oral anticoagulant prophylaxis following low molecular weight heparin.

Methods: Seventy-two major orthopaedic surgeries (32 total knee arthroplasty, 19 total hip replacement, 16 hip fracture) had been performed between January 2012 to October 2012 in Yeditepe University Hospital. Thirteen patients were male and 59 patients were female. The mean age of the patients was 69 (range; 43–96). Forty-one patients had risk factors related to venous thromboembolism. After 12 h from the surgery; 2 × 30 mg enoxaparin was given subcutaneously to all patients throughout following in hospital. After the discharge from the hospital; 1 × 10 mg rivaroxaban was prescribed to all of them. Short-term prophylaxis (for 10 days) was administered to the patients with knee prosthesis. Long-term prophylaxis (for 30 days) was administered to the patients with hip prosthesis and patients operated for hip fracture who had two or more risk factors.

Results: Venous doppler ultrasonography was performed to all patients after 6–12 weeks from the surgery. Venous thromboembolism was not detected in any of the patients.

Conclusions: Venous thromboembolism prophylaxis with enoxaparin following by rivaroxaban is an effective modality in patients who undergo major orthopaedic surgery.

PO 254

Start-register (Survey on anticoagulated patients register): the first year of activity

Antonucci E[1], Magrini N[2], Marongiu F[3], Pengo V[4], Poli D[5], Tripodi A[6] and Palareti G[7]

[1]University of Florence, Firenze; [2]CEVEAS, Modena; [3]University of Cagliari, Cagliari; [4]University of Padua, Padua; [5]AOU Careggi, Florence, Florence; [6]University of Milan, Milan; [7]University of Bologna, Bologna, Italy

Background: Oral anticoagulation treatment with vitamin K antagonist (VKA) has been shown to be effective in numerous randomized clinical trials, but despite the potential clinical benefits they are underused especially in patients at high risk of bleeding. In the last years many efforts are directed towards the development of novel orally anticoagulants (NOA) and many clinical trials were conducted to compare the efficacy and safety of the different therapy. However, in the setting of clinical trials, there is a very tight control therapy, resulting in lower rates of therapeutic failure. This makes difficult not only the assessment of the value of NOA but the evaluation of their health-economic benefits.

Aims: The purpose of START-Register is to provide information to help physicians on evaluation of treatment option, aiding treatment selection in their patients. In addition it is also aimed to improve our knowledge on the disease, (including epidemiologic, diagnostic, prophylactic and therapeutic information), on analysis of different possible treatments (monitoring, dosages, frequency of controls), and on therapy used (protective efficacy, complications during therapy or after suspension).

Methods: Participatings enroll all patients that meet predefined eligibility criteria, and data of each patient including indication to treatment, underlying conditions and type of anticoagulant were collected on the web-site of the register.

Results: From September 2011 to December 2012 active participating members are 68; 3016 patients (males 54%) were prospectively enrolled. The indication to treatment was: atrial fibrillation in 58% of patients, thromboembolic events in 30%, mechanical heart valve in 5%. Patients underwent elective cardioversion was 6%. VKA were used in all patients enrolled and bridging therapy with low-molecular-weight-heparin was used in 42% of patients.

Conclusion: START-Register, a multicenter observational prospective and non-interventional register, will allow us to enhance our understanding of the risk-benefits of the various anticoagulant drugs and therapy options.

PO 255

Dabigatran overdosis vs. disseminated intravascular coagulation

Azevedo AP, Gago T and Freire I

Hospital São Francisco Xavier, Lisboa, Portugal

Background: Dabigatran is a direct thrombin inhibitor obtained from dabigatran etexilate, an oral prodrug that is hydrolyzed in the liver. Dabigatran is 80% renally excreted with a half-life of approximately 13 h with a glomerular filtration rate (GFR) of > 80 ml/min, and 18 h with a GRF of 30–50 ml/min. Peak plasma concentration is in the range of 100–400 ng/ml. Trough concentrations are in the range of 20–150 ng/ml.

Clinicians and pathologists require knowledge how routine coagulation assays are affected not only with therapeutic doses but also with overdose levels. Although there is a dose-dependent effect of dabigatran on laboratory clotting assays, the results are dependent on the last dose of drug taken and the factors that influence pharmacokinetics such as GFR. There is also a marked variation of results concerning the reagents used, mainly in fibrinogen measurements. These way clotting assays (PT, aPTT, TT and fibrinogen) may be misinterpreted by clinicians.

Aims: Presentation of a clinical case with bleeding complications, and how the misinterpret of coagulation assays evolution can influence diagnosis.

Methods: Eighty-three years old female, with personal history of atrial fibrillation, asthma, type two diabetes, hypertension, osteoporosis and dyslipidemia, treated with dabigatran, amiodarone, metformin and multiple analgesia. She was admitted for analgesic therapy adjustment and decision on possible surgical intervention, following ancient osteoporotic fracture of L4. At admission, her laboratorial control revealed anemia, leukocytosis and thrombocytopenia, elevated RPC and abnormal renal function. No coagulation tests were done. On the second day of hospitalization, without apparent triggering factor, starts prostration, hematochezia, bruising at venipuncture sites and oral cavity bleeding during nasogastric intubation. New laboratorial control revealed not clottable PT, aPTT and fibrinogen Clauss, with a severely worsening of inflammatory/infection markers. Given these results, clinicians formulated two diagnostic hypotheses: severe DIC by sepsis vs. iatrogenic effects caused by dabigatran.

Pathologists were asked to interpret coagulation assays. Platelets and D-Dimmers were done and the diagnosis of severe DIC was concluded to be unlikely/excluded.

Therapy with dabigatran was discontinued. Multiple transfusion therapy was administered, on the third day the bleeding diathesis stopped and on the fifth day the coagulation assays normalized.

Conclusions: New oral anticoagulant, dabigatran, a direct inhibitor of thrombin, can induce big changes in coagulation assays: not clottable TP, aPTT and Clauss fibrinogen.

In the case presented, the results (prolonged aPTT and PT, falsely low fibrinogen) associated with severe hemorrhage were wrongly inter-

preted, suggesting DIC. In reality, the patient had no changes in fibrinogen (hypo or dysfibrinogenemia). By the other hand, D-Dimmer and platelets measurement could help to exclude DIC.
Despite disruption of dabigatran immediately after start of bleeding complaints, these persisted for two more days and coagulation assays took 5 days to become normal, although the half-life of dabigatran is shorter.
The use of these drugs in the general population and outside the context of clinical trials induces differences regarding the safety established. These differences may be particularly relevant in populations underrepresented in these trials, like the elderly and individuals with impaired renal function, as in this case.

PO 256

Efficacy and safety of thromboprophylaxis with use of LMWH and warfarin in the traumatology-orthopedic hospital

Bozhkova SA, Borisov AM, Tikhilov RM, Novokshonova A and Cibin AV

R.R. Vreden Russian Research Institute of Traumatology and Orthopedics, St-Petersburg, Russia

In 2011 in our hospital were performed 20 584 orthopedic operations, 6 230 of them were associated with high venous thromboembolism (VTE) risk. Total fatality rate was 0.07% (15 cases). Lethality from pulmonary embolism (PE) compounded 0.01% – two cases.
We studied efficacy and safety of our local Protocol of Thromboprophylaxis, based on the 8th edition of ACCP Guidelines, 2008.
The investigation was retrospective. We analyzed medical cards of 732 patients after total hip or knee replacement (THR, TKR) in 2011. Most of surgery operations were performed with neuroaxial anesthesia. There were 68.7% women. The mean age of the patients was 56.7 ± 10.7. Primary arthroplasty was performed in 663 cases (87.9% – THR, 12.1% – TKR), revision surgery – in 55 cases (THR – 91%, TKR – 9%). The mean duration of primary joint replacement was 93.0 ± 27.8 min, revision arthroplasty – 129.7 ± 51.5 min. Inpatient treatment was 13.4 ± 0.7 days after surgery. A 99.87% of surveyed patients were supposed to have high risk of VTE. A 88.5% of all patients were older than 40 years, therefore, they appeared to have extra risk factor of VTE. A 6.3% of aged upwards 75 years composed a group of particularly high risk of VTE and hemorrhagic complications associated with anticoagulants. The VTE prophylaxis by low molecular weight heparins (LMWH) was started 12 h before surgery in 100% cases. The mean duration of a course LMWH was 10.3 ± 0.8 days (dalteparin sodium was received by 71.6% patients, nadroparin calcium – 17.6%, enoxapain sodium – 9.2%). In one case low dosage of dalteparin was used due to the improper risk stratification. Since the 7th-8th days all patients received warfarin. It recommended to 99.7% of patients after the release. Early mobilization (77.3% of patients) and graduated elastic compression stockings (37.9%) were used as unspecific thromboprophylaxis. We detected no hemorrhagic complications, which lead to cancellation of anticoagulants. Four VTE were observed (0.52%). One patient (woman, 63 years old) died due to pulmonary embolism at 9th day after THR. For other patient (woman, 83 years) PE was diagnosed at 10th day after surgery, at 29th day – sharp cardiovascular insufficiency and death were developed. Both cases of fatal PE after THR were associated with cancellation LMWH while target level of INR was not yet achieved by warfarin intake. Superficial vein thrombosis was detected in two patients (0.26%) by ultrasonography at 8–10 days after surgery.
The study showed that routine use of the Protocol was effective and safe. However, have been revealed insufficient use of mechanical VTE prevention methods and difficulties with selection of warfarin dosage. Thus, more frequent use of mechanical thromboprophylaxis and use of new oral anticoagulants, which doesn't require laboratory monitoring and selection of the dose, can raise the efficacy of the Protocol. Monitoring of Observance of the local Protocol and the analyses of all VTE cases are necessary to establish the causes of these complications and to find ways to improve it.

PO 257

Identification of brodifacoum exposure and subsequent monitoring of treatment and recovery using functional markers of vitamin K status

Christian AD[1], Card DJ[2], Gilmore R[3] and Harrington DJ[2]

[1]GSTS Pathology; [2]St. Thomas' Hospital, London, UK; [3]Galway University Hospital, Galway, Ireland

Background: Superwarfarins are highly potent, freely available vitamin K antagonist type anticoagulants that are widely employed as rodenticides. They exert their effect by blocking the vitamin K epoxide reductase complex (VKOR) thereby limiting the recycling of vitamin K from the inactive, oxidised form (vitamin K 2,3-epoxide) back to the metabolic form (vitamin K hydroquinone). Vitamin K is an essential micronutrient utilised as a cofactor for vitamin K dependent carboxylase which is required for the post-translational activation of various vitamin K-dependent proteins, most notably in this case, coagulation factors II, VII, IX and X.
Aims: We describe a case of superwarfarin exposure in a 20 year old male who presented in April 2011 (approximately 6 weeks post superwarfarin exposure) with left calf pain and the subsequent use of functional vitamin K status markers to successfully monitor recovery and guide treatment. At presentation, ultrasound showed extensive haemorrhage. The patient's Hb was 6.2 g/dL, PT > 120 s and APTT > 240 s. He was immediately given 3500 units of 4-factor Prothrombin Complex Concentrate and 20 mg IV phytomenadione (vitamin K_1 [K_1]) (Konakion). The INR subsequently corrected, however it increased once more over the following days to 1.4. In response, the daily phytomenadione dose was increased to 40 mg. The INR corrected and remained normal with continued daily K_1.
Methods: A serum sample was collected and a superwarfarin screen performed by normal-phase HPLC with diode array detection. K_1 and vitamin K_1 2, 3-epoxide (K_1O) were measured by reversed-phase HPLC with in-line chemical reduction and fluorescence detection. Undercarboxylated prothrombin (PIVKA-II) was measured by ELISA.
Results: Brodifacoum, a long-acting superwarfarin with a clearance half-life of approximately 20–100 days was detected 100 μg/L. Superwarfarin action was confirmed by an elevation in the circulatory concentration of PIVKA-II to levels greater than those seen in anticoagulated patients (> 7 AU/mL) and by detection of K_1O at a highly elevated concentration relative to K_1. Monthly monitoring of brodifacoum and vitamin K markers was performed and is ongoing. Brodifacoum was not detectable in any subsequent samples (collected at intervals since April '11) presumably due to hepatic pooling; however its ongoing effects were evidenced by elevated PIVKA-II and K_1O. PIVKA-II remained elevated until 180 days post-presentation and then returned to normal (undetectable [< 0.2 AU/mL]), indicating complete correction of the coagulation defect by ongoing phytomenadione administration. K_1O remains highly elevated relative to K_1 (ratio = 1.2–3.7) 530 days post-presentation.
Conclusions: The use of novel laboratory markers conferred a number of benefits not seen with conventional coagulation assays: Confirmation of diagnosis by the direct measurement of brodifacoum; evidence that ongoing action was not a consequence of repeated-exposure; monitoring of treatment with vitamin K; biochemical evidence of continued vitamin K antagonism 18 months post-exposure. These results indicate this patient still requires treatment with phytomenadione at this time with further monitoring of vitamin K markers to determine when treatment should be discontinued.

PO 258

In vitro assessment, using thrombin generation, of the applicability of Prothrombin Complex Concentrate as an antidote for Rivaroxaban

Dinkelaar J[1], Molenaar PJ[1], Ninivaggi M[2], De Laat B[2], Brinkman HJA[3] and Leyte A[1]

[1]OLVG, Amsterdam; [2]Maastricht University, Synapse BV, Maastricht; [3]Sanquin Research, Amsterdam, The Netherlands

Background: Rivaroxaban has been approved as antithrombotic agent for prevention of venous thrombo-embolism for specific indications. At present no antidote is appointed and no guidelines have been formulated for the measurement of Rivaroxaban reversal.

Objectives: In this *in-vitro* study, we evaluated the influence of prothrombin complex concentrate (PCC: Cofact) on the anticoagulant effects of Rivaroxaban as measured by prothrombin time (PT) and various thrombin generation tests.

Methods: Plasma and whole blood samples from healthy volunteers were spiked with Rivaroxaban in concentrations up to 800 μg/L, PCC was added to these samples in concentration ranges as used clinically to reverse anticoagulant effects of vitamin K antagonists (VKA). PT, endogenous thrombin potential (ETP) and calibrated automated thrombography (CAT) assays were measured with varying tissue factor (TF) concentrations.

Results: Addition of PCC to Rivaroxaban spiked donor samples did not result in normalization of PT and thrombin generation lag time In contrast, normalization of ETP and CAT area under the curve did occur. However the response on PCC addition was strongly TF concentration dependent and in whole blood less PCC was required for Rivaroxaban reversal as compared to plasma.

Conclusions: PCC does not neutralize the lengthening effect on PT and thrombin generation lag time of Rivaroxaban anticoagulated blood *in vitro*, however total thrombin formation could be normalised. Performance of the different thrombin generation tests is assay condition dependent. Therefore, prospective studies are needed tot clarify which assay condition and parameter describes *in vivo* haemostasis best in Rivaroxaban patients that are treated with PCC.

PO 259

Defibrotide interactions with newer oral anticoagulants and antithrombotic agents

Fareed J, Hoppensteadt D, Iqbal O, Cunanan J, Bansal V, Abro S and Wahi R

Loyola University Medical Center, Maywood, IL, USA

Introduction: Clinical trials of defibrotide, a polydisperse mixture of porcine-derived single-stranded oligonucleotides demonstrate benefits for the treatment and prophylaxis of hepatic veno-occlusive disease (VOD) in hematopoietic stem cell therapy. This study investigated the effect of defibrotide on the anticoagulant and antiprotease actions of the newer oral anticoagulants.

Materials and Methods: Whole blood drawn from 25 healthy individuals was supplemented with 250 ng/mL of each of the individual oral anticoagulant drugs alone and with 100 μg/ml defibrotide. Celite activated clotting time (ACT) measurements were made. For the plasma based assays, a fixed concentration of defibrotide (100 μg/mL) was supplemented with defibrotide to pool plasma alone and with each of the individual oral anticoagulants (0–1000 ng/mL). To investigate the effect of defibrotide on agonist induced platelet aggregation PRP was prepared with varying amounts of defibrotide (0–100 μg/ml). To test the effect of defibrotide on warfarin, plasma samples from patients with INR range of 1.5–3.0 were supplemented with 100 μg/ml and the PT/INR was re-determined.

Results: While apixaban and rivaroxaban did not prolong the ACT, dabigatran produced a modest increase at 250 ng/mL; addition of newer oral anticoagulants to defibrotide supplemented plasma did not prolong the PT. Dabigatran showed a slight interaction in the aPTT assay. Defibrotide, did not impact agonist induced platelet aggregation. Defibrotide, alone and with newer oral anticoagulants, did not increase the PT/INR values of plasma samples collected from warfarin treated patients at concentrations of up to 100 μg/ml.

Conclusions: Based on the indications for the new oral anticoagulant drugs, their circulating levels and rapid clearance, it is unlikely that defibrotide will produce any interactions with these drugs.

PO 260

Dabigatran etexilat overdose and life-threatening gastrointestinal bleeding

Hajsmanova Z, Slechtova J, Sigutova P and Lavickova A

University Hospital, Plzen, Czech Republic

Background: New oral anticoagulants – dabigatran, rivaroxaban, apixaban and others – are small-molecule, selective inhibitors that bind to the selective coagulative site of vitamin K-dependent factors Xa and IIa. These drugs are attractive for patients due to the peroral drug form, a fixed dose administered once or twice daily to patients with normal body weight and renal function. There is no need for laboratory drug efficacy monitoring when the standard conditions are met.

One great disadvantage is the fact that elderly people can easily overdose on it and their renal function can change over time rapidly. A specific antidote has not yet been developed.

We would like to present our experience with life-threatening bleeding that was managed successfully. Our case report deals with a 83-year-old lady with numerous comorbidities.

(diabetes mellitus, ischemic heart disease, etc.)

She was admitted to hospital for weakness and pre-shock status, when she had been treated with the standard dose of dabigatran (Pradaxa®, Boehringer Ingelheim) 150 mg twice daily for atrial fibrillation. Melaena wad occurred shortly before admission, verified in the hospital, and so the urgent gastrointestinal tract examination was indicated. The laboratory results of both the blood count and haemocoagulative parameters were severe even critical (Hb 76 g/L, APTT- R 3.16, TT more than 120 s, fibrinogen 0.33 g/L, D-dimers 0.81 mg/FEU). dTT was 500 ng/ml ten h after the last dose of dabigatran.

Volume resuscitation and complete haemodynamic support was self-evident.

The lower dose of FEIBA (approximately 25 IU per kg b.w.) was administered to the patient as a bolus immediately before gastroendoscopy. A bleeding stomach ulcer was proved and successful surgical haemostasis followed. The persisting pathological haemocoagulative parameters were normalized by fresh frozen plasma infusions during following 2 days, so APTT – R became lower to 1.8, PT- R 1.66, while pathological thrombin time more than 120 s persisted.

In spite of the fact that the woman was resuscitated because of malignant bradycardia, now she is again being treated with dabigatran etexilate for persistent atrial fibrillation.

Conclusion: This is our first experience with FEIBA used for dabigatran overdosing treatment. We were afraid to administer higher dose of FEIBA due to the hypercoagulative woman′s state. rFVIIa would have been the further step to stop bleeding.

PO 261

Incidence of thromboembolic and bleeding events according to the timing of prophylaxis after orthopedic major surgery

Hwang HG, Kim MS, Lim G, Lee HH, Lee HU and Ji JW

Soonchunhyang university Gumi Hospital, Gumisi, South-Korea

Background: Venous thromboemolism, including deep vein thrombosis and pulmonary embolism represents major concern after orthopedic major surgery. But concern about bleeding complication after surgery

may make orthopedic surgeon hesitate to start anticoagulation with low-molecular weight heparin (LMWH) for more than 6 days in real practice even though it is recommended to retart 6–8 h after wound closure.

Aims: This study is designed to provide the information regarding the incidence of venous thromboembolism or bleeding according to the timing of anticoagulation with LMWH after major orthopedic surgery.

Methods: Patient who underwent major orthopedic surgery with femur fracture from July 2013 to December 2013, were retrospectively identified and reviewed with chart. Orthopedic surgery included bipolar hemiarthroplasty and closed reduction with interal fixation. Patients who received prophylaxis with LMWH within 5 days of surgery were classified as group 1, and after 6 days as group 2. Patients who need to have briding therapy due to anticoagulation therapy with warfarin were excluded. Whether there are events of venous thromboembolism or bleeding complication were followed for 30 days of procedure. Major bleeding was defined as drop of hemoglobin level of 20 g/L or more, or leading to transfusion of 2 or more units of whole blood or red cells or bleeding in critical organ.

Results: Sixteen patients were included. There were 5 men and 11 women, ranging in age form 67 to 90 years with a mean age 78.8. Site of femur fracture was right in 11 patients. Preoperative LMWH injection was done in 14 patients (87.5%). Mean number of injection after operation was 9.4. Interval between surgery and injection postoperative was 4.72 $\pm$ 1.98 (range, 0.5 to 8 days) overall, 3.55 $\pm$ 1.52 (range 0.5 to 5 days) in Group 1, and 6.67 $\pm$ 0.75 (Range 6–8) in Group 2. Pulmonary embolism occurred in one patient 2 days after procedure in Group 2. Major bleeding occurred in one paitent 3 days after procedure in Group 2.

Summary/Conclusion: Limitation is small number of data, but no one showed bleeding complication in Group 1. It is important to follow the recommendation that prophylaxis with LMWH be started 6–8 h after wound closure to prevent venous thromboembolism.

PO 262

Profiling anticoagulants from hematophagous animals: an on-line post-column bioactivity assay with parallel mass spectrometric identification

Iyer K[1], Slovak M[2], Kool J[3] and Kini MR[1]

[1]National University of Singapore, Singapore, Singapore; [2]Slovak Academy of Sciences, Bratislavia, Slovakia; [3]VU University Amsterdam, Amsterdam, The Netherlands

Background: Cardiovascular and cerebrovascular diseases are among the most dreaded killers in most developed countries. There have been numerous anticoagulants that have been developed to circumvent deaths and debilitation due to these diseases. Over the years, natural sources such as plant and animal extracts have proven to contain a wide array of pharmacologically important compounds. Since the salivary gland extracts of hematophagous animals like ticks and mosquitoes are rich in anticoagulants, these exogenous proteins can be used as therapeutic agents based on their highly specific targeting. These pharmacologically active anticoagulants inhibit central enzymes of the blood clotting cascade. As these inhibitors are present in min amounts, they are difficult to identify using traditional analytical scale chromatographic approaches.

Aim: We propose to identify novel potent inhibitors of the key enzymes involved in the blood coagulation cascade.

Methods: We propose to identify novel potent inhibitors through the development of a miniaturized workflow for on-line post-column profiling of the crude salivary gland extracts. In this miniaturized workflow, purification is first performed via nano liquid chromatography. Thereafter, the eluent is split into two lines, one being fed into an on-line post-column bioassay where its anticoagulant properties are tested. The other is fed into a mass spectrometer for compound identification. As the bioassay and MS-guided identification are carried out in parallel, we will be able to match the proteins with its corresponding activity. In this manner, profiling of the salivary gland extracts is achieved through a single tandem workflow. The development of this technique, counters the constraints posed by the limited amounts of exogenous compounds available from these hematophagous animals. This miniaturized workflow will be used to profile the salivary extracts of ticks and mosquitoes.

Conclusion: With the identity of the anticoagulants from the hematophagous animals being elucidated, they can be recombinantly expressed and purified from suitable expression systems. This will allow the study of the mechanisms of these inhibitors so that their therapeutic potentials can be explored further.

PO 263

Are the complications of anticoagulant treatment with vitamin K antagonists in atrial fibrillation gender dependent?

Kovacev JB, Novakovic-Anucin SL, Gnip S, Radovic P, Canak V, Filipov P and Mitic G

Clinical Centre of Vojvodina, Novi Sad, Serbia

***Background*:** It is well known that patients with atrial fibrillation are at great risk for thromboembolic complications. Long-term anticoagulant treatment is recommended in that case. Atrial fibrillation affects males more than females. Several studies have shown that females are at higher risk of thromboembolic complications. Still there are insufficient evidence about gender-related complications.

Aims: The aim of our study was to compare the incidence of thromboembolic and haemorrhagic complications between genders. We also assessed the risk of these complications in relation to the CHA_2DS_2-VASc and HAS-BLED score and time spent in therapeutic range.

Methods: The study included 224 patients treated with vitamin K antagonists, followed for 851 patient-years in the Departmant of Haematology, Haemostasis and Prevention of Thrombosis, Clinical Centre of Vojvodina. Our group consisted of 119 (53%) male and 105 (47%) female patients. International Normalized Ratio measurements have been done periodically and maintained at recommended range of 2.0–3.0. Thromboembolic and haemorrhagic complications were registered during regular controls by clinical examination, diagnostic procedures such as nuclear magnetic resonance, computing tomography scan, endoscopic procedures, then laboratory analyses (examination of urine sediment) and patient history. Risk of ischaemic stroke was estimated using CHA_2DS_2-VASc score, while HAS-BLED score was used to assess the risk of haemorrhagic complications.

Results: All patients were classified into three categories by CHA_2DS_2-VASc score- at low risk 4 (1.8%), moderate risk 16 (7.1%) and high risk 204 (91.1%). The most numerous were patients over 65 years- 184 (82%). The most frequent comorbidities were hypertension (70%), vascular diseases (38%) and diabetes mellitus (23%). Risk of thromboembolic complications was higher in male patients ($P = 0.002$). Using HAS-BLED score 84 (38%) patients were at low risk and 140 (62%) were at high risk of haemorrhagic complicationts, but there was no significant difference in the incidence of complicationts between genders ($P = 0.915$). Both genders were at the same risk of haemorrhagic complications ($P = 0.358$). One hundred and thirty-nine (62%) patiens with stable INR had the same incidence of thromboembolic and haemorrhagic complications compared to those with labile INR- 85 (38%).

Summary/Conclusions: Small sample study showed that all patients were at great risk of thromboembolic complications, male more than female. Complications of anticoagulant treatment were not gender dependent.

PO 264

Laboratory coagulation assays and ROTEM thromboelastography in monitoring the reversal of dabigatran with FEIBA and haemofiltration

Leong J, Thomson E, Ali A, Jarrold U and Kanagasabapathy P
Royal Infirmary of Edinburgh, Edinburgh, UK

Background: Dabigatran, a direct thrombin inhibitor, is increasingly prescribed in the management of atrial fibrillation. There remains no effective reversal agent for patients presenting with bleeding or requiring emergency surgery. In the case of life threatening bleeding, the only effective treatment recommended by the manufacturers is haemodialysis. *FEIBA* (factor VIII inhibitor bypassing agent) has been purported as a potential reversal agent for dabigatran. However, there is limited data on the clinical efficacy in humans. Clinical management is further complicated by routine coagulation laboratory assays, which can only provide limited information in these emergency situations. *ROTEM* thromboelastography represents a whole blood haemostasis assay capable of providing rapid results in the perioperative and emergency setting. We present a clinical case of dabigatran reversal in a 74-year-old patient who presented with septic shock and acute renal injury secondary to duodenal ulcer perforation.
Aims: To present our clinical experience using *FEIBA* in the perioperative setting for the reversal of dabigatran. To discuss the potential role for *ROTEM* thormboelastography in monitoring dabigatran reversal. Finally, to highlight the limited efficacy of CVVH (continuous venovenous haemofiltration) in plasma clearance of dabigatran.
Methods: *ROTEM* thromboelastography (INTEM, EXTEM, FIBTEM), dabigatran assays (BIOPHEN DTI Kit HYPHEN BioMed), APTT assay reagent (SynthASil IL) and PT assay reagent (recombiplastin-IL).
Results: This 74-year-old patient was admitted with a 3 day history of abdominal pain and septic shock. Radiological investigations confirmed a perforated duodenal ulcer requiring emergency surgery. On admission, APTT>210s and PT>140s compatible with dabigatran accumulation secondary to acute kidney injury (eGFR 20 [baseline > 60]) corresponding to dabigatran levels 1.68 μg/ml. *ROTEM* Thromboelastography performed at baseline: INTEM CT 1660s, MCF 5 mm, while α-angle and CFT were immeasurable. The patient was taken to theatre. Pre-operatively, Vitamin K 10 mg IV and *FEIBA* 2500 IU (50 IU/kg) were administered.
Immediately post *FEIBA*, *ROTEM* thromboelastography parameters show an improvement: INTEM CT 1336s, MCF 23 mm, CFT 1651 and α-angle 13°. The patient underwent an omental oversew of the duodenal ulcer with no significant bleeding complications. There was minimal bleeding noted by the surgical team perioperatively. At two h post *FEIBA*, INTEM parameters suggest decreasing haemostatic efficacy (CT 2036s, MCF 5 mm and the α-angle and CFT were immeasurable). Dabigatran levels were 1.71 μg/ml, APTT and PT were prolonged again with no end point. The patient was transferred to the intensive care unit where CVVH (Xenium XPH 130 filter) was started for management of acute kidney injury. CVVH was noted to have little effect on dabigatran levels (pre = 1.71 μg/ml, post = 1.56 μg/ml). Post-operatively no clinical signs of bleeding were detected and no further doses of *FEIBA* were administered. The patient subsequently died 2 days post surgery with complications related to bowel ischaemia.
Summary: We highlight an effective clinical response to *FEIBA* for dabigatran reversal in the perioperative setting. We demonstrate the potential role for *ROTEM* thromboelastography in monitoring dabigatran reversal. Additionally, as demonstrated by dabigatran assay monitoring, CVVH does not achieve plasma clearance of dabigatran and therefore cannot be considered as a therapeutic option.

PO 265

Are point-of-care devices useful for monitoring bleeding risk under rivaroxaban treatment?

Mani H, Herth N, Kasper A, Schuettfort G, Weil Y, Linnemann B and Lindhoff-Last E
Johann Wolfgang Goethe- University Hospital, Frankfurt, Germany

Objective: Monitoring of rivaroxaban may be required in emergency situations when acute lifethreatening bleeding or thrombosis occurs or when operations need to be planned. The aim of this study was to investigate *ex vivo* the time- and concentration-dependent effects of rivaroxaban on point-of-care devices (POCT).
Methods: POCT was performed in blood samples of 27 consecutive patients who received 10, 15 or 20 mg/od of rivaroxaban; the samples were collected prior to and two h after drug intake at steady state. Twenty-five patients receiving phenprocoumon and 20 healthy individuals were also enrolled in this study. The whole blood prothrombin time (PT), activated partial thromboplastin time (aPTT) and activated clotting time (ACT) were determined using the GEM PCL Plus coagulation system. Additionally, PT was measured on the CoaguCheck XS. In citrated plasma the PT, aPTT and drug concentration were determined.
Results: Two h after the drug administration, significant, concentration-dependent prolongations of PT, aPTT and ACT were observed to different extents. The PT measured using GEM PCL Plus (range 15.1–116.5 s) was most sensitive to the rivaroxaban plasma concentrations (range 0.0–430.1 ng/ml). The PT ranges determined using CoaguCheck XS (11.2–26.4 s) or Neoplastin Plus® (12.0–37.6 sec in plasma) resulted in decreased good differentiation between the maximum concentration and through levels of the rivaroxaban administration.
Conclusion: Whole blood PT values that are assessed with POCT systems, such as the GEM PCL Plus, enabling dose-dependent determination may be helpful to monitor the target specific oral anticoagulants as rivaroxaban in critical situations.

PO 266

Topical use of antithrombotics

Ng L[1], Monagle K[1], Ignjatovic V[2] and Monagle P[1]
[1]*The University of Melbourne;* [2]*Murdoch Childrens Research Institute, Parkville, Vic., Australia*

Background: Antithrombotics are usually administered intravenously, subcutaneously or orally. However, topical application of anticoagulants is reported.
Aims: To review the available literature regarding clinical conditions, topical anticoagulant treatment and resulting positive or adverse effects and subsequently attempt to ascertain their safety and efficacy.
Methods: Interrogation of MEDLINE/Pubmed databases for topical anticoagulant treatments between 1/1/1990 and 11/12/2012 using the search terms 'topical' and: heparin; warfarin; low molecular weight heparin; tissue plasminogen activator; urokinase; streptokinase; activated protein C. Review articles were used for cross-referencing and corroboration and excluded from further analyses.
Results: There were 42 studies reported in 11 different clinical conditions. Most studies were randomized, placebo controlled trials, prospective cohort studies or case reports. The clinical conditions in which topical anticoagulants were used included microangiopathy, acute haemorrhoids, periodontitis, dermatitis, phlebitis, burns, ocular conditions and surgery, blunt force impact, scars, clinical conditions associated with superficial venous thrombosis (SVT), and other.
The most commonly used topical anticoagulant is heparin, used in 83% of the studies analyzed. Other treatments utilized were activated protein C (APC), tissue plasminogen activator (tPA), streptokinase and low molecular weight heparin (LMWH). APC, tPA and LMWH were administered as liquids, whereas heparin and streptokinase were

applied via more than 1 method, such as gels, pastes, liquids and sprays.
Dosage of different anticoagulants, if they were stated, varied depending on clinical conditions.
Most studies reported mean improvements or resolution of symptoms/condition in patients. A 8.6% of studies reporting heparin treatment had no resolution or improvement of outcome and 1 study related to streptokinase treatment reported no outcome. A further 19.0% of studies reported adverse effects, such as allergic reactions, mild to moderate pain, mild contact urticaria and pruritus. A 16.7% of which involved heparin and the remaining 2.3% APC. However, it was not made clear in 9.5% of studies if the negative effects were a direct result of the anticoagulant treatment investigated.
Summary/Conclusion: Topical anticoagulant treatment is used in differing ways in different clinical situations and gives rise to variable outcomes. Further research has to be conducted to match clinical conditions with their safest and most effective topical treatment.

PO 267

Improving vitamin K antagonists management through daily low dose vitamin K supplementation

Paoletti O, Cancellieri E, Zimmermann A, Bassi L, Damiolini E, Zambelli S and Testa S

Haemostasis and Thrombosis Center, A.O. Istituti Ospitalieri, Cremona, Italy

Background: VKA therapy is a lifesaving treatment, used in the primary and secondary prevention of both arterial and venous thrombosis. It is characterized by a high intra/inter-individual variability due to drug interactions, genetic factors, intercurrent diseases and dietary vitamin K intake. As shown in literature, instability of anticoagulation may be associated with a low dietary intake of vitamin K. As a consequence of INR variability an increase of bleeding and thrombotic complications is observed.
Case report: A 79-year-old man, without significant previous diseases, was admitted to a cardiological division, because of the onset of atrial fibrillation at high frequency. Warfarin was immediately started in association with low molecular weight heparin at therapeutic dose. Five days after discharge the patient was re-admitted because of epistaxis and over-anticoagulation, showing a PT INR = 12, immediately normalized with concentrated prothrombin complex and vitamin K.
One month after restarting anticoagulation patient condition was as follow: very low quality treatment (time in the therapeutic range = 5%), high frequency of INR monitoring (2–3 times/week), very low mean warfarin posology (1.75 mg/week). Within possible non genetic causes of high variability, only the concomitant treatment with amiodarone could have only partially explained the high sensitivity to AVK. CYP2C9 and VKORK1 genotypes were measured and showed aplotype A/A VKORK1 that is associated to a major sensitivity to warfarin. To control the high INR variability, we decided to treat the patient with a supplementation of low dose of vitamin K (50 mcg/die). Rapidly we observed a stabilization of INR levels, with an improvement of quality treatment: time in the therapeutic range reached the 65%; frequency of INR monitoring was reduced to 1 control each 2–3/weeks, warfarin posology was stabilized at 3.75–5 mg/week.
Discussion: This case report shows us that therapeutic instability of warfarin treatment is strongly associated to the high sensitivity and low dose requirement. As known, genotyping both CYP2C9 and VKORK1, helps to identify patients that show an early response to VKA therapy with a consequent risk of overdosage and haemorragic complications.
Besides variations in dietary intake of vitamin K can have a significant effect on anticoagulant response to oral anticoagulants. In this case we observed that supplementation with a low dose of oral vitamin K contributes to improve anticoagulant stability, with a consequent reduction of both hemorrhagic and thrombotic risks. For this reason a healthy dietary regimen containing enough fruits and vegetables should be recommended to each patient on vitamin K antagonists despite previous recommendations. Probably direct oral anticoagulants may improve and simplify anticoagulation management of very AVK unstable patients.

PO 268

A personalized system to enhance INR monitoring

Paoletti O[1], Linder M[2], Zimmermann A[1], Bassi L[1], Delpero N[1], Valdes R[2], Dellanoce C[1] and Testa S[1]

[1]Haemostasis and Thrombosis Center, A.O. Istituti Ospitalieri, Cremona, Italy; [2]PGXL Laboratories, Louisville, KY, USA

Background: Warfarin is the most commonly used oral anticoagulant drug and dose requirements are influenced by genetic and non-genetic factors. Due to the difficulty in determining an individual's proper warfarin dose, therapy is typically initiated with a standard dose followed by INR monitoring. A Personalized Medicine Interface Tool (PerMIT) is a software utility that supplies critical guidance to warfarin dosing decisions by modeling the dose requirements and response characteristics of individual patients based on their genotypic and physical characteristics.
Aims: The central objectives of this study were to 1) test the hypothesis that in comparison to patients who demonstrate above average time in therapeutic range, patients who experience a low time in therapeutic range demonstrate a greater proportion of dosage adjustments which are inconsistent with status of achieving pharmacokinetic steady state, and 2) to determine the proportion of above range INR's which are preceded by trends in the plasma concentration time profile that would have predicted the out of range INR event.
Methods: We conducted a retrospective analysis of fifty patient treated with warfarin. A database including patient characteristics, CYP2C9 and VKOR C*1* genotypes and the first thirty days of warfarin dosages and INR measurements was created to estimate maintenance dose and graphical display of the calculated S-warfarin plasma concentrations ([Cp]) and INR measurements. From the graphical display of the patient's measured INR values and calculated plasma concentration time profiles, the following data were extracted:
A Time in therapeutic range (TTR, 2.0–3.0) was determined based on linear interpolation
B Average daily dose administered when the INR was within range
C C.Number of INR measurements of > 3.0 that were predicted by the concentration time profile
D percentage of dosage decisions that were consistent with interpretation of the plasma concentration time profile
Methods: The time maintained within the target therapeutic range (TTR) was significantly greater ($70 \pm 0.15\%$ vs. 31 ± 0.15, $P < 0.0001$) for those patients where 60% or more of the dosage decisions were consistent with the plasma concentration time profile. Overall 9 of 28 (32%) INR measurements that exceeded 3.0 were predicted by a preceding increase in plasma concentration. Within the group with the greater average TTR, above range INR's were more common (18 vs. 10) and were less often predicted by the plasma concentration time profile (22% vs. 50%). This appears to be associated with fluctuations in the INR which are independent of changes in plasma S-warfarin concentration. Among the patients with the lower TTR, a greater proportion of INR's were below range (54.7% vs. 26.6%). In each of the groups, the average difference between the PerMIT estimated maintenance dose vs. the average daily dose for the TTR period was approximately 0.95 mg/d.
Conclusions: These data support the hypothesis, that a patient's INR response can be maintained within the therapeutic interval for a greater proportion of time when dosing decisions are guided by the plasma concentration time profile.

PO 269

The effect of application of fresh frozen plasma on prothrombin time in the patients overdosed with oral anticoagulant medicaments

Paunovic M, Jankovic-Orešcanin B and Šuput-Tomaš L
Clinical Centre 'Zvezdara', Belgrade, Serbia

Background: Risk factors in patients who receive oral anticoagulant therapy (OAT) are age, severe kidney disease, liver disease and cardiovascular diseases, as well as unstable anticoagulant effect. According to current recommendation, in case of bleeding, when INR is larger that 9, fresh frozen plasma (FFP) is administered, in a dose of 10–20 ml/kg or concentrate of prothrombin complex 50 U/kg and 1 mg of the vitamin K intra venous.
Aims: The aim of the paper was to determine to what extent the application of FFP improve protrombin time (PT) in the bleeding OAT overdosed patients.
Material and Methods: To determine coagulation status, blood samples were taken by standard procedure. PT was done using recombinant rabbit thromboplastin (HemosIL) with ISI 1.1 on ACL 7000 apparatus. Control PT was done 12 h after the administration of FFP. Retrospective counting was done from the protocol for hemostasis and delivery of blood and blood products.
Results: From 1 January 2011 to 31 December 2011, 40 patients were treated in our institution due to bleeding. Most frequent forms of bleeding were gum bleeding (7%), nasal bleeding (35%) and rectorragia (58%). In 14 patients, INR was immeasurable, while in remaining 26 it ranged from 7.83 to 14.4. After FFP was administrated in the dose of 15 ml/kg, 10 patients returned to therapeutic range (INR 2–4), out of whom only one belonged to the group with immeasurable INR.
Conclusion: In overdosed OAT patients, the administration of FFP only does not reduce INR to therapeutic range, which is also found in the paper by other authors.

PO 270

Use of protrombin complex concentrates for urgent reversal of dabigatran in the emergency department: a pilot study

Quintana M[1], Borobia AM[1], Martinez Virto A[1], Fabra S[1], Rivera A[1], Sánchez Casado MNM[2] and García Erce JA[3]
[1]Hospital Universitario La Paz, Madrid; [2]Hospital Virgen de la Salud, Toledo; [3]Hospital San Jorge, Huesca, Spain

Background: Hypothetically prothrombin complex concentrates (PCC) could overcome the anticoagulant effect induced by thrombin and factor Xa inhibitors because PCC contains coagulation factors II, VII, IX, and X in a high concentration and they are known to enhance thrombin generation. While in an animal model infusion with PCC reversed the biological effect of rivaroxaban, data for dabigatran are not as clear-cut.
Objectives: The aim of this study was to describe our experience from the emergency department with the urgent reversal of anticoagulation with dabigatran using a prothrombin complex concentrate.
Methods: An observational study of hemorrhagic complications was carried out in patients treated with dabigatran over a period of 12 months (July 2011 to June 2012).
Results and Conclusions: We report a pioneer experience in five patients on the suitability of PCC used for the reversion of the anticoagulant effect of a direct thrombin inhibitor. PCC was used successfully in our emergency department and was able to control major bleeding events. Based on the small amount of data, we suggest further evaluation of the use of PCC in reversing massive hemorrhage caused by dabigatran.

PO 271

Comparative study of medication compliance to two anticoagulants in the prevention of venous thromboembolism in orthopaedic surgery

Ribeiro MJ[1], Morgado M[1], Morgado S[1] and Martinez J[2]
[1]University of Beira Interior; [2]Hospital Centre of Cova da Beira, Covilhã, Portugal

Background: Rivaroxaban (Riv) is a selective, direct Factor Xa inhibitor indicated in the prevention of venous thromboembolism in adult patients undergoing elective hip or knee replacement surgery (HKRS). It was introduced in the pharmacotherapeutic formulary of the Hospital Centre of Cova da Beira (CHCB) on February/2011. It is administered orally, which is a potential advantage in terms of compliance when compared to enoxaparin (Eno).
Aims: The aim of this study was to compare adherence to Eno vs. Riv in adult patients undergoing elective HKRS. The occurrence of adverse drug reactions (ADRs) was also compared in both groups.
Methods: Cross-sectional study of outpatient compliance to Eno or Riv, in patients undergoing KHRS in CHCB, from February/2011 to April/2012. The evaluation of medication adherence was carried out using a validated questionnaire and the occurrence of ADRs was evaluated in a structured interview.
Results: The study included a total of 84 patients, who underwent elective knee (45 patients) or hip (39 patients) surgery; 42 patients were subjected to therapy with Eno (18 knee + 24 hip) and 42 with Riv (27 knee + 15 hip). In all, 90.5% patients were considered adherent to medication, but it was not observed a significant difference ($P = 0.71$) between patients anticoagulated with Eno (92.9% adherent) or Riv (88.1% adherent). Similarly, there was no significant difference ($P = 1$) in medication adherence between patients undergoing knee or hip surgery. However, there was a significantly higher occurrence of ADRs ($P = 0.002$) in patients treated with Eno (38.0% patients reported ADRs attributable to this drug, mainly hematoma in the site of injection) when compared to patients treated with Riv (9.5% patients reported ADRs attributable to this drug, mainly gastrointestinal and skin disorders).
Conclusions: Although it was not observed a significant difference in adherence to subcutaneous Eno vs. oral Riv, which may be potentially attributed to the short-term anticoagulation therapy (2–5 weeks), the occurrence of ADRs was significantly lower in patients treated with the oral anticoagulant. This difference in drug-related adverse events differs from other studies that detected similar adverse-event profiles. From a methodological point of view, this is a small cross-sectional study and our results must be considered exploratory in nature.

PO 272

The course of D-Dimer levels in patients getting Rivaroxaban in therapeutical doses

Rott H, Halimeh S, Kappert G and Siebert M
Coagulation Centre Rhine-Ruhr, Duisburg, Germany

Background: D-Dimer levels are associated with thromboembolic risk. Patients with atrial fibrillation or after thromboembolic diseases with high D-Dimer levels have a higher risk of thromboembolic diseases.
Usually D-Dimer levels fall to normal range during an effective anticoagulation.
Aims: To view the course of D-Dimer levels in patients receiving Rivaroxaban.
Patients and Methods: We investigated the course of D-Dimer levels before and 4 weeks after starting oral anticoagulation with Rivaroxaban in 56 patients in during the year 2012.
The Rivaroxaban dose was 15 or 20 mg per day according to renal function. The patients had atrial fibrillation or venous thromboembolic disease and had an indication for oral anticoagulation (e.g. CHADS2-Score > 2, recurrent thromboembolic disease, severe throm-

bophilia). There was no patient with acute thromboembolic disease, so that no patient had an indication for 2 × 15 mg/day.
Results: Of these 56 patients: 26 patients (46%) had normal D-Dimer levels before and after intake of Rivaroxaban17 patients (31%) had D-Dimer levels above normal range before therapy with Rivaroxaban an normalized after 4 weeks of Rivroxaban therapy nine patients (16%) had D-Dimer levels above normal range before starting rivaroxaban and D-Dimer levels fell, but stayed above the normal range four patients (7%) had normal D-Dimer during therapy with vitamin-K-antagonist and D-Dimer levels rose above normal range after switching to RivaroxabanSummary:
In summary about 23% of our patients had D-Dimer levels above the normal range despite anticoagulation with Rivaroxaban.
No thromboembolic event occurred during the investigation in these 56 patients regardless of the D-Dimer level. However, the follow up was too short because the investigation time was only up to 12 month.
Conclusion/Discussion: It is not known, what it means clinically that a subgroup of patients have D-Dimer levels above normal range despite oral anticoagulation with Rivaroxaban.
Does it mean, these patients have a higher thromboembolic risk than patients with normal D-Dimer levels during anticoagulation?Do these patients need higher Rivaroxaban doses for effective anticoagulation, for example 15 mg twice daily?A long term follow up of these patients is needed to get more clinical data and to see, it the elevation of D-Dimer during anticoagulation is clinical relevant.

PO 273

Safety of enoxaparin sodium (subcutaneous injection kit) used in clinical settings in patients undergoing abdominal surgery (general surgery and gynecology) – specified drug-use survey

Sakon M[1], Kobayashi T[2], Wada H[3] and Seo N[4]
[1]*Nishinomiya municipal central hospital, Nishinomiya;* [2]*Hamamatsu Medical Center, Hamamatsu;* [3]*Mie University, Tsu;* [4]*Museum North Avenue Clinic, Takamatsu, Japan*

Background/Aims: A specified drug-use survey in Japanese patients who underwent abdominal surgery (general surgery and gynecology) was conducted from March 2009 to June 2012 to evaluate the safety of CLEXANE® Subcutaneous Injection Kit 2000 IU used in clinical settings.
Patients and Methods: The survey included patients who started treatment with CLEXANE® Subcutaneous Injection Kit 2000 IU for cesarean section and for whom preoperative creatinine clearance could be calculated using the Cockcroft formula. In this survey, patient characteristics at enrollment, adverse drug reactions (ADRs), bleeding ADRs, and incidence rate of pulmonary thromboembolism were investigated.
Results: In this survey, 769 cases were collected by continuous registration in participating facilities from 131 facilities in Japan and 9 cases were excluded from the safety analysis. Of the remaining 760 patients (528 general surgery cases and 232 gynecology cases), two patients were excluded from the efficacy analysis, resulting in 758 patients (526 general surgery cases and 232 gynecology cases) evaluated for efficacy. The mean age of patients in the safety analysis was 61.9 years. BMI indicated 33.9% were obese (≥25 kg/m^2) and 66.1% were non-obese (< 25 kg/m^2); malignant tumor was the most frequently observed underlying disease. The mean duration of study treatment was 5.9 days.
There were 100 adverse effects (81 patients) observed, with an incidence rate of 10.7%. Among these, 35 adverse effects (30 patients) were hemorrhagic adverse effects with an incidence rate of 3.9%. The common adverse effects were abnormal hepatic function, posttreatment hematoma and increase in alanine aminotransferase, all of which are known adverse events of the drug. Seventeen severe adverse effects (11 patients) were observed with an incidence rate of 1.4%. Furthermore, pulmonary thromboembolism and deep vein thrombosis were observed in 4 (0.5%) and 1 (0.1%) patients, respectively, but none of these had a fatal outcome (death).
Conclusions: The specified drug-use survey on CLEXANE® Subcutaneous Injection Kit 2000 IU used in clinical settings in patients undergoing abdominal surgery (general surgery and gynecology) did not reveal any potential new safety signals.

PO 274

Availability of laboratory monitoring of new oral anticoagulant (rivaroxaban)

Sukhanov V[1] and Petrova O[2]
[1]*Regional Hospital #1;* [2]*Regional Oncology Dispansary, Ekaterinsburg, Russia*

Background: Bleeding is still a frequent complication for patients on treatment with newly developed oral anticoagulants. One of the main reasons for this is the rejection of the need of laboratory monitoring. Rivaroxaban (R) is a direct factor Xa inhibitors and can be taken orally in fixed doses once or twice a day. R doesn't have readily available assay to measure its anticoagulant effect (AE) so far.
The aim of this study was to evaluate the possibility of measuring AE of R by one of well-known routine methods – blood recalcification technique (RT).
Methods: From 2012 to 2013, we have studied 309 patients (pts) (M/F 158/151; mean age 59 ± 8 years, range 39–68 years) with acute, symptomatic, objectively confirmed (bilateral ultrasound) proximal deep-vein thrombosis (DVT), without symptomatic pulmonary embolism. Pts initially received therapeutic doses of LMWH (enoxaparin): 1 mg/kg twice daily. In 49 pts there was no any net clinical or ultrasound benefit after 5–7 days of initial anticoagulant treatment, therefore we decided to replace LMWH on R to all of them (after preliminary investigation of RT). We started therapy with recommended doses of R: 15 mg twice daily for 3 weeks and then 20 mg per day. Method of RT in short: the basic idea of RT is the recovery of ionized calcium initial concentration in citrated blood (balanced RT). In our method we use lower concentration of calcium than in balanced RT. Empirically we have found that this alteration increases sensitivity of the test to detection of blood hypercoagulation (BHC). RT was determined by thromboelastography (TEG 5000, the USA): time of reaction 'r' – normal range = 660–960 s. Blood analysis was taken after 3–4 h of LMWH injection or swallowing R.
Methods: Forty-nine pts had BHC (range = 375–428 s) after 5–7 days of initial treatment with LMWH assessed by TEG. Replacement by R increased 'r' to normal or hypocoagulation values (range = 685–3450 s). Twenty-eight percent pts had significant blood hypocoagulation after 3 days of therapy R (range = 1220–3450 s). All the changes of R doses (to 20–15–10 mg daily) were induced by TEG values (aimed value – normocoagulation of blood). Net clinical and objective benefits of R therapy began to be detected on the 3rd to the 12th day. There was no case of bleeding in our pts.
Conclusions: Laboratory monitoring is possible and desirable in some cases for the selection of doses of rivaroxaban. TEG is a simple and available method for dose adjustment of new oral anticoagulant (R) therapy. This assay allows individualizing the therapy making it more effective and safe.

PO 275

New treatments and old effects: Dabigatran-induced leukocytoclastic vasculitis

Valero Núñez M, García Navarro I, Mena Rodríguez F, Benet Campos C, Luis Hidalgo MM, Bautista Claver T and Mayans Ferrer JR

Hospital Arnau de Vilanova, Valencia, Spain

Background: Oral anticoagulant therapy is increasingly used for the prevention and treatment of thromboembolic complications of vascular disease. Until recently, we have depend on the vitamin K antagonist class drugs, now the new oral anticoagulants (direct thrombin inhibitors and factor Xa inhibitors) are available. Bleeding is the most serious complication of the use of this drugs. All trials (RE-LY, ROCKET AF, ARISTOTLE) showed non-inferiority or superiority for the efficacy outcome vs. warfarina and rates of major bleeding complications were similar or even reduced. We report a case with a unpublished complication in a patient who starts treatment with dabigatran.

Case report: A 70 year old man with medical history of hypertension and smoking years ago. Diagnosed in February 2005 of atrial fibrillation, then started anticoagulation with acenocumarin which was stopped in June 2005 after successful electrical cardioversion.

In July 2007 was diagnosed with persistent atrial fibrillation CHA_2DS_2-VASc 2, HAS-BLED 2 and starts again acenocumarin therapy with INR (International Normalized Ratio) target between two and three.

From the begining of treatment had regular levels of INR with regular dosis of acenocumarin (16 mg weekly) until October 2011 when was admitted with ischemic stroke of cardioembolic origin. This occurred 24 h after cardioversion. The INR on admission was 1.83. And it was complicated with hemorrhagic transformation. The hospitalization lasted 4 months. At the time of discharge the patient was independent for almost all basic activities of daily living.

In November 2012 acenocumarol treatment was suspended and initiate treatment with dabigatran 150 mg twice daily. The rest of the usual treatment remained unchanged for months.

Just 10 days after the change the patient developed lower limb palpable purpuric lesions, some with vesicles of hematic content. We reduced dabigatran dose to 110 mg twice daily. But the skin lesions continued to evolve with pelvic extension and appearance of superficial necrosis (pictures). Blood count was normal, INR 1.44, TTPAr 2.15 and creatinine 1.34 mg/dl. Detailed coagulation study was normal.

Skin biopsy disclosed leukocytoclastic vasculitis.

Dabigatran was suspended and began low molecular weight heparin at prophylactic doses, oral prednisone and topic treatment.

Actually the lesions improved (pictures) and the patient has resumed acenocoumarin therapy without further incident. Next days, the results to rule out another possible etiology of vasculitis will be ready.

Discussion: In addition to unexpected bleeding, skin reactions like photosensitivity, maculopapular vesicular urticarial eruptions, purple toes syndrome, skin tissue necrosis, and vasculitis are one of the uncommon adverse effects of the vitaminK antagonists therapy.

We report a leukocytoclastic vasculitis with skin tissue necrosis case. The cause of this was seemingly dabigatran because of the close temporal relationship between exposure to the drug and the onset of the symptoms, and the resolution of the lesions after dabigatran was discontinued. Illustrates this observation a new rare association between vasculitis and dabigatran? Clinicians should be aware of this potential adverse effect and recommend interrupting the drug intake when temporal relation is evocative.

Like all new drugs, we need more experience in daily clinical practice, outside clinical trials.

PO 276

Laboratory testing in new oral anticoagulants

Vavilova TV[1], Belyavskaya O[2], Sirotkina OV[1] and Samokhovetz VA[2]

[1]North-West State Medical University named after I.I.Mechnikov; [2]City Diagnostic Centre, Saint-Petersburg, Russia

New oral anticoagulants (NOAC) showed clinical benefits and 'non inferiority' in compare with traditional and were approved in many countries. They don't need in laboratory control and are used in fix dozes. But the problem of interpretation of testing results in laboratory haemostasis for these patients in routine practice is unsolved.

The Aim to estimate the routine haemostatic parameters in patients received NOAC and compare it with thrombotic and haemorrhagic events.

Methods and objectives: Thirty-one patients with non valvular atrial fibrillation were included – 24 received direct thrombin inhibitor dabigatran (42–81 years old, 11 male, 13 female) in dose 110 mg bid (11) and 15 mg bid (13) and seven patients received direct anti-Xa inhibitor rivarixaban 20 mg od (64–76 years old, 3 male, 4 female). Quik test, APTT, thrombin time (TT), FVIII activity, vWF antigen, D-dimers (D-d) were measured (STA Compact, Stago reagents). Observational time – from 3 up to 6 months. The results are presented as median, 25 and 75 percentiles (Me [25%; 75%]); statistic Mann-Witney U-criteria was used. In all cases renal function was estimate before treatment and glomerular filtration rate (GFR) were calculated: it fluctuated from 43 ml/min to 98.8 ml/min.

Methods: We found significant prolongation of APTT and TT in dabigatran group: 43.7 [30.0;51.3] s and 148.6 [51.2;218.1], respectively. The mean values in rivaroxaban group were 28.0 [26.0;30.0] s and 17.1 [16.4;17.7], $P < 0.01$. Markers of activation (FVIII, vWF, D-d) varied widely in both groups and didn't decrease during observational time. There were no significant differences between two dabigatran dosing groups or any correlation with GFR, probably in the result of small groups.

We had no thromboembolic complications, but 3 hemorrhagic events: macrohematuria and sclera hemorrhage (dabigatran), vaginal hemorrhage (rivarixaban).

Conclusion: There is significant prolongation of APTT and TT on dabigatran in distinction of rivaroxaban, without correlation with adverse events. It was surprised the absence of activation markers redaction under NOAC therapy. We need further investigation with higher number of patients.

PO 277

Influence pharmacogenetics analysis on adequacy and safety of therapy by indirect anticoagulants

Vorobyeva NA, Rogozina AS and Vorobyeva AI

NSMU, Arckhangelsk, Russia

In clinical practice pharmacogenetics analysis and pharmacogenetics algorithm dosing of indirect anticoagulants are introduced to optimize the therapy these drug.

The aim to estimate influence pharmacogenetics analysis for adequacy and safety of therapy indirect anticoagulants at inhabitants of Northwest region of the Russia.

Materials and methods. Prospective not randomized cohort research. The pharmacogenetics analysis (PGA) is performed to 100 patients receiving therapy of coumarin. Supervision term over patients is 6 months. PGA was performed with polymerase chain reaction in real time. All patients were divided into four groups according to received prothrombin test results. Data processing was held with use of Microsoft Excel 2003 and SPSS 17.0 software.

Methods: Therapeutic hypocoagulation has been reached at 58% patients for average 6 ± 4.2 days (criterion efficiency of therapy is level international normalised ratio 1.8–3.0). The normal genotype of

PGA (CYP2C9, VKORC1-1639 G>A) has been revealed at 25% patients, 70% patients had the episodes of bleedings, genotype defined propensity to superfluous hypocoagulation has been revealed in 20% cases and 44% patients had bleeding. The supporting dose calculated on Gage et al. model receved of the all patients made 5.3 ± 0.7 mg.
Conclusions: The pharmacogenetics analysis will not replace adequate laboratory monitoring with level INR which reflecting safety therapy of indirect anticoagulants.

PO 278

Intensity of bleeding following tooth extraction is moderated by personality traits independently of anticoagulant therapy

Zolfaghari S[1], Harenberg J[1], Marx S[1], Hassani P[1], Fischer J[1], Damian M[2] and Frölich L[2]
[1]Clinical Pharmacology; [2]Geriatric Psychiatry, Mannheim, Germany

Background: Anticoagulation with dose adjusted vitamin-K antagonists (VKA, therapeutic range of the international normalized ratio (INR) of 2–3) and low dose aspirin (65–330 mg daily) enhance bleeding following tooth extraction. However, intensity of bleeding varies substantially between patients. Guidelines disagree regarding interruption or continuation of anticoagulation for tooth extraction.
Aim: We hypothesized that personality traits may moderate bleeding intensity following tooth extraction independent of anticoagulant therapy with VKA or aspirin.
Methods: A total of 180 patients (77 female, 103 male, 49.9 + 15.3 years [mean, standard deviation]) underwent tooth extraction without interruption of anticoagulation. The study was accepted by the local university ethics committee and patients gave written informed consent prior participation. Sixty three patients did not take any anticoagulant (group 1), 60 patients were on aspirin (group 2), and 57 patients on VKA (INR 2–3, group 3). Patients completed a validated state-trait anxiety inventory (STAI), and a personality inventory with 12 dimensions (Freiburger personality inventory [FPI]). Based on results of a focus group with patients before tooth extraction, and a self-developed questionnaire (ZAI) was set up on general attitudes regarding general feeling and anxiety before tooth extraction. The 43 items of the ZAI were reduced to six factors by multifactorial regression analysis. Dentists (JF, PH) rated bleeding intensity with a score from 0 to 9 according a standardized protocol during and following the intervention. The moderating effects of the STAI and FPI dimensions on the bleeding index were calculated by correlation matrices and for the factors of the ZAI by multinodal logistic regression analysis.
Results: Intensity of bleeding after tooth extraction was higher in group 3 (score < 6 in 63%, score > 6 in 37% of patients) compared to group 1 (92% and 8%) and group 2 (78% and 22%) and higher in group 2 compared to group 1 (all $P < 0.005$, chi-square test). Personality traits influenced the bleeding intensity independently of anticoagulation: higher anxiety values of STAI questionnaire and of the FPI dimensions self consciousness, somatic distress, and emotionality correlated positively ($P < 0.0001$) and lower values for satisfaction ($P < 0.02$) and extraversion ($P < 0.003$) correlated negatively with increased values of the bleeding index. Moderating factors for a higher bleeding index of the ZAI were fear for dentist visits, treatment, complications and risks of intervention (all $P < 0.001$).
Conclusion: The intensity of bleeding following tooth extraction is influence by anticoagulant therapy with VKA and aspirin and independently of the anticoagulants by certain personality traits and previous experiences of patients with tooth treatments. Personality traits and specific experiences of patients with previous and fears for other surgical interventions may also influence bleeding intensity of other surgical interventions independently of anticoagulation. The effect of new oral anticoagulants in this context remains to be determined.

PO 279

Deep vein thrombosis of the penis: an unusual but severe complication of prostatic abscess: case-report and review of the literature

Alatri A, Calanca L, Schaller M-D, Sermier A and Mazzolai L
CHUV – Lausanne University Hospital, Lausanne, Switzerland

Venous thrombosis of the penis has most often been related to the superficial venous system, an affection commonly referred to as Mondor's penile disease. Thrombosis of penis deep venous system (PDVT) has been rarely reported and must be clearly distinguished because it may cause serious clinical complications.
In this report, we describe the case of a 66-year-old patient, hospitalized for prostatic abscesses and septic shock, presenting with a PDVT. Drainage of prostatic abscesses and treatment of septic shock (antimicrobial with piperacillin/tazobactam and support treatments) were immediately undertaken. Patient was also treated with anticoagulant therapy (low-molecular-weight heparin and vitamin K antagonists. Duplex ultrasound showed vein recanalization after 6 months of anticoagulant treatment. Local clinical evolution was favorable despite severe initial manifestation presenting with a high probability of major necrotic sequel of penis.
This is the first reported observation of PDVT associated with infection. At our knowledge, only five cases of PDVT have been reported in the literature. Outcome was negative in 3 cases resulting in penis necrosis or persistent erectile dysfunction. PDVT has been associated with Behçet's disease and heterozygous factor V mutation, Henoch-Schonlein purpura and heterozygous factor II mutation, hyperhomocysteinemia, activated protein C resistance and heterozygous factor V mutation, trauma and elevated factor VIII levels. Duplex ultrasound can be used to easily distinguish between superficial and deep venous penile systems. Additionally, it allows analyses of arterial blood flow as well as penile structures. Use of other imaging techniques, such as MRI or CT-scan, provide additional and different information that may be helpful in better targeting a differential diagnosis, in evaluating an associated neoplasia, or in detailing proximal extension of thrombosis.
Anticoagulant treatment should avoid potentially serious complications in penile structures drained by the deep venous system, thus hindering thrombosis extension to still patent segments. Additional therapeutic options (i.e. thrombolysis or thrombectomy) may be considered depending on the severity of the clinical picture and according to availability of resources and skills personnel. Identification and treatment of an underlying cause provoking PDVT should always be looked for. Searching for other prothrombotic conditions must also be undertaken to optimize anticoagulant treatment duration.

PO 280

Over-representation of thoracic outlet obstruction in patients with unprovoked upper extremity deep vein thrombosis

Chan HW, Ning S, Chan AK, Rebello R and Lau K
McMaster University, Hamilton, ON, Canada

Background: Upper extremity deep vein thrombosis (UEDVT) is a rare condition. Compared with lower extremity DVT, UEDVT has lower risk of pulmonary embolism but it may cause considerable morbidity due to post-thrombotic syndrome. The optimal duration of treatment was 3 months according to the ACCP guidelines. Primary or unprovoked UEDVTs are a subset of UEDVTs that occur in the absence of established risk factors such as catheter-induced injury or malignancy. A potential cause of primary UEDVTs has been postulated to be venous thoracic outlet obstruction. Paget-Schroetter Syndrome (PSS), effort-induced axillary or subclavian vein thrombosis resulting from vigorous and sustained upper extremity movements have been described before. However, the prevalence and role of thoracic outlet

obstruction, in particular intermittent venous outflow obstruction as a significant risk factor for UEDVTs remain unclear.

Aims: To evaluate the correlation between positional venous thoracic outlet obstruction and UEDVT.

Methods: Nine consecutive cases of unprovoked UEDVT referred over a 2 year period (2010–2012) to a tertiary care center in Hamilton, Ontario, Canada were reviewed. All patients were screened for thrombophilia. Contrast-enhanced 3D magnetic resonance angiography (cMRA), combined with provocative manoeuvres with the arms in abducted and resting positions, was performed for all patients to look for thoracic outlet obstruction. Additional T2-weighed images were performed with the affected arm in resting position to identify soft tissue structures including brachial plexus. Detailed chart reviews were conducted to look for additional risk factors for thromboses.

Results: Three of 9 (33.3%) patients had a history of sustained arm movements. Of these patients, all had evidences of thoracic outlet obstruction causing venous compression on MRA. The other 6 (66.6%) patients did not have a history of vigorous or sustained arm movements. Four of these six patients (66.7%) had evidence of thoracic outlet obstruction causing venous compression on MRA. None of the nine patients had clinical symptoms consistent with positional venous thoracic outlet syndrome. Overall, seven of nine patients (77.8%) had evidence of venous thoracic outlet obstruction on MRA when the affected arm was in abduction position, with one patient having obstruction with arms in both abduction and resting positions.

Summary/Conclusions: Positional thoracic outlet obstruction causing intermittent venous blockade is over-represented in patients with unprovoked UEDVT. If available, cMRA combined with provocative manoeuvres should be performed in this patient population to define the underlying pathology associated with the venous obstruction. Whereas thoracic outlet obstruction presents as an ongoing factor associated with UEDVT, the need for extended therapy beyond 3 months in this patient population should be readdressed. Further recurrence may also be prevented by therapeutic strategies to avoid positional venous obstruction.

PO 281

Venous thrombosis and plasma homocysteine levels in the cardiac pacing patients

Domagala TB[1], Lelakowski J[2], Kotula-Horowitz K[1], Janczura M[2], Dziedzina S[1] and Musial J[1]

[1]Jagiellonian University School of Medicine; [2]The John Paul II Hospital, Krakow, Poland

Background: Despite major advances in the techniques of pacemaker implantation, these procedures are still associated with many complications, occurring both early and late during the follow-up. Patients who undergo the implantation of a pacemaker, or a defibrillator, are at risk of thrombosis associated with transvenous leads. Increased homocysteine levels are related to the occurrence of venous thrombosis (VT), but whether this relation is actually causative still remains unclear, as does the association between this amino acid and the complications in the cardiac pacing patients.

Aim: To assess whether the occurrence of venous thrombosis and plasma homocysteine levels are associated with the actual mode of cardiac pacing.

Methods: The study group comprised 92 subjects (38 females, mean age 71 ± 7.58 years) with a cardiac pacemaker. Subjects were divided according to the actual mode of cardiac pacing into Group A (64 subjects; mean age 69.96 ± 7.86 years) with physiological (DDD) pacing and Group B (28 subjects; mean age 73.27 ± 6.79 years) with non-physiological (VVI) pacing, respectively. Cardiac pacemakers were implanted due to SSS, AVB (II, III gr.), atrial fibrillation cum brady-arrhythmiae, respectively. Transthoracic echocardiography was performed prior to and after pacemaker implantation. Screening for C677T polymorphism of MTHFR was carried out by the standard method. The plasma homocysteine levels before and after 7 days, within 1, 3, 6 and 12 months of pacemaker implantation were measured. The levels of D-dimers, fibrinogen, tissue factor (TF), factor VII, plasminogen activator inhibitor-1 (PAI-1), interleukin-6 (IL-6) and hsCRP) were also determined.

Results: The two groups differed with respect to the pacing mode. During the 18-month follow-up period 10 subjects developed VT, i.e. 11.76% of the entire study population (5 in Group A and 5 in Group B; $P = 0.12$). The symptoms of VT occurred in 10 subjects within the post-implantation period (mean of 13.06 months; 7–17 months). The carrier frequency for 677T allele was similar in both study groups (0.296 vs. 0.327; p = ns). There were 5 (7.81%) and 3 (11.54%) homozygous for allele 677T of the MTHFR gene (Group A and Group B, respectively, $P = 0.61$). At baseline, plasma homocysteine levels were higher in Group B subjects (14.98 ± 3.47 μM *vs.* 13.07 ± 3.48 μM; $P = 0.02$). Also after pacemaker implantation, mean plasma homocysteine levels were significantly higher in Group B subjects ($P = 0.04$). Also, in the Group B subjects only, after pacemaker implantation, plasma homocysteine levels remained increased non-significantly for up to 3 months (14.98 ± 3.47 μM *vs.* 16.75 ± 6.69 μM *vs.* 15.40 ± 50 μM *vs.* 15.54 ± 3.05 μM; for baseline, 7 days, 1, and 3 months, respecively), and then spontaneously reverted to baseline values.

Conclusions: The MTHFR 677TT genotype and plasma homocysteine levels were not related to the risk for VT. The elevated homocysteine levels following pacemaker implantation may well be attributable to the actual mode of cardiac pacing.

PO 282

Ageing of the venous valves as a new risk factor for venous thrombosis in the elderly – the BATAVIA pilot study

Karasu A, Šrámek A, Rosendaal FR and Van Hylckama Vlieg A

Leiden University Medical Center, Leiden, The Netherlands

Background: Increasing age is a strong risk factor for venous thrombosis (VT). Previously, we have shown that ageing leads to damaged venous valves, i.e. thicker and less functional valves. Ageing of the venous valves has, as yet, not been investigated *in vivo* in relation to the risk of venous thrombosis.

Aims: The aim of this study is to assess the effect of valve thickness and function on the risk of venous thrombosis.

Methods: Analyses were performed in the Biology of Ageing and Thrombosis: Appraisal of Valve thickness and function, and *in vivo* Assessment – the BATAVIA study. We will invite 100 patients aged 70 years and older with a first deep venous thrombosis of the leg between 2008 and 2011 and 100 controls subjects without thrombosis. We will perform an extensive ultrasound examination of the venous valves in the popliteal vein in the non-affected leg, as the non-affected leg represents the stage of the ageing process of the venous valves in the affected leg prior to the thrombotic event.

We excluded all patients with a recurrent VT in the contralateral leg and patients with a history of deep venous surgery in the lower extremities.

The valves of the popliteal vein were imaged with a 9 MHz linear probe using B-mode ultrasonography. Valve closure time (VCT) was assessed as an indicator for valve function using an automatic inflatable cuff. After the examination, a short interview was conducted to obtain information on post-thrombotic syndrome and varicose veins.

This study is still ongoing. Currently we present the results from the pilot study ($n = 20$). At the time of the ISTH conference, complete results of this study will be available.

When complete data for cases and control subjects are available, relative risks adjusted for age and sex will be estimated by calculating odds ratios (OR) and their 95% confidence intervals (95% CI). This study was approved by the Medical Ethics Committee of theLeidenUniversityMedicalCenterand all participants gave written informed consent.

Results: Currently, measurements are available for the first 20 patients. Mean age of the participants was 77.8 (range 74–90). In 18 of 20 participants valve parameters could be measured. Mean thickness of the valves was 0.43 mm (range 0.31–0.53 mm). Mean VCT was 0.35 s (range 0.2–1.2 s), which shows that venous reflux was present in some patients.
Conclusion: This pilot study shows that *in vivo* visualization of venous valves and measurement of valve thickness by ultrasound is feasible. Complete results will show whether ageing of the venous valves, i.e. an increase in valve thickness and a decrease in valve function, is associated with an increased risk of venous thrombosis in the elderly.

PO 283

Management and treatment outcomes of venous thromboembolism (VT)

Nori FS, Foyn S, Førsund A, Kahrs J and Ghanima W
Østfold Hospital in Fredrikstad-Norway, Fredrikstad, Norway

Background: Deep vein thrombosis (DVT) and pulmonary embolism (PE) collectively known as VT are acute medical emergency affecting 1/1000 inhabitant. VT is often predisposed by risk factor. The symptoms of VT are non-specific and the diagnosis requires objective tests. Anticoagulation is the mainstay of VT treatment. Clinical outcomes after VT include recurrent thrombosis, cancer and mortality.
Aim: The aim of this study was to explore risk factors, clinical presentation, treatment modalities and mortality after VT.
Methods: This study represents cases of VT registered in the Thrombosis Registry of Oestfold the 'The Troll registry' during the period 2005–2011. This quality control registry includes base-line and follow-up data on all patients managed for VT in Oestfold county of Norway. First registration is considered as index event. The register is approved by the Norwegian Social Science Data Service.
Results: In total 1308 objectively verified VT events were registered in 1231 patients 660 (54%) males. These were classified as DVT in 683 (52%), PE in 565 (43%) and both in 60 (5%). Median age at diagnosis was 64 years (IRQ = 50–76). At time of data analysis 322 patients were dead, including 131 (20%) of DVT patients, 182 (34%) of PE and 11(18%) of those with both diagnosis. There was significantly higher mortality among PE compared to DVT ($P < 000.1$). Median time to death in DVT and PE were 0.9 years (Range = 0–6) and 0.5 years (0–7), respectively. Thirty-five percent of those having PE and 21% of DVT died within first 90 days following diagnosis.
A risk factor was identified in 798 (61%) of the events; these were: previous VT 321 (25%); family history of VT 192 (15%); immobilization 220 (17%), including 101 (8%) orthopedic surgery, other general surgery 50 (4%), trauma 57 (4%), medical disease 12 (1%); active cancer 262 (20%); long-haul flights 120 (9%); contraceptive pills/HRT 107 (8%); sedentary life style 82 (6%); known thrombophilia 60 (5%); pregnancy 21 (2%).
Pain, swelling and/or tenderness were presenting features of DVT in 482 (75%); 539 (83%); 351 (55%), while dyspnea and/or chest pain were found in 353 (66%) and 271 (50%) of PE, respectively. Seventy-one (13%) of PE had received antibiotic by general practitioner (GP) last 4 weeks before diagnosis. A 524 (77%) of DVT and 11 (2%) of received ambulant treatment. Median duration of hospital stay in DVT/PE was 4 and 5 days. Twenty (4%) of PE and 12 (2%) of DVT received thrombolysis.
Summary/Conclusions: This study describes unselected population of VT. A recognizable risk factor of VT was found in 61%. Despite wide use of thromboprophylaxis 17% of VT were predisposed by a surgical or medical condition requiring immobilization. These should have been prevented if adequate thromboprofylaxis was given. Thirteen percent of PE were misdiagnosed by GP as respiratory tract infection indicating the need for greater awareness for this condition. There was significantly higher mortality among PE patients than DVT.
Such quality control registries are required to monitor the quality of management and unravel eventual weaknesses.

PO 284

Non-inherited causes of newly diagnosed venous thromboembolism in Croatia in 2011: Croatian Cooperative Group for Hematologic Diseases (CROHEM) study

Pulanic D[1], Gveric-Krecak V[2], Nemet-Lojan Z[3], Holik H[4], Coha B[4], Babok-Flegaric R[5], Komljenovic M[6], Petrovecki M[7], Zupancic Salek S[1], Labar B[1] and Nemet D[1]
[1]Clinical Hospital Center Zagreb, Zagreb; [2]General Hospital Sibenik, Sibenik; [3]General Hospital 'Dr. Tomislav Bardek', Koprivnica; [4]General Hospital 'Dr. Josip Bencevic', Slavonski Brod; [5]General Hospital Varazdin, Varazdin; [6]General Hospital 'Hrvatski ponos', Knin; [7]Dubrava Clinical Hospital, Zagreb, and Rijeka University School of Medicine, Zagreb, Croatia

Background: Venous thromboembolism (VTE) is a major medical health problem associated with significant morbidity and mortality. VTE is a multifactorial disease, resulting from a complex interaction of genetic and acquired factors. The incidence and characteristics of VTE in Croatia has not been well described.
Aims: To investigate non inherited causes of VTE among newly diagnosed patients with secondary VTE in Croatia.
Methods: Croatian Cooperative Group for Hematologic Diseases (CROHEM) conducted observational non interventional epidemiological study from January 1st until December 31st 2011 analyzing medical records of newly diagnosed patients with VTE from 5 major general hospitals (Sibenik, Knin, Koprivnica, Slavonski Brod, and Varazdin) in 4 different Croatian counties (Sibenin-Knin County, Koprivnica-Krizevci County, Brod-Posavina County, and Varazdin County). Study was approved by a medical ethics committee of each hospital.
Methods: There were 642 new cases of VTE in 2011; 389 (60.59%) of them with deep vein thrombosis (DVT), 218 (33.96%) with pulmonary embolism (PE), and 35 (5.45%) cases of both conditions. There were 280 (43.6%) males (median age 65 years) and 362 (56.4%) females (median age 74 years, $P < 0.001$ compared to male). Among them, 371 (57.8%) were secondary and 271 (42.2%) were idiopathic VTE. Recidivism of VTE was diagnosed in 78 patients (12.15%). There was no difference in recidivism between secondary and idiopathic VTE. Although patient population with VTE was in general old (median age 71 years), patients with secondary VTE were younger than those with idiopathic VTE (median age 69 vs. 74 years, $P < 0.001$). There was no gender difference between them. The most frequent causes of secondary VTE were cancer (40.4% of secondary VTE) and trauma, surgery and immobilization (37.5% of secondary VTE), while other causes of secondary VTE were less frequent (other diseases (e.g. neurological diseases with paralysis, autoimmune diseases, inflammatory bowel diseases) (17.9%), sepsis (9.7%), central venous catheter (3.25%), pregnancy [2.16% of secondary VTE]). More than one non inherited risk factor for VTE had 43.40% of patients with secondary VTE. Among all 642 VTE patients, 69 (10.75%) died, 35 (50.73%) of them having VTE as a main cause of death. More patients died among secondary VTE (55 deaths of 371 secondary VTE, 14.8%) than among idiopathic VTE patients (14 deaths of 271 idiopathic VTE, 5.2%) ($P < 0.001$).
Summary/Conclusion: Many cases of secondary VTE had more than one underlying non inherited condition for development of VTE. The most common risk factors for VTE were malignancy, trauma, surgery, and immobilization. Secondary VTE had higher mortality than idiopathic VTE. As non inherited risk factors for VTE, such as surgery and cancer, are applicable to more people, improved thromboprophylaxis in these settings might substantially lower the incidence of VTE.

PO 285

Audit of completion of compulsory documented risk assessment for venous thrombosis

Quinn K[1], Lavery RC[1], Speers H[1] and Benson G[2]

[1]*Belfast City Hospital;* [2]*Northern Ireland Haemophilia Centre and Thrombosis Unit, Belfast, Northern Ireland*

Background: Venous thromboembolism (VTE) is historically a poorly managed risk in hospitalised patients and it is responsible for the deaths of an estimated 60,000 people in the UK each year. In order to reduce the risk of VTE, the Belfast Health and Social Care Trust introduced a thromboprophylaxis policy in December 2011 which gave detailed guidance on appropriate VTE risk assessment for all hospitalised patients. This policy is in conjunction with a standard printed VTE risk assessment which has been part of the hospital drug kardex since 2010. In March 2012, we initiated auditing of the completion of the trust VTE risk assessment and have continued auditing on a monthly basis since then. We started our audit in one hospital base within the trust and have since progressed the audit to involve all four hospitals within the Belfast Trust, encompassing 2111 inpatient beds.

Aims: The overall aim of our audit is to increase the completion rate of VTE risk assessment within the Belfast Trust. We have set our target completion at 95%.

Methods: Three auditors collected data on a monthly basis. Every inpatient drug kardex was reviewed for completion of the VTE risk assessment. Data was collated and written feedback was given to each ward within the hospital regarding their current performance.

Results: At the start of the audit, the completion of VTE risk assessment at site one was 53.9%. After 9 months of auditing and feedback, the completion has improved to 72%. At site two, initial completion was 48.5%. This has only improved to 51.3% following 4 months of auditing and feedback. The completion rate for site three, which is the regional elective orthopaedic unit, was initially 58.2% and this has dramatically improved to 91.8% after 4 months of auditing. At site four, which is in the early stages of audit, the initial completion of 40.6% has improved to 43.6% after 2 months of audit.

Conclusion: Since the introduction of the VTE risk assessment and Trust Policy, the completion target of 90% has only been achieved at one hospital site within the Belfast Trust. The completion rate at the remaining three sites is improving, but at a much slower rate. Our audit is on-going on a monthly basis at all sites and we hope to see continued improvement in all hospitals within the trust through feedback to wards and heightened awareness of the need for VTE risk assessment.

PO 286

Is MTHFR 677 genotyping a link that can be missed from the chain of assessment of the venous thrombosis risk?

Vuckovic BA, Mitic G and Ilic TA

Clinical Center of Vojvodina, Novi Sad, Serbia

Background: Venous thrombosis is common cause of morbidity and mortality in most developed countries. It may develop as a consequence of numerous inherited and acquired risk factors, and a sinergy of these factors further increases the risk of this disease. Efficient recognition and management of risk factors for venous thrombosis are very important in reliable risk stratification, and recommendations about analyses available for detecting risk factors that would respect cost-benefit aspects are necessary for routine clinical practice with individuals already affected by the thrombotic process and for prevention of this disease.

Aim: The aim was to clarify whether determination of homocysteine or methylenetetrahydrofolate reductase (MTHFR) 677 genotyping has a greater clinical significance in the daily practice of preventing venous thrombosis and its complications.

Methods: A total of 110 subjects were enrolled. Among them 55 venous thrombotic patients (case group, mean age 41.24 ± 12.13 years) and 55 healthy controls with no history of any thrombotic event (control group, mean age 42.47 ± 10.92). Patients and controls were age and sex matched. Plasma homocysteine concentration was determined using a fluorescence polarization immunoassay method. Hyperhomocysteinemia was defined as plasma homocysteine levels above 12 μM. Detection of the MTHFR 677 C or MTHFR 677 T allele was performed through real-time PCR on ABI PRISM 7000 Sequence Detection System instrument, using the assay for allelic discrimination. Statistical analyses were performed using the Statistic 10 software. Informed consent was taken from the subjects. An institutional committee had approved the study protocol.

Results: Statistically significantly higher mean homocysteine concentration was found in cases compared to in controls (12.94 ± 5.08 μM vs. 9.72 ± 3.82 μM; $P < 0.001$), and there was significantly higher incidence of hyperhomocysteinemia in cases (63.6% vs. 18.2%; $P < 0.001$). Comparison of subjects with idiopathic venous thrombosis and those with secondary venous thrombosis did not show a significant difference in relation to homocysteine levels (13.47 ± 6.85 μM vs. 12.46 ± 2.73 μM; $P = 0.980$). On the basis of the results of genetic testing for mutations in the MTHFR 677 gene, cases and controls were classified into homozygous carriers of the mutation (677 T/T), heterozygous carriers (677 T/C) and non-carriers (677 C/C). There were no significant differences in homocysteine concentrations between the three case subgroups (13.02 ± 2.09 μM vs. 12.55 ± 5.98 μM vs. 13.84 ± 6.50 μM; $P = 0.169$) as well as between the three control subgroups (9.21 ± 2.37 μM vs. 10.07 ± 4.90 μM vs. 10.13 ± 2.58 μM; $P = 0.706$). Also, there were no significant differences in incidence of three genotypes between cases and controls ($P = 0.650$). However, comparison of the levels of homocysteine between the subgroups of patients and subgroups of healthy controls showed that there is no significant difference in homocysteine levels in the 677 T/T carriers in case group compared to 677 T/T carriers in control group (13.84 ± 6.50 μM vs. 10.13 ± 2.58 μM; $P = 0.114$), while there is significant difference between 677 T/C carriers in case group and 677 T/C carriers in control group (12.55 ± 5.98 μM vs. 10.07 ± 4.90 μM; $P = 0.014$), and between non-carriers among patients and non-carriers among controls (13.02 ± 2.09 μM vs. 9.21 ± 2.37 μM; $P < 0.001$).

Conclusion: Our results suggest that determination of plasma homocysteine concentration has a much more significant clinical role in the prevention of venous thrombosis compared to MTHFR 677 genotyping.

PO 287

Factor VII levels and genetic polymorphisms in severe preeclampsia

Godoi LC, Gomes KB, Carvalho M and Dusse LMS

University of Minas Gerais, Belo Horizonte, Brazil

Background: Preeclampsia (PE) is a syndrome characterized by the onset of hypertension and proteinuria in normotensive pregnant women, after the twentieth week of pregnancy. The PE is associated with a hypercoagulable state even more evident that the physiological condition of pregnancy. The actual model accepted for the blood coagulation process detaches the tissue factor (TF) as the essential factor to trigger the coagulation cascade pathway, which leads to fibrin blood clot formation. When vascular damage occurs, blood is exposed to TF that binds to factor VII (FVII), activating it (FVIIa). The TF/FVIIa complex activates directly factors X and IX, resulting in thrombin generation and consequently in fibrinogen cleavage into fibrin monomers. Previous studies suggest a relation between FVII gene polymorphisms, -402GA and -401GT, and its plasma levels.

Aim: The aim of this study was to evaluate FVII plasma levels, the FVII gene polymorphisms and the occurrence of severe PE.

Methods and Results: A group of 94 pregnant from Brazil with severe PE were evaluated. Plasma levels of FVII were not significantly different when compared the genotypes AA X AG X GG regarding the -402GA polymorphism ($P = 0.078$) and the genotypes GG X GT X TT in -401GT polymorphism (0.082). The correlation between the polymorphisms -402GA and -401GT and FVII plasma levels was also not significant ($P = 0.144$ and 0.053, respectively).
Summary/Conclusion: The results demonstrated that there isn't an association between reduced levels of FVII and the presence of alleles -402G and -401T in pregnant with severe PE.

PO 288

Investigation on expression pattern of VKORC1 in mouse brain

Liphardt K[1], Czogalla KJ[2], Baader S[3], Watzka M[2] and Oldenburg J[2]
[1]*University Clinic Bonn;* [2]*Institute of Experimental Haematology and Transfusion Medicine;* [3]*Institute of Anatomy and Cell Biology, Bonn, Germany*

Background: The role of vitamin K is well-known in the coagulation cascade. Additionally, vitamin K plays also a role in bone metabolism and cell cycle regulation. Vitamin K dependent (VKD) proteins are classified according to their structure and homology: proteins belonging to coagulation (factor II, VII, IX and X, protein C), proteins important for cell cycle (growth arrest protein 6 (Gas6) and protein S), calcium-binding proteins (osteocalcin and matrix gla protein, MGP) and proteins with unknown function (proline-rich gla proteins 1 and 2 and transmembrane gla proteins 3 and 4). Biological activation of VKD proteins depends on posttranslational γ-carboxylation by γ-glutamyl carboxylase (GGCX). Vitamin K is reduced to hydroquinone by the enzyme VKORC1 (Vitamin K epoxide reductase complex, subunit 1). Hydroquinone then serves as a cofactor for GGCX, rendering VKD proteins biological active. Thereby, hydroquinone is oxidized to epoxide which is reduced by VKORC1 back to the hydroquinone form of vitamin K (known as vitamin K cycle).
Aims: The function of vitamin K in blood coagulation is well established. However, the role beside coagulation is less understood. The analysis of mRNA expression of VKORC1 in brain could clarify the overall knowledge of vitamin K.
Methods: A probe with a length of 558 bp from murine VKORC1 cDNA was cloned into the pBluescript SK II + vector comprising T3 and T7 RNA polymerase promoters. By *in vitro* transcription DIG-labeled RNA probes were generated. *In situ* hybridization (ISH) was performed using paraffin mouse brain sections.
Results: We examined the expression pattern of VKORC1 in brain of 11 days (P11) old mice by ISH. VKORC1 mRNA was present in the Purkinje cells of the cerebellum and in the pyramidal neurons of the hippocampus.
Conclusion: Based on our results we suggest that VKORC1 is expressed in mouse brain and an additional function of vitamin K beside coagulation should be taken into account. Therefore, further studies are needed to study the detailed role of VKORC1 in the context of brain development and function.

PO 289

Establishment of a reference interval for canine FVIIa level in healthy client owned dogs

Lövgren KM[1], Kristensen AT[2], Wiinberg B[1], Tranholm M[1] and Knudsen T[1]
[1]*Novo Nordisk A/S, Måløv;* [2]*University of Copenhagen, Copenhagen, Denmark*

Background: Administration of recombinant human activated FVII (rhFVIIa) is efficacious and safe for treatment of FVII deficiency as well as inhibitor complicated haemophilia A and B. Dogs are phenotypically appropriate models for human FVII deficiency and haemophilia research, and administration of rhFVIIa has proven effective in dogs. Still, little is known about normal canine FVII and FVIIa levels in healthy dogs.
Aims: Establish a reference interval for activated canine FVII clotting activity (cFVIIa:Clot) based on samples from a population of healthy normal dogs.
Methods: Stabylite plasma from 41 healthy dogs of different breeds, ages and sexual status, were analysed in a species specific FVIIa:Clot assay, with all canine reagents. A standard curve was generated with recombinant activated canine FVII (rcFVIIa) and used to convert clotting times to FVIIa concentrations. The reference interval (RI) was calculated using The Reference Value Advisor.
Results: The 95% RI for cFVIIa:Clot was 1.4–29 ng/ml, mean 5.3 ng/ml, similar to what has previously been reported for human FVIIa:Clot at 4 ng/ml (0.5–8.4 ng/ml).
Conclusions: The results demonstrate that dogs have a similar FVIIa level to humans, which further supports the dog as a valuable animal model for FVIIa research.
This study was approved by the Companion Animal Ethics and Administrative Committee at the DepT. of Veterinary Clinical and Animal Sciences, University of Copenhagen, and by the Novo Nordisk Ethical Review Committee. For all dogs recruited the owners provided a signed consent form.

PO 290

Congenital factor VII deficiency and surgery in a single center experience

Park YS[1], Park JK[2] and Choi E-J[3]
[1]*Kyung Hee University Hospital at Gangdong, Seoul;* [2]*Busan Paik Hospital, Busan;* [3]*Catholic University of Daegu School of Medicine, Daegu, South-Korea*

Background: Congenital factor VII (FVII) deficiency is a rare hemorrhagic disorder that can cause excessive bleeding during and after surgery in affected patients. The recombinant form of activated factor VII (rFVIIa, NovoSeven^{R} from Novo Nordisk, Bagsvaerd, Denmark), which was developed as a second-generation bypassing agent, has recently been used in the management of bleeding for patients with congenital FVII deficiency.
Aims: We review the results of surgical procedures in patients with congenital FVII deficiency at our center and describe the safety and effectiveness of surgery with rFVIIa or with an antifibrinolytic agent without rFVIIa.
Methods: We reviewed the results of nine surgical procedures in six patients with congenital FVII deficiency at the Kyung Hee University Hospital at Gangdong, Seoul, Korea, between January 2008 and December 2012. We administrated rFVIIa preoperatively in seven patients and postoperatively in six patients. We administrated rFVIIa pre-and postoperatively. FVIIa was administrated every 4 h with the first dose being administered 0.5 h preoperatively at least 48 h with dose 15–30 /kg. After 48 h, the frequency was reduced according to the patient's clinical status. FVII levels were measured before testing and then again after the intravenous administration of routine dose FVIIa.
Results: Between January 2008 and December 2012 at our center, nine operations were performed successfully and no complications were observed in the six patients with congenital FVII deficiency. The median age of the patients was 10 years (range, 2–37 years). The median level of FVII activity was 2% (range, 0.6–7%). Four major orthopedic procedures, 1 tonsillectomy, 1 hydrocelectomy and 3 dental extractions were performed. The median duration of hospitalization was 6 days (range, 0–15 days). rFVIIa was administered at all procedures, except the dental extraction that was performed using only antifibrinolytic agents without any replacement. FVII levels were very various

depending on each individual. No bleeding or thrombogenic complications were observed in any case.

Conclusion: Patients with congenital FVII deficiency who require surgery can be treated efficiently and safely with rFVIIa or antifibrinolytic agents. rFVIIa was well tolerated and maintained effective hemostasis and showed good clinical outcome after the major surgery. Knowledge of the patients' previous bleeding history and their response to rFVIIa should be helpful in managing bleeding during surgery in patients with factor VII deficiency.

PO 291

Pharmacodynamic effects of escalating dosages of a new recombinant human Factor VIIa (LR769) in congenital hemophilia A or B patients

Powell J[1], Kluft C[2], Moerland M[3], Frieling J[4] and Valentino LA[5]

[1]University of California Davis, Sacramento, CA, USA; [2]Good Biomarker Sciences, Leiden, The Netherlands; [3]Centre for Human Drug Research, Leiden, The Netherlands; [4]rEVO Biologics, Framingham; [5]Rush University Medical Center, Chicago, IL, USA

Background: Congenital Hemophilia A and B treatment may be complicated by the development of inhibitors to the deficient factor. In such cases factor replacement becomes ineffective, and use of a bypassing agent is needed to treat bleedings or in the peri-operative period. A recombinant form of activated Factor VII has been available for this purpose. In this study, the pharmacodynamic effects of a new recombinant human Factor VIIa (LR769) produced by LFB/rEVO Biologics are tested.

Aims: The objectives of the study are to assess the pharmacodynamic effects over time of LR769 after a single dose of 25, 75, and 225 μg/kg in hemophilia A or B patients with or without inhibitors.

Methods: Two sites in the USA and 1 in the Netherlands are participating. The study was approved by the IRB/EC of the institutions and performed consistent with the Declaration of Helsinki. Informed consent was obtained prior to any study activities. It is an open label, randomized, cross-over study. Fifteen adult hemophilia A or B patients with or without inhibitors will be treated in three dosing cohorts. Each patient is treated in two cohorts on two separate occasions, according to one of three sequences: 25 and 75 μg/kg, 25 and 225 μg/kg, or 75 and 225 μg/kg. Each dose cohort consists of 10 administrations.

Serial sampling to obtain plasma for performing several pharmacodynamic parameters are taken at baseline and up to and including 24–36 h after administration. Assays performed include a) Thrombin generation assay output (at variable assay conditions and made sensitive to variations at high doses), including lag time, time to peak, peak, and endogenous thrombin potential; b) activated partial thromboplastin time; c) prothrombin time; d) Prothrombin fragments 1 + 2; e) D-dimer; f) thrombin-antithrombin complex; g) thromboelastometry using RoTEM, including evaluation of lysis.

Results: The first cohort has been successfully treated without any safety issues, and dosing is continuing. At the time of the conference the evolution over time of the pharmacodynamic parameters will be presented.

Summary: In order to provide hemophilia patients with inhibitors additional therapeutic options, a new recombinant human FVIIa (LR769) is being developed. This study provides important information in the target population on the pharmacodynamic effects of LR769 in order to determine the appropriate dose and frequency of administration for further clinical efficacy studies.

PO 292

Pharmacodynamic effects of two recombinant FVIIa products in anticoagulated healthy volunteers

Reijers J[1], Moerland M[1], Frieling J[2], Levi M[3], Kluft C[4], Guan Z[1], Freijer J[1] and Burggraaf J[1]

[1]Centre for Human Drug Research, Leiden, The Netherlands; [2]REVO Biologics, Framingham, MA, USA; [3]Academic Medical Centre, Amsterdam; [4]Good Biomarker Sciences, Leiden, The Netherlands

Background: For many years, recombinant human activated coagulation factor VII (rhFVIIa) has been used for the treatment of haemophilia A or B patients with inhibitors to factor VIII or IX. The effectiveness of treatment is determined by assessment of bleeding cessation, however, a lack of a clear correlation between pharmacodynamic (PD) and pharmacokinetic (PK) parameters hinders dose optimisation and development of new rhFVIIa products. Therefore PK and PD properties of two rhFVIIa products (LR724 and eptacog alfa) were assessed in healthy volunteers, who were pre-treated with fondaparinux to induce an anticoagulated state. LR724 is a novel rhFVIIa product under development.

Methods: This double-blind clinical study was approved by an independent medical ethics committee and informed consent was obtained from all participants. Thirty-six healthy male subjects were dosed in a randomised fashion to placebo ($n = 6$), 15, 45 or 90 μg/kg rhFVIIa (6/0:6/6:6/6, LR724/eptacog alfa). Subjects received 5 mg fondaparinux subcutaneously 2 h prior to intravenous bolus administration of study drug. FVIIa activity and antigen, thrombin generation (TGT), coagulation times, and markers of coagulation activation were assessed regularly up to 24 h. Based on the observed effect profiles, a PK-PD model for PT and TGT lag time was developed with NONMEM.

Results: Both products induced a dose-dependent increase in FVIIa activity; up to 1000-fold baseline at 90 μg/kg. Apparent half-life ranged from 1.9 to 2.8 h. Reversal of the fondaparinux-induced anticoagulant state was observed: significant reductions for TGT lag time (−15.9% and −20.9% for 45 and 90 μg/kg) and related parameters (time to peak, velocity index) and increase of AUC and peak value, PT (−21.8% and −26.0% for 45 and 90 μg/kg) and APTT (−5.6% at 90 μg/kg). Prothrombin fragment 1 + 2 (+96.0%) and TAT complex level (+83.9%) were only significantly increased at the highest dose level of rhFVIIa. D-dimer and fibrinogen levels did not change significantly.

The FVII activity time-course followed 2-compartment kinetics, and was modelled, including endogenous FVII activity as a cosine function of clock time, fitted to data from the placebo group. This PK model was incorporated into a maximum effect PK-PD model to describe the effects on PT and TGT lag time. For PT a flat baseline time-profile was used and for TGT lag time a fondaparinux (anti-Xa) concentration-dependent component. Adding a 1-compartment PK model for anti-Xa data from the placebo group resulted in a robust model for the interaction between fondaparinux and the effects of the two products on TGT lag time.

Conclusion: By applying a fondaparinux challenge, pharmacodynamic effects of LR724 and eptacog alfa could successfully be evaluated and modelled in healthy volunteers. This clinical study demonstrated that PT and TGT lag time are good markers to accurately assess the relation between rhFVIIa dose level and procoagulant effect. Simulations with this model may guide future drug development, and demonstrated that repeated administration of both 45 and 90 μg/kg rhFVIIa at a 2- or 3-h interval would result in a maximal pharmacodynamic effect.

PO 293

The association of FXIII val34leu polymorphism with cerebrovascular thrombosis in Iranian patients

Sajjadi SM[1], Samiei S[1], Kheirandish M[1], Tabatabaei SMR[1] and Azadi A[2]

[1]*Iranian Blood Transfusion Organization;* [2]*Tabriz University of Medical Sciences, Tabriz, Iran*

Background: A G to T substitution in exon 2 of the FXIIIA gene results in the replacement of Valine with Leucine in amino acid 34. It has been suggested that this substitution (FXIII Val34Leu polymorphism) would be a predisposing factor for intracerebral hemorrhage or a protective factor against venous thrombosis. Furthermore, FXIII Val34Leu polymorphism has a significant heterogeneity among different population.

Aim: An investigation into the role of FXIII Val34Leu polymorphism in cerebrovascular thrombosis in Iranian patients using a case-control study.

Method: Thirty-three patients with cerebrovascular thrombosis who were admitted to Iranian Blood Transfusion Organization (IBTO) thrombosis and hemostasis laboratory were selected as case group. The control group were consisted of 100 age and sex matched healthy subjects. FXIII Val34Leu polymorphism were genotyped by using polymerase chain reaction (PCR)-restriction fragment length polymorphism (RFLP) method. Cfo1 was used as the restriction enzyme.

Results: No significant differences was observed between the prevalence of Val/Val (wild type) genotype in case (75.8%) and control groups (64.0%). On the other hand, the prevalence of FXIII Val34Leu polymorphism was not significantly different in cases (24.02%) and controls (36%) with a Pv of 0.151 and odds ratio of 0.569 (95% confidence interval: 0.233–1.392).

Summary/Conclusion: According to the similar results in both groups, we concluded that the presence of FXIII Val34Leu polymorphism is not associated with cerebrovascular thrombosis in Iranian population.

PO 294

The evaluation of cases with Factor X deficiency in Southern East of Turkey

Soker M[1], Karabel M[1], Yildirim A[2], Oymak Y[3], Kelekci S[1] and Karabel D[1]

[1]*Dicle University, Diyarbakir;* [2]*Diyarbakir Children Hospital, Diyarbakir;* [3]*Harran University, Sanliurfa, Turkey*

Backgrounds and Aim: Factor X (FX) is the component of both extrinsic and intrinsic coagulation cascade and is the first enzyme of the common pathway which results in thrombus. Congenital FX deficiency (FXD), an autosomal recessive inherited disease, is an extremely rare coagulation defect with only 50 cases of congenital FXD been reported in the world literature so far, with the incidence of 1:500,000–1,000,000 in the general population. In this study we aimed to investigate the clinical and laboratory data of the patients diagnosed with FXD applied to our clinic with bleeding diatesis.

Methods: The files of the 15 patients (7 female, 8 male) diagnosed and followed-up for FXD within the last 4 years were evaluated retrospectively. The patients' age, gender, presenting complaints, physical examination findings, factor levels, the clinical follow-up results and treatments were recorded.

Results: The mean age of the patients was 29 months (min-max:1–144 months). The most presenting complaints were easy bruisability (n = 8; 53%) and epistaxis (n = 8; 53%). The other presenting complaints were gum bleeding (n = 5; 33%), hemarthtosis (n = 5; 33%), subcutanous hematoma (n = 4; 26%), oral mucousal bleeding (n = 3; 20%), hematuria (n = 1; 6.6%), gastrointestinal bleeding (n = 1; 6.6%), respectively. FX leveles were < 1% in 6 patients, 1–5% in 4 patients, > 5% in 5 patients. Heparin added-PCC was used for prophlaxy (n = 11; 73%). Any treatment related complication was not observed.

Conclusions: The clinical features in patients with FXD is independent from factor levels. There is not any single prophylactic scheme for all patients. Heparin added-PCC can be used safely for effective prophlaxy. We suggest that family history is important when considering prophlaxy and in patients with life-threatining bleeding or with FXD sibling the prophlaxy should be introduced in the early course.

PO 295

Safety and pharmacokinetics of three doses of a new recombinant human Factor VIIa (LR769) in congenital hemophilia A or B patients

Valentino LA[1], Reijers J[2], Freijer J[2], Frieling J[3] and Powell J[4]

[1]*Rush University Medical Center, Chicago, IL, USA;* [2]*Centre for Human Drug Research, Leiden, The Netherlands;* [3]*rEVO Biologics, Framingham;* [4]*UC Davis, Sacramento, CA, USA*

Background: Congenital Hemophilia A and B treatment may be complicated by the development of inhibitors to the deficient factor. In such cases factor replacement becomes ineffective, and use of a bypassing agent is needed to treat bleedings or in the peri-operative period. A recombinant form of activated Factor VII has been available for this purpose. In this study, a new recombinant human Factor VIIa (LR769) produced by LFB/rEVO Biologics is tested. The goal is to provide patients with Hemophilia A and B who develop inhibitors a cost-effective alternative treatment option.

Aims: The objectives of the study are to assess the safety and pharmacokinetic (PK) properties of LR769 after a single dose of 25, 75, and 225 μg/kg in hemophilia A or B patients.

Methods: Two sites in the USA and 1 in the Netherlands are participating. The study was approved by the IRB/EC of the institutions and performed consistent with the Declaration of Helsinki. Informed consent was obtained prior to any study activities. It is an open label, randomized, cross-over study. Fifteen adult hemophilia A or B patients with or without inhibitors will be treated in 3 dosing cohorts. Each patient is treated in 2 cohorts on 2 separate occasions, according to one of three sequences: 25 and 75 μg/kg, 25 and 225 μg/kg, or 75 and 225 μg/kg. Each dose cohort consists of 10 administrations. Safety assessments include physical examinations, hematology and biochemistry labs, adverse events, anti-rhFVIIa antibodies and antibodies to host related impurities. PK samples to determine FVIIa activity (with a modified clotting method insensitive to TFPI) are taken at baseline and up to and including 24–36 h after administration.

Results: The first cohort has been successfully treated without any safety issues, and dosing is continuing. At the time of the conference full safety (on repeat exposure) and PK data will be available and presented.

Summary: In order to provide hemophilia patients with inhibitors additional therapeutic options, a new recombinant human FVIIa (LR769) is being developed. Safety and PK data that will be presented will provide the basis for further clinical efficacy studies.

PO 296

Extracorporeal shockwave lithotripsy (ESWL) in a patient with congenital fator VII deficiency and von Willebrand disease

Villaca PR, Okazaki E, Zeinad-Valim AK, Rocha RF, Sandoval EPN, Kato RB, Chedid-Neto EA, Chamone DAF and D'Amico EA

Hospital das Clínicas – University of Sao Paulo, Sao Paulo, Brazil

Background: Congenital factor VII deficiency is a rare autosomal recessive bleeding disorder, which prevalence is estimated in 1:500,000. Von Willebrand disease is the most common inherited coagulopathy,

with an incidence of 1%, and is one of the most frequent causes of bleeding in women with menorrhagia. An important complication of ESWL is perirenal/intrarenal hemorrhage, described in up to 20%-25% of the cases. We report the management of the ESWL procedure in a patient with association of these two coagulopathies.
Case report: A 30-year-old woman with von Willebrand disease and congenital FVII deficiency had symptomatic nephrolithiasis. Her complaints were: oral bleeding, menarche with excessive menses and necessity of blood transfusion, vaginal hemorrhage after the second delivery, and other episodes of metrorrhagia related to uterine myomas, controlled with hormonal contraceptives. Laboratory data showed prolonged PT (19%) and APTT (R = 1.38), FVII:C = 3%, FvW:Ag = 38%, FvW:RCo = 20%, RIPA = normal, FVIII: C = 41%. DDAVP test: adequate responsiveness to desmopressin. Ultrasonography of urinary tract: image compatible with stone in the right renal pelvis of 1.2 cm. The patient received one dose of rFVIIa (20 mcg/kg) and DDAVP (0.3 mcg/kg) before ESWL. rFVIIa was maintained at the same dose, 4/4 h for 24 h and 6/6 h in the second and third days; daily dose of DDAVP (0.3 mcg/kg) was continued for 2 days. rFVIIa was guided by testing FVII, and was 135% in the third day after ESWL. The patient developed mild hematuria for 4 days, as expected in these procedures, and low back pain requiring oral analgesia for 3 days. Ultrasonography after 1 month from the procedure showed no stones and the patient was asymptomatic.
Summary: There are few studies regarding ESWL in patients with coagulopathy in the medical literature, since this treatment option is contraindicated in the presence of uncorrected bleeding disorders. These studies address individuals with hemophilia and vonWillebrand's disease, but none of them reported patients with congenital factor VII isolated or in association with other coagulopathy. In this case, the best treatment option for nephrolithiasis was ESWL, whose stone-free rate described for calculi diameter of 2 cm or less is about 66% to 99%. Moreover, the percutaneous nephrolithotomy adds greater risk of complications. It is known that the level of factor VII is not a good predictor of bleeding and prior hemorrhagic history should be considered. Despite the history of bleeding of the patient reported, which could generate some doubts, low levels of factor VII and the procedure with great potential for bleeding justify the prophylactic use of rFVIIa. As the best of our knowledge, this is the first case report of a patient with factor VII deficiency and von Willebrand disease undergoing to ESWL whose management with DDAVP and rFVIIa resulted in good clinical course, with no abnormal bleeding.

Case report: A 30-year-old woman with von Willebrand disease and congenital FVII deficiency had symptomatic nephrolithiasis. Her complaints were: oral bleeding, menarche with excessive menses and necessity of blood transfusion, vaginal hemorrhage after the second delivery, and other episodes of metrorrhagia related to uterine myomas, controlled with hormonal contraceptives. Laboratory data showed prolonged PT (19%) and APTT (R = 1.38), FVII:C = 3%, FvW:Ag = 38%, FvW:RCo = 20%, RIPA = normal, FVIII: C = 41%. DDAVP test: adequate responsiveness to desmopressin. As the best of our knowledge, this is the first case report of a patient with factor VII deficiency and von Willebrand disease undergoing to ESWL whose management with DDAVP and rFVIIa resulted in good clinical course, with no abnormal bleeding.

PO 297

Risk factors most predictive of venous thromboembolism among hospitalized children

Woller SC[1], Stevens S[1], Larsen GY[2], Jones JP[3], Evans S[1], Lloyd JF[1], Aston TV[1] and Elliott G[1]

[1]Intermountain Medical Center, Murray, UT; [2]University of Utah, Salt Lake City, UT; [3]Kaiser-Permanente, Los Angeles, CA, USA

Background: Venous thromboembolism (VTE–deep vein thrombosis and pulmonary embolism) is rare in children and associated with hospitalization. VTE causes an increase in morbidity, mortality, hospital length of stay, and cost. Several risk factors for VTE in children have been described, yet those most predictive of VTE are ill-defined. A better understanding of which risk factors are most predictive of VTE may allow for identification of high risk patients, and application of selective thromboprophylaxis among those patients at greatest risk.
Aims: (i) Ascertain which among 96 putative VTE risk factors in hospitalized children ages 0–18 are most predictive of clinically overt 90 day VTE. (ii) Describe the predictive ability of these retained risk factors in the same cohort retaining only those risk factors meaningfully additive in enhancing risk prediction.
Methods: All hospitalizations to a pediatric hospital between 1 January 2005 and 31 December 2010 were identified. The electronic medical record was searched for ICD-9 codes and procedures demonstrative of clinically overt VTE and putative VTE risk factors. Logistic regression with applied weighted retention modeling placing value on retaining the fewest risk factors most predictive of VTE was employed. Bootstrap analysis provided an unbiased estimate of predictive performance.
Results: Among 93,742 admissions, 783 VTE events (0.84%) occurred. Those risk factors retained as predictive of 90-day VTE varied by age group, and are ordered from most to least predictive. Among ages 0–1 year old (214/25,483; 0.84%) ICU stay, prior VTE, hypercoagulability, peripherally inserted central venous catheter (PICC), congenital heart disease, elevated Charlson Comorbidity Index (CCI) and chronic respiratory failure (CRF) were predictive with an area under to receiver operating characteristic curve (AUC) of 0.88. In ages 1–14 (387/55,085; 0.7%) CCI, ICU stay, prior VTE, hypercoagulability, PICC, central venous catheter, thrombocytosis, and obesity were retained with an AUC = 0.85. In ages 14–18 (182/13,174; 1.38%) risk factors of elevated CCI, IUC stay, prior VTE, height, cancer congestive heart failure, sepsis, hypercoagulability, L-aspiraginase therapy and PICC were associated with an AUC = 0.85. Among all children ages 0–18 (783/93,742; 0.84%) ICU stay, CCI, prior VTE, PICC increasing weight, hypercoagulability, and cancer were most predictive with an AUC = 0.85.
Summary: VTE among children is rare and most prevalent in the youngest and teenagers. Identifying the risk factors most predictive of VTE can aid in the identification of high risk patients. Next steps might include prospective validation of VTE risk assessment models in children, and investigating the benefit of selective thromboprophylaxis among children at highest risk for VTE.

PO 299

Non-catheter deep venous thrombosis in pediatric patients: data from a single hospital

Gimenez V, Martinez M, Costa A, Alba L, Fynn A, Cuello MF, Schuttemberg V, Aznar M, Fernandez R and Formisano S
Hospital de Niños S M Ludovica, La Plata, Argentina

Background: Although the incidence of deep venous thrombosis has increased over the last decade, non catheter-related (NC-DVT) is uncommonly seen in childhood and adolescence.
Aim: To determine the demographic, clinical and treatment of NC-DVT in children in a single centre.
Methods: Clinical data were retrospectively reviewed of all DVT admitted to our service from 2000 through 2012 and analysed NC-DVT.
Results: One hundred and eighteen pts were admited in our service (91 pts with catheter-related DVT and 27 with non catheter related thrombosis – the mean age was 12 year [range 1–15 years] Site of thrombosis were: femoral 17, jugular 4, popliteal 3, inf cava 2, subclavia 1). Diagnosis was made using venous compression ultrasonography Doppler and TC SCAN. The most frequent underlying clinical condition were: infections 14 pts (sepsis 5, abscess 3, otomastoiditis 2, osteomyelitis 1, supurative adenitis 1, varicella 2. Staphylococcus aureus was the predominant pathogen 6 pts (43%). Other risk factors associated were malignancy 3 pts (ALL 1, NBL 1) autoimmune disease 4 pts, nephrotic syndrome 2 pts, burn 1 pts. Only 3 pts (all adolescences) had spontaneous deep thrombosis: 1 Homozygous V Leiden factor, 2 negative thrombophilia screen: Prothrombin 21210, MTHF, factor V Leiden, PAI, lupus anticoagulant, protein C, protein S. antithrombin, antiphospholipid antibodies. Only 2 pts had positive familiar history of venous thrombosis. Anticoagulation began with unfractionated heparin 2 pts, LMWH 25 pts followed by anticoagulation with acenocumarol. LMWH anti Xa level was obtain in 12 pts and adjust level of 0.5–1 U/ml. Post- thrombotic syndrome was seen in pts 26% of children.
Conclusions: Non catheter deep venous thrombosis in children is usually multifactorial, in associations with underlying disease. The strongest risk factors in our patients was infections. In our population spontaneus deep thrombosis was rare 11% of the NC-DVT and 2.5% of all patints included with deep venous thrombosis. The mainly group risk was present always on adolescents.

PO 300

Successful bivalirudin use in a child post liver transplant

Massicotte P, Bruce AK and Bauman M
University of Alberta/Stollery Childrens Hospital, Edmonton, AB, Canada

Background: Thrombosis of the hepatic and portal arterial/venous system is a severe complication associated with high morbidity following liver transplant in children < 10 kg. To prevent or treat thrombosis unfractionated heparin (UFH) is the anticoagulant used due to the short half life (1–2 h). The Stollery Anticoagulation guideline post liver transplant suggest 10 u/kg/h UFH, and in the absence of bleeding, increasing to age appropriate dosing. Effect is monitored using the aPTT and anti-Xa level. When UFH resistance occurs, and measured heparin effect is minimal, despite doses exceeding 35 u/kg/h, there are few available alternatives in children. Bivalirudin, a direct thrombin inhibitor, has advantages, as demonstrated in adults, including short half life (25 min), no reliance on hepatic metabolism or antithrombin (AT) levels, monitoring using the aPTT, and renal clearance. Unfortunately, there is little safety and efficacy data in children, with a few case reports and one dosing study published and there is lack of reversibility. However, the use of bivalirudin in children who have challenges with UFH anticoagulation, including heparin resistance and low levels of antithrombin, may provide more consistent anticoagulation.
Aim: To describe the first use of bivalirudin as thromboprophylaxis in a child post liver transplant.
Methods: A 14 month old male child with maple syrup urine disease (branched chain ketoaciduria) who underwent a cadaveric donor liver transplant.. Pre transplant thrombophilic testing including antiphospholipid antibody, lupus anticoagulant, Factor V Leiden, prothrombin gene 20210, Protein C, S, and AT was normal. Post-transplant he was started on UFH 10 u/kg/h post transplant and increased to 20 u/kg/h. Eight days post transplant, the child developed HAT, AT and anti-Xa levels were 0.5 u/ml and 0.1 u/ml, respectively. One month later, the child was retransplanted with a cadaveric pediatric graft. In the first 48 h, two episodes of HAT requiring intraoperative tPA to clear the thrombus occurred. Following these events, UFH dosing was maximized (up to 36 u/kg/h) with AT concentrate administered when the level was < 0.4 u/ml. Despite adequate AT levels, the UFH doses were as high as 30 u/kg/h and unable to achieve an anti Xa of 0.35 u/ml. Consequently, 3 weeks post 2nd transplant, a bivalirudin infusion of 0.6 mg/kg/h was started 2 h after UFH was discontinued aiming to maintain the PTT 60–80 s. Informed consent and ethics approval were obtained.
Results: A maximum of 6 mg/kg/h (avg 3–4 mg/kg/h) achieved the desired PTT. After 3 weeks of this regimen, the child was stable, free of thrombosis and was transitioned to age appropriate enoxaparin for 1 year.
Summary/Conclusions: Bivalirudin is an alternative to UFH in children following liver transplant who are heparin resistant, have low AT levels and do not have severe renal failure. Further studies to determine safety and efficacy are urgently required.

PO 301

A case of extensive recalcitrant IVC thrombosis in a teenager with Behçet disease

Nakar C[1], Gupta S[1], Xavier F[1], Rampersad A[1] and Natarajan K[2]
[1]Indiana Hemophilia and Thrombosis Center; [2]St. Vincent Medical Group, Indianapolis, USA

Background: Behçet is a rare immune-mediated relapsing multisystem vasculitis most commonly presenting during the 3rd–4th decade of life. Prevalence ranges depending on geography (1/15,000–500,000). Behçet's is characterized by a triad of uveitis, recurrent oral and genital ulcers and is diagnosed mainly by clinical criteria. Vascular involvement may occur in 40% with a potential dismal outcome. Vasculitis with associated thrombosis is more common in the venous system of the lower extremities followed by the vena cava. Although Behçet's has variable manifestations, venous thrombosis is not common in the pediatric population.
Case Report: Seventeen year-old African-American male presented with 1½ months of worsening fatigue and subsequent shaking chills, night sweats and weight loss. He was admitted to a local hospital with extensive evaluation during a 2 week hospitalization revealing elevated inflammatory markers (ESR > 140 mm/h; CRP > 80 mg/L), nodular pulmonary infiltrates, complete thrombosis of common iliac veins, inferior vena cava (IVC) with thickened walls, and renal veins. After transfer to a tertiary center on warfarin, MRV confirmed extensive venous thrombosis with potential vasculitis, and extensive collaterals. Based on pustulosis at IV sites, acneiform rash, scrotal ulcer, history of recurrent oral ulcers, he was diagnosed with Behçet's and began high dose methylprednisolone with resolution of systemic symptoms within a few days. He underwent successful catheter directed thrombolysis (EkoSonic Device and tPA) with stent insertion in both iliac veins. Shortly thereafter he experienced acute IVC obstruction with significant LE edema that resolved after stent insertion at the level of a narrowed possibly hypoplastic hepatic IVC. Due to a Heparin dependent antibody ELISA (1.068 OD), Argatroban was utilized. Post thrombolysis, an Argatroban dose up to12 mcg/kg/min was required; dose prior to thrombolysis was 1.5 mcg/kg/min. Serotonin release assay was negative and he was discharged on enoxaparin with targeted

levels at the high therapeutic range. With steroid therapy inflammatory markers normalized. Five months later, with rising inflammatory markers (ESR 86 mm/h, CRP 46 mg/L), he complained of left LE symptoms and was found to have recurrent iliac vein and IVC thromboses. Repeated thrombolysis with stent insertion was performed due to severe residual stenosis. A few weeks later he reported worsening symptoms requiring repeated thrombolysis of left iliac veins. IVC imaging revealed narrowing without occluding thrombus. Post thrombolysis, Argatroban was utilized again requiring high doses; thereafter he was maintained on Enoxaparin and 81 mg aspirin daily. One week later the left iliac veins were re-thrombosesd without clinical symptoms; no intervention was performed. Currently he is maintained on Enoxaparin and 162 mg aspirin daily. Behçet's is managed with Infliximab, Methotrexate and steroids.

Summary:

1 Extensive thrombosis in pediatric patients with systemic symptoms should prompt consideration of vasculitis.
2 Control of vasculitis is critical to VTE outcome in Behçet's.
3 Aggressive anticoagulation post-thrombolysis is required with concurrent active vasculitis.
4 Observed IVC stenosis could be either congenital or resulting from vasculitis.
5 Post-thrombolysis, Agatroban dosing may significantly increase, perhaps due to higher accessible thrombin loads.
6 A false positive HIT ELISA may be observed during acute inflammation.

PO 302

Splenic infarction in a teenager associated with oral contraceptives, elevated lipoprotein a, and median arcuate ligament syndrome

Nakar C and Xavier F

Indiana Hemophilia and Thrombosis Center, Indianapolis, USA

Background: Etiologies of splenic infarcts in adults are diverse, and include hematologic disorders (benign/malignant), hypercoaguable states (including oral contraceptives and lupus anticoagulant), embolic disorders (including paradoxical emboli), vascular disorders, collagen/autoimmune vascular disease, trauma and operative. The majority in adults are related to hematologic malignancies/myeloproliferative diseases or thromboembolic conditions. However, in pediatric patients splenic infarct in the absence of a hemoglobinopathy is rare, and etiologies differ compared to the adult population.

Case Report: A 14-year-old female Caucasian athletic teenager experienced sudden middle-left upper abdominal pain which resolved spontaneously, but recurred approximately three times the following week. Due to worsening consistent pain, she was evaluated and found to have elevated WBC (18.8 K/mcL) prompting CT scan that demonstrated a large splenic infarct. Ultrasound Doppler revealed a wedge shape infarct with patent splenic artery/vein. The patient utilized combined oral contraceptive for menometrorrhagia for 1½ years. Hematology evaluation 2 weeks after initial symptoms revealed an asymptomatic female with ESR 45 mm/h, CRP 2.5 mg/dL, D-Dimer 2127 ng/mL, platelet count 879 K/mcL, factor VIII (FVIII) activity 192%. Further evaluation revealed normal/negative; echocardiography, hemoglobin electrophoresis, ANA, rheumatoid factor, JAK 2, PNH, amylase and IBD markers. Thrombophilia work-up revealed elevated fasting lipoprotein a (182 nM) and compound heterozygous MTHFR mutation with normal homocysteine level. FVL, P20210, protein C, protein S, antiphospholipid antibody and ATIII were normal/negative. Approximately 1 month from initial symptoms, acute abdominal pain prompted repeat imaging for recurrence and complications including pseudocyst, abscess or rupture. CTA for vasculitis/vascular anatomy demonstrated abnormal inferior hooked shaped narrowed celiac artery with mild post stenotic dilatation. Ultrasound Doppler revealed high velocity in celiac axis and low resistance wave form at hepatic/splenic arteries. The patient had a very soft low-pitched epigastric bruit. The patient was treated with 81 mg aspirin daily.

Summary:

1 Thromboembolism in pediatric patients may result from combined risk factors. This rare case demonstrates splenic infarct with combined oral contraceptives, an elevated LPa and abnormal vasculature. This report emphasizes a variety of critical factors:
2 Combined oral contraceptives represent well-documented thrombotic risk factor; this risk decreases with increasing length of therapy but is not negligible.
3 LPa has gained increased awareness as a thrombotic risk factor in pediatric patients, but treatment remains without consensus. Niacin and/or aspirin have been reported in specific cases, yet concerns regarding niacin and stroke exist.
4 Although celiac artery thrombosis was not detected, the combination of median arcuate ligament syndrome and splenic infarct should raise the possibility of thromboembolism.
5 We suggest that splenic infarct evaluation should include early vascular anatomic imaging to assist in diagnosis and consideration of thromboembolism.
6 Compound heterozygous MTHFR mutation with a normal homocysteine did not contribute to this patient's risk.
7 This report provides additional important information to the few published articles addressing splenic infarction and thromboembolism, celiac artery thrombosis and oral contraceptives use, and median arcuate ligament syndromes in pediatrics.

PO 303

Inherited antithrombin deficiency: description of a pediatric series in a single center

Sciuccati GB, Pieroni G, Hepner MD, Pepe C, Annetta ES, Feliu Torres AS, Cervio C, Frontroth JP and Bonduel M

Hospital de Pediatria Dr. JP Garrahan, Ciudad Autónoma de Buenos Aires, Argentina

Inherited antithrombin deficiency (IAD) is associated with increased risk of arterial and venous thrombosis in children and adults. Antithrombin (AT) deficiency is classified depending on the phenotype, defined by plasma AT activity and antigen levels, as types: I (quantitative) or II (qualitative): IIa (reactive center defects), type IIb (heparin binding domain defects), and type IIc (pleiotropic defects). Very few clinical and laboratory data on IAD in neonates and children have been reported.

Objectives: To describe the clinical manifestations, phenotype and genotype analysis, treatment and outcome in a series of neonates and children with IAD evaluated in a single center. From March 1992 to March 2012, 613 patients (pts.) younger than 18 years old with objectively confirmed arterial and/or venous thrombosis were studied for inherited and acquired thrombophilia. Asymptomatic children with a family history of IAD were also evaluated. Patients with low AT activity in plasma were classified according to AT antigen levels. AT activity levels were measured by chromogenic amidolytic methods, using bovine factor Xa and thrombin-based assays. Antigen concentrations were tested by Laurell rocket electrophoresis and immunoturbidimetric test. Progressive anti-factor-Xa activity assay was utilized to identify type IIb IAD. Age-related local reference values were used. Molecular analysis of AT gene (SERPINC1) was performed at the Mayo Clinic College of Medicine (Rochester, USA).

Seven children from 6 unrelated families were diagnosed with IAD. Six children had a family history of thrombosis. Four patients (2 girls/2boys, age range 21 days-11.6 years) had thrombosis in one or more sites: intracardiac thrombosis, 1pt.; renal veins, 2 pts.; inferior vena cava, iliac and femoral veins, 2pts.; pulmonary embolism, 1 pt.; and arterial ischemic stroke (AIS), 1pt.. Infection was the only risk factor detected in 2pts. No pt. had catheter related thrombosis.

Type I IAD was detected in 2pts: 1pt. was heterozygous for SERPINC1 R129X, FV Leiden and PT20210 mutations while no AT

mutations were identified in a 6-year-old girl with AIS. Type IIb IAD, AT Budapest 3, was detected in 2pts. from Gypsy families, one of them was heterozygous and had S.*pneumoniae* sepsis before the first thrombotic event, and the other was homozygous and presented perinatal renal vein thrombosis with extension into inferior vena cava. In the three asymtomatic patients, type I IAD heterozygous for a new mutation (p.Lys71LysfsX113) was found in a 16.8 year-old adolescent and type IIa IAD heterozygous AT Cambridge I was detected in two 3.8 year-old twin girls. The therapy used was: AT concentrate, heparin and indefinite vitamin K antagonists (VKAs), 3pts; tissue plasminogen activator, 1pt; aortic thrombectomy, 1pt and aspirin, 1pt. All the pts. are alive. One pt. presented severe post-thrombotic syndrome, 1pt. developed unilateral renal atrophy, and 1pt. with renal impairment required kidney transplant and had recurrent thrombosis while receiving VKAs.
This is one of the largest pediatric series of IAD. The clinical manifestations and evolution were highly heterogeneous. A novel mutation was detected. The long-term follow-up of these patients with IAD variants, along with phenotypic and genotypic characterization, would allow for evaluation of their thrombotic risk.

PO 304

The assessment of risk factors for rhrombosis in children

Smalisz S and Klukowska A
Medical University of Warsaw, Warsaw, Poland

Background: Thrombosis occurs much less frequently in children than in adults.
Aims: We tried to estimate the risk factors for thrombosis in pediatric population.
Methods: We analyzed 70 cases (32 boys, 38 girls) in children referred to the Department in 2007–2012 due to thrombosis. All patients were assessed: age at onset, location and cause of the clot. All analyzed patients underwent screening for congenital thrombophilia.
Results: Age of thrombosis was from the first week of life to 17 years, median 6.5 years. Arterial thrombosis occurred in 11 (16%), venous in 59 (84%) patients. Thrombi were localized mostly in the deep veins of the extremities (n = 27, 38%) and venous sinuses central nervous system (n = 15, 21%). The most common causes of thrombosis were: congenital thrombophilia (n = 27, 39%%), infection (n = 15, 21%), surgery (n = 14, 20%), thrombocythemia was found in 2 (3%) patients. Two patients had hyperhomocysteinemia. Six (8%) patients had no underlying cause thrombosis. The patients with congenital thrombophilia (n = 27, 39%) had the following defects: protein S deficiency in 7 (26%), protein C deficiency in 4 (15%), antithrombin deficiency in 7 (26%), prothrombin gene mutation in three patients (11%), and mutation of the factor V Leiden in 6 (22%) patients. Eight patients with thrombophilia performed an additional risk factor for thrombosis.
Conclusions: The most common location of thrombosis in children are deep veins of the limbs. The most common causes of thrombosis in this age group are: inherited thrombophilia, infection and surgery. In all paediatric patients with thrombosis diagnostic tests in the direction of congenital thrombophilia are indicated.

PO 305

Clinical utility of age specific natural anticoagulant levels in children with thrombosis

Soundar EP[1], Kostousov V[2], Jariwala P[1], Bilen O[2] and Teruya J[2]
[1]Texas Children's Hospital; [2]Baylor College of Medicine, Houston, USA

Background: Normal healthy children have lower levels of natural anticoagulants such as antithrombin (AT), protein C (PC), and protein S (PS) when compared to adults. Further decline in levels of natural anticoagulants is commonly seen in pediatric patients with thrombosis. It is therefore important to know the role of decreasing levels of natural anticoagulants in predicting thrombosis in children. The use of age appropriate, highly specific cut-off levels for AT, PC, and PS may assist the physicians simplify clinical decisions about additional confirmatory tests.
Aims: Our aims were to define highly specific cut-off values for natural anticoagulants in two groups of children aged < 10 years and 10–18 years (group 1 and group 2, respectively), and to assess the predictive ability of these cut-off levels to identify patients with thrombosis.
Methods: Retrospective review of charts from 2004 through 2010 was performed after institutional review board approval for patients on whom physicians requested a hypercoagulation panel in our pediatric tertiary care children's hospital. Three hundred and sixty-five patients were identified, and their AT, PC, and PS levels were extracted from the laboratory database. Receiver operating characteristic (ROC) analysis was done to define specific cut-off values for AT, PC, and PS levels with a high specificity of 90%. Positive likelihood ratios (LR+) were calculated to quantitate the probability of thrombosis in pediatric patients.
Results: Among 365 patients (age range: 3 days to 17 years), 182 (48.2%) patients had confirmed thrombosis. There were 174 patients (46.6%) in group 1 and 191 patients (53.4%) in group 2. The medians and interquartile ranges of the anticoagulant levels in the two groups were as follows: AT [99% (76–118) vs. 101% (89–112), P = 0.48], PC [78% (52–101) vs. 104% (85–133), P < 0.001], and PS [75% (59–89) vs. 80% (63–104), P = 0.03]. In group 1, cut-off levels for AT, PC, and PS were 56%, 34%, and 35%, respectively at 90% specificity. In group 2, it was found to be 86%, 73%, and 49% for the same specificity. The LR+ for group 1 were 1.3 for AT, 1.8 for PC, and 1.4 for PS that translated into an increase in the post-test probability of the presence of thrombosis by about 10%. For group 2, the LR+ were 9.1 for all the three laboratory variables that translated into an increase in its probability by 45%.
Conclusions: In children aged less than 10 years, a significant decrease of the natural anticoagulant levels from the age specific normal levels increase the probability of the presence of thrombosis by only about 10%. However, in children aged 10–18 years, a minimal decrease in their levels increases the probability by about 45%. Therefore, a fall in natural anticoagulant levels strongly predicts thrombosis in older children between 10 and 18 years of age. Physicians may consider additional testing to confirm thrombosis for this subset of pediatric patients in a hospital setting.

PO 306

Antiphospholipid antibodies in neonates and babies with clinically significant thrombosis

Svirin P[1], Zharkov P[2], Larina L[3], Vdovin V[1], Shiller E[1] and Podcherniaeva N[4]
[1]Izmailovskaya Children Hospital; [2]Russian National Center of Paediatric Hematology, Oncology and Immunology; [3]Russian Research Medical University; [4]1 Moscow Medical University, Moscow, Russia

Background: We note increase frequency of thrombotic events among newborns and infants. There are some condition in structure of prothrombotic factors in this group, including such common factors as premature, infections, blood vessel catheterisation, low level of antithrombin, protein S and protein C. However sometimes there is prognostically significant factor – rise of level of antiphospholipid antibody (APA). Children with high level of APA may need in long-term treatment with anticoagulants.
Aims: To estimate frequency of increasing APA in children, who had thrombotic events under 1 years old. To monitor APA titer during next few years.

Methods: We observed 42 children suffer from thrombotic events during first year of life. All episodes were confirmed with ray-path methods (ultrasound, CT, MR). Primary diagnostic furthermore includes determination of antithrombin, protein C, protein S level, lupus anticoagulant (LA). Concentrations of antibody to cardiolipin, phospholipids, betta-2-glycoprotein-1 were measured twice, with 3–4 month intertrial interval. During catamnesis all rates measured 1–4 times a year.
Results: Our group consist of 19 female and 23 mail. Six of them were premature newborns. First event of thrombosis until the age 1 month was in 12, between 1 and 3 month – 10, between 4 and 6 month – 4, and from 6 to 12 month – 16. Twenty children had venous thrombosis, 3 – arterial thrombosis, 15 – ischemic stroke, 2 – intracardiac, 1 – intracranial venous sinus. Level protein C less 30% had 2, protein S less 30% – 1, antithrombin III less 30% – 1. Relationship between catheter and thrombosis was in 19, infection as underlying condition was found in 20. Eight children had high level of APA in first detection. High level of APA revealed in 5 (11.9%) children at the second detection. Ten and more time increasing level of APA (antibody to betta-2-glycoprotein-1) fined in 2; 2–10 time increasing observed in 2; one patient had 1,5 time increasing of APA. LA was positive in 2. In 1 year of observation, level of APA had impaired in all patients. It become normal in one, and stays significantly higher in other.
Summary/Conclusions: Amount of rise level of APA in children, suffer from thrombotic events during first years of life is not so rare condition. These parameters must be checked in such patients.

PO 307

Neonatal cerebral sinus venous thrombosis associated with congenital chylothorax and congenital nephrosis: report of two unusual cases

Yau I, Diab Y and Moharir M
Hospital for Sick Children, Toronto, Canada

Background: In neonates, cerebral sinus venous thrombosis (CSVT) represents a serious thrombotic condition which is often multifactorial. Early diagnosis and timely management is increasingly considered to influence outcome as anticoagulant therapy prevents propagation of thrombosis.
Aim: We report CSVT presenting in association with two rare neonatal disorders: congenital bilateral chylothorax and congenital nephrosis.
Methods/Results: The first case is a full-term male infant who was found to have congenital bilateral chylothorax which required chest tube drainage. A routine head ultrasound (HUS) showed thrombosis of the superior sagittal sinus prompting CT venography (CTV) revealing extensive deep and superficial venous system thrombus formation (Images A & B). The second case is a male infant born at 34 weeks of gestation who was found to have dysmorphism and intra-uterine growth restriction. He subsequently suffered acute cardio-respiratory decompensation and was found to have congenital nephrosis as well as grade 4 bilateral intraventricular hemorrhage (IVH) on HUS. A subsequent head MRV and CTV demonstrated left transverse sinus thrombosis (Images C & D).
Discussion: Although the risk of systemic thrombophilia has previously described in both these conditions, there have not been any reports of neonate CSVT in association with congenital chylothorox to date and only one published case available in the context of congenital nephrotic syndrome. The exact mechanism of thrombophilia is poorly understood but it is plausible an acquired hypercoagulable state resulting from protein loss and likely volume depletion were responsible for the development of CSVT in both cases. The clinical threshold for suspecting CSVT should be low in any neonate presenting with seizures with a medical condition that results in loss of natural physiological anticoagulant factors and fibrinolytic factors.

PO 308

Analysis of different mechanisms through hydrogen sulphide (H2S) would inhibit platelet aggregation

Bermejo IE[1], Saenz DA[2], Alberto MF[1] and Rosenstein RE[2]
[1]*Haematological Research Institute of the National Academy of Medicine;* [2]*Facultad de Medicina, Universidad de Buenos Aires, Buenos Aires, Argentina*

Background: Hydrogen sulphide (H_2S) is the most recent of the gasotransmitters to be identified and investigated. H_2S is an important endogenous modulator, which exhibits beneficial effects on the cardiovascular system. However, the mechanisms involved in the different effects on platelets pathways are still unclear.
Objective: In order to investigate H_2S inhibitory pathways on platelet function we performed several tests: the opening of KATP-channels, the cGMP and cAMP accumulation, fibrinogen binding (B-Fg) and Ca^{2+} influx.
Methods: Tests were performed using platelet rich plasma (PRP) (300×10^9 plat/L). Sodium hydrogen sulfide (NaHS) was used as H_2S donor and 100 μM glibenclamide (Glib) as a selective K + -channel blocker. Samples were preincubated with buffer, 100 mM glib (during 30 min) at 37 °C, then with or without NaHS (1, 5 and 10 mM) for 2 min before adding 2 μg/mL collagen as agonist. The expression of fibrinogen binding (B-Fg) and Ca^{2+} influx were assessed by flow cytometry using mean fluorescence intensities. cGMP and cAMP accumulation by RIA were measured as pmol/10^6plat. Student's *t*-test control vs. NaHS.: * = $P < 0.05$, ** = $P < 0.01$.
Results: H_2S significantly inhibited platelet aggregation ($P < 0.01$) induced by 2 μg/ml Col. Glib failed to block the inhibition induced by NaHS. The accumulation of cGMP and cAMP in presence of NaHS have no statistical difference 10 ± 2 vs. 9 ± 1 and 5 ± 1 vs. 4 ± 2 respectively. Levels of B-Fg (126 ± 12 vs. 15 ± 5)** were inhibited in the presence of H_2S, and Ca^{2+} influx was unaffected.
Conclusion: Platelet aggregation induced by collagen was significantly inhibited in a concentration-dependent by NaHS. The test with Glib ruled out the role of KATP channel in H_2S-induced antiaggregation. The accumulation of cGMP and cAMP confirmed that these are not the mediators of the inhibitory effect of NaHS.
This result, together with a significant blocked of B-Fg levels, suggest the inhibition on platelet function would be through another signaling pathway, such as CalDAG-GEFI/Rap1.Thus, H_2S may constitute a novel target for antithrombotic drug development.

PO 309

Platelet activation and abnormal Ca2+ homeostasis in women with gestational diabetes mellitus

Bichan VD[1] and Zabarovskaya ZV[2]
[1]*Belarusian State University;* [2]*Belarusian State Medical University, Minsk, Belarus*

More than 50% women diagnosed with gestational diabetes mellitus (GDM) will develop type 2 diabetes mellitus in their future life. Platelets from patients with type 2 diabetes show abnormalities in intracellular Ca^{2+} homeostasis that are involved in platelet hyperaggregability and the development of thrombotic complications. The aggregational activity of platelets can be changed due to various factors, including reactive oxygen species (ROS). The aim of this study was to investigate the effect of H_2O_2 on aggregation and Ca^{2+} mobilization in human platelets from pregnant women with GDM and Type 1 diabetes mellitus (DM) *in vitro*.
We compared 36 pregnant women with GDM (24.68 ± 5.12 years), 14 pregnant women with Type 1 DM (24.31 ± 3.68 years), 24 healthy pregnant women (HPW) (23.96 ± 5.18 years) and 15 healthy non-pregnant women (HNPW) (23.82 ± 4.58 years). There were no significant differences in fasting glycaemia (5.38 ± 0.41) mM for GDM (6.27 ± 0.21) mmol/for pregnant women with Type 1 DM

(4.61 ± 0.17) mM for HPW and (4.82 ± 0.14) mM for HNPW (or in glycated hemoglobin levels (6.78 ± 0.21%, 6.94 ± 0.13%, 5.96 ± 0.56% and 5.83 ± 0.61% accordingly). Platelet aggregation and disaggregation was determined by light transmission using computerized analyzer of platelet aggregation. Intracellular Ca^{2+} concentration in the platelets was determined using the fura 2-AM.

The platelet aggregates produced under the influence of H_2O_2 are unstable, destroyed spontaneously, and the aggregation is replaced by disaggregation. In this study where gestational diabetic and Type 1 DM pregnancies compared to normal pregnancies, the disaggregation at the pregnant women with GDM and Type 1 DM was lower 1.2 and 1.3 times than in the control group, respectively. The resting platelet cytosolic Ca^{2+} concentration in group of pregnant women with GDM did not vary in compared with HPW. When platelets were treated with 1 μM thapsigargin (TG), a specific inhibitor of SERCA, plus ionomicin (50 nM), there was a transient increase in cytosolic Ca^{2+} concentration due to release followed by Ca^{2+} extrusion. Since the peak response was not significantly different in all groups of subjects, the amount of Ca^{2+} accumulated in the stores must be similar. However, the rate of decay cytosolic Ca^{2+} concentration to resting levels was significantly slower in platelets from pregnant women with GSD. Immediately after the addition to the platelets of H_2O_2, the intracellular concentration of Ca^{2+} did not change (the lag-period), but subsequently its concentration increased and then decreased to the basal level. The release of intracellular Ca^{2+} upon H_2O_2 stimulation was at the same level in all groups of women, but after the addition of 2 mM $CaCl_2$ to H_2O_2 stimulated cells the increase of intracellular Ca^{2+} concentration were greater in the pregnant women with GSD with respect to the healthy pregnant women.

We conclude that H_2O_2 was likely involved in the enhancement of intracellular Ca^{2+} concentration observed in platelets from pregnant women with GDM and Type 1 DM, which might lead to platelet dysfunctions. H_2O_2-dependent enhanced Ca^{2+} entry in diabetic donors might be explained by an increased amount of H_2O_2 or a greater sensitivity to oxidation by this ROS in diabetic platelets.

PO 310

Detection of high platelet reactivity induced by release reaction by light transmission aggregatometry and the ways to prevent it

Buryachkovskaya L[1], Uchitel IA[1], Sumarokov AB[1] and Lomakin NV[2]

[1]Russian Cardiology Research Complex; [2]Central Clinical Hospital of the Presidential Department, Moscow, Russia

Background: High platelet aggregation plays a key role in thrombosis. The reveal of high platelets activity can help to prevent thrombotic complications by prophylactic therapy. Broad spectrum of methods proposed to solve this problem. We suggest the simple use of light transmission aggregation (LTA) for detection of high level of platelets aggregation induced by release reaction.

Aims: The aim of our study was to evaluate platelets features in atherosclerosis patients that can lead to additional risk of thrombotic complications and to fin the ways of its diminution.

Methods: Platelets aggregation in 724 patients (pts) with stable ischemic heart disease due to CAD and 36 healthy subjects (HS) was studied by simultaneous analysis of the mean aggregate size changes and light transmission (LTA) using an aggregation analyzer BIOLA (Russia). ADP at doses 1.0 and 5.0 μM was taken as an agonist. Platelet microaggregates were assessed by scanning electron microscopy. All patients did not receive any antiplatelet therapy before platelets investigation for at least 2 week.

Results: In 29 from 724 CAD pts platelets 1.0 μM ADP induced aggregation was significantly elevated and biphasic (48 ± 14.2% vs. 5.2 ± 2.8% in HS $P < 0.01$) during first 5 min of registration and didn't decrease in time. Second wave started after 2 min and quickly reaches a maximum as a result of intraplatelet agonists secretion. In most of CAD pts ($n = 695$) 1.0 μM ADP aggregation was 9.7 ± 5.4% without second wave and generally with disaggregation. 5.0 μM induced ADP aggregation was 53.2 ± 14.1% in this group vs. 56.8 ± 15.4% in other 29 pts (normal range 25–68%, $P = 0.3$) without second wave and disaggregation. In 29 pts spontaneous aggregation was recorded by LTA method and its level was the same as if it was ADP induced but started at 9th-14th min (45.7 ± 12.3%). In other CAD pts and HS spontaneous aggregation was not defined by LTA. In whole blood of all 29 pts were detected microaggragates contained from less than 10 platelets. In blood of the rest pts and HS microaggragates were absent. In 23 from 29 pts were neurological symptoms (12-dizziness, 4-depression, 8-cephalalgia, 1-TIA). Aspirin therapy decreased platelet aggregation to normal ranges in 25 pts and was ineffective in 4 pts in whom clopidogrel was medication of choice. In pts who were taking antiaggregant therapy microaggregates disappeared and the symptoms reduced.

Summary/Conclusions: high platelet aggregation is closely associated with risk of unfavorable thrombotic events at CAD pts. The appearing of microaggregateds in whole blood worsens microcirculation and lead to neurological symptoms. One of possible reasons is revealed by us release reaction, which induce not only the growth of agonist induced aggregation but also to spontaneous aggregation phenomenon. In most such cases aspirin normalized platelets status and clopidogrel can be a good substitution in cases of aspirin inefficiency. LTA is a good sensitive method in such situation, but the time of registration must be prolonged up to 20 min.

PO 311

Impedance aggregation comparing three different anticoagulant matrices performed on whole blood samples from healthy subjects

Castellone D[1], Stroobants AK[2] and Dummermuth A[3]

[1]Roche Diagnostics, Indianapolis, USA; [2]Academisch Medich Centrum, Amsterdam, The Netherlands; [3]Roche Diagnostics International, Rotkreuz, Switzerland

Background: Whole blood platelet aggregation is measured on the Multiplate® analyzer (Roche Diagnostics) using impedance aggregation. The Multiplate® uses a test cell containing two pairs of electrodes made of highly conductive silver-coated copper. Activated platelets adhere and aggregate on the metal sensor wires causing increased electrical resistance. The increase of impedance is transformed to arbitrary aggregation units (AU) and plotted against time. The overall platelet activity is expressed by the parameter area under the aggregation curve (AUC), which is affected by the total height of the aggregation curve as well as by its slope.

Aim: To determine the effect of three different anticoagulants, which can be in use in different laboratories, for whole blood platelet aggregationusing seven different agonists to determine ranges appropriate for each anticoagulant.

Methods: Adult subjects ($n = 67$) were determined to be healthy and free from any anti-platelet medication for at least 10 days via a questionnaire assessment. Blood from the same healthy subjects was prospectively collected under informed consent in three different anticoagulant matrices: NaCitrate (sodium citrate, 3.2%), LiHeparin (lithium heparin, 75 USP units) and hirudin, 15 μg/ml). Platelet count was verified to be $> 100 \times 10^9$/L. Agonists were randomized and whole blood platelet aggregation was performed on the Multiplate analyzer within three h of sample collection. Agonists tested were ADP adenosine-5′-diphosphate (ADPtest), arachidonic acid (ASPItest), collagen (COLtest), thrombin receptor activating peptide (TRAP), ristocetin high dose (RISTO Hi), ristocetin low dose (RISTO Lo), and prostaglandin E1 reagent and adenosine-5′-diphosphate (ADP HS).

Results: The mean and ± 2 standard deviation (SD) AUC range was calculated for each agonist and anticoagulant combination. The results

are expressed below as 'mean U (range U)' for each combination. ADPtest (final concentration of 6.5 μM) with hirudin yielded 93.4 (55.4–131.2), LiHeparin yielded 102.6 (65.0–140.2), and NaCitrate yielded 80.5 (43.9–117.1). ASPItest (final concentration of arachidonic acid 0.5 mM) in hirudin resulted in values of 108.5 (68.6–148.3), with LiHeparin 112.7 (71.5–153.9), and with NaCitrate 75.8 (46.6–105). For Coltest (final concentration 3.2 μg/ml), hirudin yielded 86.8 (53.6–120), LiHeparin yielded 94.3 (58.3–130.3), and NaCitrate yielded 64.5 (39.5–89.5). TRAP (final concentration 32 μM) with hirudin resulted in values of 129.9 (83.7–176.1), with LiHeparin 129.4 (87.2–171.6), and with NaCitrate 104.5 (68.7–140.3). Ristocetin was tested in high and low concentrations (0.77 mg/ml and 0.2 mg/ml). Results for each concentration, high and low respectively, were as follows: with hirudin 117.1 (53.3–180.9), 13.1 (0–37); with LiHeparin 113.1 (63.5–162.7), 25.0 (5.4–44.6); with NaCitrate 92.6 (36.4–148.8), 11.2 (2.4–20.0). Only hirudin and LiHeparin were used in the ADP HS measurement (final concentration of 9.4 nM), with hirudin yielding 79.9 (35.1–124.7) and LiHeparin yielding 96.4 (49.8–143).

Summary and Conclusions: The mean results from identical samples treated with each agonist using different anticoagulants resulted in different ranges. For all agonists, 3.2% NaCitrate consistently yielded lower values, while LiHeparin yielded higher values. It is important for laboratories to utilize ranges that reflect the anticoagulant used in testing. Having improper ranges can result in possible misdiagnosis of patients.

PO 312

Changes in platelet aggregation after impact with vipoxin and its componends isolated from Vipera ammodytes venom

Danchev D[1], Goranova Y[2], Atanasov V[1] and Petrova S[2]

[1]Military Medical Academy; [2]Sofia University St. Kl.Ohridski, Sofia, Bulgaria

Background: The neurotoxin vipoxin, isolated from the venom of *Vipera ammodytes meridionalis*, consists of basic, highly toxic phospholipase A_2 (PLA_2) and an acidic and non-toxic component acting as an inhibitor of PLA_2.

Aim: Objective of our study is to track the response of platelet aggregation in the presence of vipoxin and phospholipase A_2 in different concentrations, initiated by inducers, adenosine diphosphate (ADP), collagen and arachidonic acid (AA).

Methods: Vipoxin and its components were isolated from Bulgarian *Vipera ammodytes meridionalis*.

The turbidimetric method of Born (1962) was followed using a dual channel Lumi-aggregometer 700, Chronolog Corp, USA. Human platelet-rich plasma (0.45 ml) maintained at 37 °C was preincubated with vipoxin and PLA_2 for 2 min in a siliconized glass cuvette with constant stirring. The aggregation was initiated by adding ADP 10 μM, collagen 2 μg/ml and AA 0.5 mM and was traced out within 6 min.

The concetrations of vipoxin were 30, 50, 70, 90 μg/mL and a concentrations of PLA_2 were 15, 25, 35, 45 μg/mL.

Results: Different mechanisms of inhibition of platelet aggregation by PLA_2 toxin could be involved and tested in the process depending on the inductor used.

We found the inhibitory effect of phospholipase A_2 on platelet aggregation initiated by ADP, collagen and AA. The use of collagen and AA, inducing inhibition of platelet aggregation reaches 100% at the highest concentration of PLA_2 (45 μg/mL). Platelet aggregation in the presence of vipoxin is not affected and utilizing a three inducers.

Conclusion: The PLA_2 inhibits agonists-induced platelet aggregation in a dose-dependent mode. The results showed that the enzyme renders different effect according to inducers applied.

PO 313

New approach to determination of the intravascular platelets activation in patients with ischemic heart disease

Drozd L[1], Markava I[2], Miadzvedzeva E[2], Gelis L[2] and Syroezhkin S[1]

[1]Heat and Mass Transfer Institute, National Academy of Sciences of Belarus; [2]Scientific-practical Centre of Cardiology, Minsk, Belarus

Background: Atherothrombotic processes and tromboishemic complications which dominate among the cardiovascular diseases are the leading cause of the patients with ischemic heart disease (IHD) death. However, the atherothrombosis diagnostics is often carried out not in the early stages, but in the late stages of its development, when we have the apparent clinically tromboishemic complications and acute cardiovascular events.

The goal of our study was to identify the diagnostic criteria for patient's stratification on the groups with thrombogenic risk on the basis of the overall evaluation new and previously known markers of atherothrombosis. This will improve the quality of early diagnostics of atherothrombosis, especially in patients with asymptomatic IHD.

Methods: Two hundred and fifteen people were studied: 144 patients with unstable angina, 49 individuals with stable angina and 22 healthy volunteers. The study included: electrocardiographic monitoring, echocardiography, 6-min walking test and coronary angiography. Laboratory studies included: blood test, measurement of cardio specific enzymes level, biochemical blood analysis with the definition of inflammation markers (C-reactive protein), levels of homocysteine, myeloperoxidase and endothelin-1. Platelet aggregation properties were studied by turbidimetric method on platelet aggregation analyzer with adenosine diphosphate disodium salt acid at the concentration of 0.5 and 2.5 μM. Hemostasis and coagulation system of natural anticoagulants were tested on hem coagulator. Morphometric characteristics of platelets – average platelets volume (APV), platelet width by volume distribution (PWD) were determined by the automatic cytoflowing hemoanalyzer. To verify the morphometric characteristics of platelets, which play an important role in atherothrombosis and in the development of tromboishemic complications in patients with IHD, we carried out a qualitative and quantitative evaluation using the atomic force microscopy (AFM). Specially developed computer algorithms were used for the estimation of the platelets state. All investigations were carried out initially and from 3, 6 and 12 months.

Methods: Using AFM were determined that the average height of platelets, the average height of clusters (aggregates) and the percentage ratio of pathologically active cells ($P = 0.04$) in patients with unstable angina is significantly greater than in patients with stable angina and in healthy person. This is indicates that there is an intravascular platelet activation. In patients with unstable angina the correlation between APV and the increase (%) abnormal platelet activity ($r = 0.71$), between APV and an average height of plate cells ($r = 0.52$) were significantly positive. The correlation of morphometric characteristics of platelets (APV, PWD) defined in the general blood analysis with morphometric parameters, verified by AFM, as well as the initial level of myeloperoxidase, homocysteine, antithrombin III, D-dimer, fibrinogen and von Willebrand factor was revealed. This indicates that AFM data may be used as diagnostic criteria of thrombogenic risk and repeated coronary events in patients with IHD.

Conclusions: The most informative diagnostic criteria are the platelet morphofunctional parameters such as APV, PWD the degree of adrenaline-induced platelet aggregation, the average height and the number of abnormal platelet activity identified by AFM, as well as markers of endothelial dysfunction, which is an independent predictor of unfavorable outcomes in patients with unstable angina.

PO 314

Inhibition of Platelet aggregation in Dengue infection does'nt correlate with anti DV-NS1 and anti PDI

Effendi AR

Division of Hematology & Medical Oncology, Jakarta Pusat, Indonesia

Background: Dengue infection is one of the major public health problems in Indonesia. The molecular mimicry between Non Structural 1 (NS-1) Dengue Virus to auto antigen on the platelets surface is currently the most evaluated pathomechanism of platelet function disorder.
Aims: In this study, we observed the correlation between anti NS-1 and anti PDI antibodies against platelets function disorder on secondary Dengue infection.
Methods: Fifty patients with secondary DV infection according to WHO criteria were observed by a cross sectional study. Patient's blood was collected on day 3, 5 and 7 after fever onset. Platelets aggregation test was done to prove the possibility of platelets dysfunction. Anti NS-1 and anti PDI antibodies were determined by solid phase ELISA.
Results: The inhibition of platelets aggregation was increased among day of observation. Means value of inhibition on day 3 is 46.6%, day 5 is 52.5% and day 7 is 56%. There is a significant difference ($P < 0.05$) of inhibition of platelet aggregation value between days of observation. The antibodies against NS-1 DV and PDI were detected in all 50 sera with the positive rate of 90% develop NS-1 antibodies and 72% of PDI antibodies, on day 3 of symptoms. The highest OD of NS-1 antibodies is detected on the day 3 and decreased on day 7. The OD of PDI antibodies was increased on day 3 and still increasing on day 7. There is weak correlation between anti NS-1 antibodies and the inhibition of platelets aggregation ($r = 0.160$; $P = 0.267$). There is no correlation between anti PDI antibodies and the inhibition of platelets aggregation ($r = -0.118$; $P = 0.578$). There is a significant correlation between anti NS-1 and PDI antibodies ($r = 0.386$–0.490), while the differences of OD between observation days are not significant ($P > 0.05$).
Conclusion: This study shows the kinetics profile of NS1 and PDI antibodies responses, which were detected by the third day of symptoms. Dengue patients' sera also inhibited platelets aggregation. NS-1 antibodies and PDI antibodies might have a role on the platelets aggregation dysfunction; however statistically there is no correlation between them. It is possible that other mechanism involve in the inhibition of platelets aggregation.
Keywords: anti NS-1 antibodies, anti PDI antibodies, inhibition platelets aggregation, secondary Dengue Infection.

PO 315

Impedance aggregometric analysis of thrombocyte function in pooled platelet concentrates in relation to storage time

Glas M, Bauer J, Schneider SO, Volk T and Kreuer S

Saarland University Medical Center, Homburg/Saar, Germany

Background: To treat hereditary or acquired thrombocytopenia/-pathy, transfusion of platelet concentrates is a common procedure in Anaesthesiology and Intensive Care Medicine. Concerning quality controls of platelet concentrates, testing of volume, platelet count and remaining leukocyte content after preparation is required by German Medical Association or NHS guidelines. Before transfusion a visual check (colour change, swirling) must be performed. At the end of storage life pH values as well as sterility have to be monitored. A routine analysis of thrombocyte function in platelet concentrates is not prescribed. Modern point-of-care devices allow a fast and reliable monitoring of platelet function and are widely used in clinical routine. Impedance aggregometry (multiple electrode aggregometry, MEA, Multiplate®, Roche AG, Grenzach, Germany) was developed for time-saving whole blood analysis and is increasingly distributed.
Aims: The aim of the present study was the implementation of impedance aggregometry for thrombocyte function in pooled platelet concentrates and to correlate MEA results with storage time.
Methods: A) After collection from pooled platelet concentrates from 2 to 4 days of age, samples were diluted by additive solution (Composol PS®, Fresenius Kabi AG, Bad Homburg, Germany). Calcium chloride was added to obtain the target calcium concentration. MEA was performed according to the manufacturer's specifications. ASPItest (0.5 mM), ADPtest (6.5 μM) and TRAPtest (32 μM) reagents were used as specific platelet activators.
B) Platelet concentrates of 5 to 12 days of age were frequently analysed by impedance aggregometry in the same manner. Furthermore pH values, pO_2, pCO_2 and glucose concentrations were evaluated at the point of Multiplate® measurement and correlated with impedance aggregometric results.
Methods: A series of dilution yielded steady impedance aggregometric results for a platelet count of 400 per nl and a calcium concentration of 5 mM. With respect to specific thrombocyte activators ASPItest and TRAPtest showed reliable results for aggregation.
A) For platelet concentrates from 2 to 4 days of age the area under the curve (AUC) was in the lower clinical reference range; however results did not differ significantly between time points. For TRAPtest a significant difference was detected between day 3 and 4 ($P = 0.035$, One Way ANOVA).
B) Analysis of platelet function from day 5 to 12 after preparation resulted in a significant decline of the AUC in ASPI- and TRAPtest on day 12 ($P < 0.001$, ANOVA on Ranks). Linear regression analysis showed weak correlation between AUC in Multiplate® and pH values or glucose concentrations respectively ($R_{pH/ASPI} = 0.351$, $R_{pH/TRAP} = 0.347$, $R_{glucose/ASPI} = 0.398$ and $R_{glucose/TRAP} = 0.405$).
Conclusion: The results of our study suggest that multiple electrode aggregometry is not only suited as a point-of-care device for testing platelet function in whole blood, but might also be a useful tool for monitoring thrombocyte function in pooled platelet concentrates.

PO 316

Increased platelet activity associates with clinical severity of ST-elevation acute myocardial infarction

Hartopo AB[1], Setianto BY[2], Achadiono NW[1] and Gharini PR[2]

[1]Universitas Gadjah Mada; [2]Universitas Gadjah Mada, Yogyakarta, Indonesia

Background: Hemangioma, most common benign vascular tumor, has natural history of proliferation in the first year of life followed by spontaneous resolution. The treatment is not universal standard with indication as following: impaired organ function and Kasabach Merritt syndrome (KMS). Alpha-interferon inhibits angiogenesis, endothelial cell migration and proliferation.
Objective: To evaluate the outcome of alpha-interferon for the treatment of hemangioma.
Methods: We recruited 35 patients with hemangioma receiving alpha-interferon followed at hemangioma clinic between January 2001- January 2011.The patients' data including sex, age, type and location of hemangioma, indication, duration, outcome and complications of treatment were reviewed.
Design: Retrospective descriptive study.
Measurements: we evaluate of the outcomes including improvement of organ function, resolution of Kasabach Merritt syndrome (KMS) and decrease hemangioma size.
Results: the number of patients was 35 patients (female = 21, male = 14) with mean age 3.2 months (range 5 days-15 months), loss follow up in 5 patients. Hemangioma was divided into cavernous (9), capillary (10), mixed (7). Location of hemangioma includes head and neck (21), extremities (7), mediastinum (3), intraosseous (1), liver (2), larynx and epiglottis (2), and scrotum (1). Average age of treatment was 4.7 months (range 5 days-18 months). Duration of response in 29 patients was 4.7 months (range 1–6 months). Indications of treatment

included KMS (1), KMS with impaired organ functions (2), impaired organ functions (30), infection (2), intracranial (1). Eleven patients were decrease in size of mass > 50%, 14 patients were decrease in size < 50% but 23 patients (82.1%) were improved organ function and resolution of KMS. Complications of treatment were elevation of liver enzymes (3), and fever (6).

Conclusions: The use of alpha-interferon was well response to improve organ function and decrease hemangioma size. Due to spastic diplegia, serious complication of alpha-interferon from previous case report studies, the consideration of this treatment should be discussed with parent in light of pro and cons.

PO 317

Mechanisms for Ang-(1-7) on the expression of talin1 induced by Ang? in human umbilical vein endothelial cells

He X, Ran W and Wen Z

Central South University, Changsha, China

Background: Renin-angiotensin system (RAS) is one of the most important regulation systems, which has played an important role on regulating physiological function, especially at cardiovascular and cerebrovascular diseases development. Integrin is a major receptor family present in the cell surface, which can induce the conglutination between cells and extracellular matrix, activated integrin $\alpha II_b\beta_3$ is mainly involved in thrombus formation through inducing platelets adhesion and aggregation. Talin 1, as the essential factor in the process of activating $\alpha II_b\beta_3$, is recently specially concerned. Previous work have proved that angiotensin-(1-7) [Ang-(1-7)] could significantly inhibit the experimental thrombosis induced by angiotensin II(AngII). However, whether Ang-(1-7) and AngII can affect thrombosis formation by means of regulating talin 1 has not been reported. In this study, we will explore the possible mechanism for the influence of Ang -(1-7) on the expression of talin 1 induced by AngII in endothelial cells.

Aims: Previous data demonstrated that Ang-(1-7) had an inhibititory effect on the talin1 expression induced by AngIIin human umbilical vein endothelium derived cell line (HUVECs). However, its mechanisms were not fully understood. The purpose of this study was to explore the inhibitory mechanisms.

Methods: HUVECs were cultured in DMEM. Talin1 antigen was measured by ELISA Kit. Talin1 mRNA was examined by semi-quantitative reverse transcription polymerase chain reaction (RT-PCR). Samples were devided into groups at random as follows: control, AngII,Ang (1-7),PDTC,AngII+ Ang (1-7) and AngII+ Ang (1-7) +PDTC.

Results: Compared with control, PDTC, which is the inhibitor of NF-κB pathway, had no marked effects on talin1 antigen when used alone, but PDTC could significantly inhibited the effects of Ang-(1-7) on talin1 expression induced by AngII($P < 0.05$).

Conclusion NF-κB pathway participates in the inhibitory process that Ang-(1-7) inhibited the expression of talin 1 induced by AngII.

PO 318

Differential platelet activation: granule release without aIIbβ3 activation indicates platelet functions independent of aggregation

Van Holten TC[1], Wisman PP[1], De Groot PG[1], Remijn JA[2], Moll FL[1], Teraa M[1], Verhaar MC[1], Urbanus RT[1] and Roest M[1]

[1]UMC Utrecht, Utrecht; [2]Gelre hospitals, Apeldoorn, The Netherlands

Background: Platelets are appreciated by their crucial role in maintaining adequate haemostasis but they are also involved in wound healing, inflammation, angiogenesis, and atherogenesis via the release of cytokines, chemokines, and growth factors from their α-granules.

Aim: To investigate the regulation of α-granule release and opening of glycoprotein IIb:IIIa ($\alpha_{IIb}\beta_3$) on the platelet surface after stimulation of their thrombin receptors.

Methods: Activation of $\alpha_{IIb}\beta_3$ or P-selectin expression on platelets stimulated with increasing concentrations of PAR-1 agonist or PAR-4 agonist, in the presence or absence of $P2Y_{12}$ antagonists (clopidogrel, AR-C69931MX or apyrase), or in the presence or absence of the prostacyclin analogue iloprost was measured with flow-cytometry using antibodies against P-selectin and activated $\alpha_{IIb}\beta_3$. Platelet-leukocyte complexes were measured with flow-cytometry, release of soluble α-granule markers PF-4, β-TG, RANTES/CCL5 and PDGF-AB was measured with ELISA.

Results: PAR-1 or PAR-4 activation in the presence of $P2Y_{12}$ antagonism (AR-C69931MX) resulted in 84% P-selectin expression compared to stimulation in the absence of $P2Y_{12}$ antagonist, whereas $\alpha_{IIb}\beta_3$ activation was reduced to 12% ($P < 0.05$). P-selectin expression was also only slightly reduced when platelets were activated with PAR-1 or PAR-4 in the presence of apyrase or iloprost (with iloprost 79% vs. without iloprost 100%; $P < 0.05$) while under the same conditions $\alpha_{IIb}\beta_3$activation was almost completely prevented (with iloprost 7% vs. without iloprost 100%; $P < 0.05$). When blood was collected from patients on clopidogrel, P-selectin expression on their platelets was 90% of platelets of untreated individuals. However, their $\alpha_{IIb}\beta_3$activation was reduced to 29% ($n = 4$). PAR-1 or PAR-4 stimulation of whole blood in presence of AR-C69931MX resulted in the formation of platelet-monocyte complexes (115% compared to stimulation in the absence of AR-C69931MX), while these complexes only express 27% of the $\alpha_{IIb}\beta_3$activation observed after stimulation in the absence of AR-C69931MX ($P < 0.05$). Similar results were found for platelet-granulocyte complexes. No differences were found in the supernatant of PAR-1 activated platelets in the presence or absence of $P2Y_{12}$ antagonist for levels of PF-4, β-TG, RANTES/CCL5, or PDGF-AB. When platelets were stimulated with ADP in the presence of AR-C69931MX, α-granule release was blocked.

Conclusions: When the $P2Y_{12}$ pathway is blocked, or when platelets are inhibited by a prostacyclin analogue, PAR-1 or PAR-4 stimulation still induced α-granule release while their $\alpha_{IIb}\beta_3$ activation is blocked. We propose that this differential activation is physiologically important because it enables the platelets to fulfil their role in inflammation, angiogenesis and atherogenesis.

PO 319

Evaluation of activation states of small GTPases in patient platelets

Horiuchi H, Yaoita N and Shirakawa R

Institute of Development, Aging and Cancer, Sendai, Japan

Background: Small GTPases are molecular switches of cellular processes that plays important roles in activated platelets. Rap1 is implicated in aggregation. Rab27 and Ral is in granule secretion. Rho is in shape change and Rac is in aggregation and granule secretion. Activation states of platelets are monitored by P-selectin and activated GPIIb/IIIa levels on platelet surface. However, it is possible that some of these GTPases are activated in platelets.

Aim: First, to establish the method for measuring activation states of small GTPases. Second, to elucidate the activation states of each small GTPases in various diseases.

Method and Results: First we developed the method for isolating platelets without activation by a gelfiltration method. Little activation was cinfirmed by FACS analysis for P-selectin expression levels. Then, we generated and purified proteins containing binding region of GTP-bound active GTPases from E coli and established so called 'pull-down assays' that allowed us to measure the activation states of Ras, Rap1B, RalA, RalB, RhoA, Rac and Rab27. After the study plan was approval by the University ethics committee, we started to measure the activation states of these GTPases in platelets of patients with and without pulmonary hypertension. In spite of small number of patients

analyzed, Ral could be highly activated among GTPases analyzed in patients with pulmonary hypertension.
Summary: We established the method to evaluate the activation states of sevelral GTPase in a real clinical setting. We could present clearer data by analyzing more patients.

PO 320

Necrotic cell material from human renal tubular cells dose dependently stimulate platelet activation, aggregation and platelet-leukocyte complex formation

Jansen MPB and Roelofs JTH
AMC, Amsterdam, The Netherlands

Introduction: Acute kidney injury (AKI) is often the result of ischemia reperfusion injury (I/R), which leads to a complex interplay between coagulation-, inflammation and cell death processes, typically resulting in renal tubular epithelial cell necrosis.
Platelets play a central role in coagulation and inflammatory processes and therefore might play an important part in the pathology of AKI. However, the role of platelets in AKI is not known to date. Necrotic cell material can function as Danger-Associated Molecular Patterns (DAMP's) and activate innate immune cells, leading to an excessive immune response and tissue damage.
Objectives: We aimed to investigate the effect of necrotic human tubular epithelial cells on platelets.
Method: Human platelets in platelet rich plasma (PRP) or whole blood were stimulated with necrotic cell material derived from a human proximal tubular epithelial cell line (HK2 cells) which were repeatedly freeze-thawed in liquid nitrogen. Platelet activation and platelet-leukocyte formation were measured by FACS analysis.
Platelet aggregation was determined using multiple electrode aggregometry (Multiplate).
Results: Necrotic cell material from human TECs dose dependently stimulate human platelets activation and aggregation in PRP. Furthermore stimulation of whole blood with necrotic TECs increases platelet-leukocyte complex formation.
Conclusions: Our data show that necrotic cell material from human tubular epithelial cells (TEC), dose dependently stimulate human platelet activation and aggregation. Furthermore necrotic TEC material enhances platelet-leukocyte complex formation. This indicates that locally released renal necrotic TEC material during renal I/R could activate platelets, leading to enhanced coagulation and inflammatory processes. This could result in further loss of renal cells and ultimately renal function during AKI.

PO 321

Comparison of different brands of agonists for light transmission aggregometry using a multichannel analyser

Van De Kerkhof D[1], Van Der Stokker A[1], Hudig C[2], Verhezen P[3], Van Wijk E[4], Stroobants A[5] and Henskens YMC[3]
[1]Catharina Hospital, Eindhoven; [2]Haga Teaching Hospital, The Hague; [3]Maastricht University Medical Centre, Maastricht; [4]Sint Elisabeth Hospital, Tilburg; [5]Amsterdam Medical Centre, Amsterdam, The Netherlands

Background: Light Transmission Aggregometry (LTA) is considered as the golden standard technique for evaluation of platelet function. The results of a worldwide survey on the assessment of platelet function by LTA showed the high variability in LTA practices (Cattaneo et al., JTH 2009). The SSC Platelet Physiology published a draft guideline after the SSC meeting in Cairo (2010) in order to standardize LTA. Furthermore, the CLSI guideline is also a useful tool in standardizing this method. The society of hematological laboratories in The Netherlands (VHL) has set a goal for 2013 and 2014 to reduce unnecessary variances in LTA results by investigating the present differences between LTA methods and by stimulating all hospital laboratories to uniform there pre-analytical and analytical variables.
Aims: One part of the Dutch LTA standardization procedure was to investigate the three most used companies in The Netherlands, who provide agonists for LTA for which the source and nature is often unknown to the users of the technique. *E.g.* different types of collagen are available of which only the fibrillary type extracted from tendons is supposed to be functional as platelet activator.
Methods: In this study different brands of collagen (Biodata, Chronolog, Horm: 2 and 5 μg/mL), ADP (Biodata, Chronolog, Sigma: 2 and 5 uM), arachidonic acid (Biodata, Hart, Sigma: 1 mM) epinephrin (Biodata, ABP, Chronolog: 5 uM) and ristocetin (Biodata, ABP, Chronolog: 0.6 and 1.2 mg/mL) were compared as agonists for LTA in healthy volunteers. All tests were performed on a PAP8e (Biodata) multichannel LTA analyzer. Six healthy volunteers refrained from smoking, eating and drinking coffee or tea for 2 h. Blood was drawn into 105 mM citrated and buffered saline using a needle of 21 gauge. Each agonist was used in relevant concentrations, conform the draft SSC guideline (Cairo, 2010) and used for analysis of thrombocyte function in platelet rich plasma (PRP) of six healthy volunteers. Platelet count of PRP was standardized to 200/nL and PRP was prepared by centrifuging blood samples at 200 g for 10 min at ambient temperature without using a brake. ANOVA with Bonferroni correction was used for statistical evaluation.
Results: The variation over the eight channels of the PAP8e was 9% for arachidonic acid (0.5 mM), 6% for collagen (5 mg/L) and 5% for ADP (1.5 μM).
The maximum amplitude of the aggregation response after agonist activation was comparable between the studied brands in case of epinephrine, arachidonic acid and ristocetin. ADP showed a non-significantly lower response for Chronolog as compared to BioData and Sigma at a concentration of 2 μM. At a concentration of 5 μM no difference was observed. In case of collagen, BioData showed a significantly ($P < 0.05$) lower response as compared to Chronolog and Horm at concentration levels of 2 as well as 5 mg/L.
Conclusions: The used formulation of collagen and ADP (only low concentration) should be considered when implementing LTA procedures and comparing LTA-results between laboratories.

PO 322

Technical validation of light transmission aggregometry using Chrono-Log, PAR8 and PAP8e

Körver-Keularts IMLW[1], Van Oerle R[2], Van Thoor L[1], Verhezen WM[1] and Henskens YMC[1]
[1]Maastricht University Medical Center, Maastricht; [2]Maastricht University, Masstricht, The Netherlands

Background: Light transmission aggregometry (LTA) is a common method used to assess platelet function. The method has never been standardized and a report (Cattaneo et al., 2009) from the platelet physiology subcommittee of the SSC of the ISTH showed a large diversity in LTA practices and advised a worldwide standardisation programme.
Aims: We compared three devices for light transmission aggregometry using fixed agonist concentrations recommended by the SSC-ISTH (Cairo, 2010). Several variables and parameters were studied: reagents from different providers, reproducibility (channels), reference values, difference between adjusted and non-adjusted platelet rich plasma (PRP), amount of patient plasma needed for testing as well as agonist volume, user-friendliness, software possibilities and financial aspects (costs of exploitation and device).
Material and Methods: We tested three LTA devices Chrono-Log 490-4D, PAR8 (Hart Biological) and PAP8e (Biodata) using 4 device-specific agonists (except for TRAP14): ADP (5 μM) (Chrono-Log,

HART, Biodata), ristocetin (1.2 μg/ml) (Chrono-Log, ABP, Biodata), collagen (2 μg/ml) (Chrono-Log for all) and TRAP 14 (10 μM) (Bachem for all three devices). Citrated blood (3.2%) was collected from 30 healthy donors not taking any medication that affects platelet function, 18 females (21–58 years) and 12 males (20–54 years) with comparable mean platelet counts 263 ± 59 × 10^9/L and 250 ± 40 × 10^9/L. LTA was tested in adjusted (250 × 10^9/L) and non-adjusted PRP (recommendations ISTH-SSC 2010). Since the majority of maximal aggregations of the agonists was not normally distributed, results were expressed as medians and 25% and 75% quartiles (inter-quartile range. IQR).

Results: Chrono-Log needed 400 μL PRP whereas PAR8 and PAP8e used only 200 and 225 μL PRP. The differences between the channels on each device is < 3.3%. Reference values for maximal aggregation with four agonists were comparable for Chrono-Log and PAR8. PAR8 reference values of non adjusted PRP were (expressed as median [25–75% IQC]): 78 (75–86) for 5 μM ADP, 88 (86–90) for 2 μg/ml collagen, 92 (90–94) for 1.2 mg/ml ristocetin and 87 (87–89) for 10 μM TRAP 14. PAP8e results were significantly lower (e.g. 20% lower for 2 μg/ml collagen). Adjustment of PRP had no significant effect on results of healthy volunteers except for TRAP. PAR8 software was less user-friendly than the PAP8e software. PAP8e was slightly less expensive (both device and exploitation costs) than PAR8. Chronolog is the most expensive.

Summary and Conclusions: Reference values for 30 healthy volunteers are very comparable for Chrono-Log and PAR8 and IQR intervals appear to be very narrow. PAP8e showed significantly lower maximal aggregation levels. For all three devices adjusted PRP was comparable to non-adjusted PRP. Variation between channels was low. Modern LTA devices used less patient sample and were cheaper in hardware and reagents.

PO 323

Fractal and euclidian geometrical descriptors of platelet shape

Kraus MJ[1], Neeb H[2] and Strasser F[3]
[1]*Praxis Geiselgasteig, Gruenwald;* [2]*University of Koblenz, Koblenz;* [3]*University Hospital of Erlangen, Erlangen, Germany*

Background: Platelet shape is traditionally classified into morphological categories (e.g. discoid, round, dendritic). Fractal Hausdorff-Besicovitch dimension (FD) and circularity (C) are mathematical descriptors for the surface roughness and roundness of irregular shapes. They can be applied to the outlines of platelets automatically detected on microscopic images.

Aims: In order to describe platelet outline structure in a mathematical accurate way suitable for statistical analysis a pilot study was performed to analyze roughness, roundness, area, peri- and diameter of platelet outlines as well as number, length and width of filopodia per platelet.

Methods: Nine hundred and twenty-eight microscopic images from six PRP-samples were acquired right after preparation. Fractal dimension (FD), circularity (C), area (A) and perimeter (P) were determined for each of the 6629 platelet-outlines (PLO). Corresponding original images of every fifteenth PLO were randomly assigned for computer assisted manual measurement of platelet-diameter and number, length and basal and apical width of filopodia (1). Automated outline detection and statistical analysis was performed using Matlab R2012b (MathWorks Inc., Natwick, USA).

Results: Mean FD of all PLO was 1.305 ± 0.078 and mean C was 0.741 ± 0.025. Only scatterplot of fractal dimension (FD) vs. perimeter (P) revealed the existence of three clearly disjoint groups of PLO (G1, G2, G3). G1-PLO had a significantly higher FD (1.337 ± 0.0075, $P < 0.001$) than G2- (1.265 ± 0.061) and G3-PLO (1.248 ± 0.056). As well the roundness of G1-PLO was higher than for G2- and G3-PLO (C_{G1} = 0.819 ± 0.188, C_{G2} = 0.665 ± 0.224, C_{G3} = 0.459 ± 0.186, $P < 0.001$). G1-PLO had lower diameter, area and perimeter and they showed less, shorter and smaller filopodia than G2- ($P < 0.001$) and G3-PLO ($P < 0.001$). Hence, PLO were automatically categorized into morphological characteristic groups with significant structural differences of platelet shape. According to our observations the smaller and rounder G1-PLO with less, shorter and smaller filopodia were mostly associated with floating, not yet adherent platelets, while the larger G2-PLO with more, longer and wider filopodia mostly represented adherent platelets. G3-PLO mainly consisted of aggregates of several platelets with large area, dia- and perimeter and numerous long and wide filopodia.

While FD values were not significantly correlated with number, length or width of filopodia, there was a significant correlation between circularity and cumulated length of filopodia (r^2 = -0.571, $P < 0.001$). Circularity clearly distinguished platelets with no (C = 0.918 ± 0.009, $P < 0.001$), few (< 3, C = 0.714 ± 0.008, $P < 0.001$) or many (> 3, C = 0.484 ± 0.019, $P < 0.001$) filopodia.

Summary/Conclusion: Fractal dimension and perimeter of platelet outline define three clearly disjoint groups that exhibit significant differences in platelets roundness and size as well as number, length and width of filopodia. The group of presumably floating platelets (G1) has significantly higher FD values than adherent (G2) and aggregated platelets (G3). Circularity is significantly different for platelets with different number and length of filopodia.

Our method can be applied to any sufficiently contrast rich image of platelets and allows the fully automated continuous numerical assessment and statistical analysis of platelet shape and its change. This will be of particular interest with regard to conditions accompanied by an increased activity of platelets (e.g. inflammatory diseases, contact activation, drug-testing).

PO 324

Absence of clinically relevant interaction between sugammadex and aspirin on platelet aggregation and coagulation

Kruithof A[1], De Kam PJ[2], El Galta R[3], Burggraaf J[1], Kluft C[4], Fennema H[3], Van Lierop MJ[3], Mihara K[3], Jagt-Smook M[3] and Moerland M[1]
[1]*Centre for Human Drug Research, Leiden, The Netherlands;* [2]*Merck, Whitehouse Station, USA;* [3]*MSD, Oss;* [4]*Good Biomarker Sciences, Leiden, The Netherlands*

Background: The selective muscle relaxant binding agent sugammadex (Bridion®) is associated with a limited and transient prolongation of activated partial thromboplastin time (APTT) and prothrombin time (PT) in healthy male volunteers. Although *in vitro* spiking experiments showed no effect of sugammadex on platelet aggregation, it was considered necessary to assess in a clinical study the potential interaction between sugammadex and aspirin because of the widespread prophylactic use of aspirin.

Methods: A randomized, double-blind, placebo-controlled, 4-period cross-over design was performed in 26 healthy male volunteers (aged 25.7 ± 7.4 years, BMI of 22.8 ± 2.9 kg/m^2, normal coagulation). Each subject was assigned to receive a single intravenous dose of 4 mg/kg sugammadex or placebo at t = 0 in the absence (period 1 and 2) or presence of aspirin (period 3 and 4). Aspirin (75 mg, oral) was

administered daily for at least 7 days prior to period 3, until and including sugammadex or placebo administration in period 4. Collagen-induced whole blood aggregation, APTT, bleeding time, sugammadex plasma concentrations, tolerability and safety were assessed. Evaluation of clinically meaningful interaction was based on true geometric mean ratios (GMRs) and corresponding 2-sided 90% confidence intervals (CI) for the different $AUEC_{3-30\ min}$ treatment comparisons (APTT and platelet aggregation) or treatment comparisons at 5 min (bleeding time). The pre-defined clinically meaningful margin was 0.75 for platelet aggregation and 1.50 for APTT and bleeding time.

Results: Aspirin treatment inhibited baseline platelet aggregation before sugammadex/placebo administration by approximately 25% (from approximately 17 Ohm to 13 Ohm in both treatment groups). Platelet aggregation did not differ between sugammadex and placebo, neither in the treatment arm with nor in the treatment arm without aspirin. The GMR for sugammadex co-administered with aspirin vs. aspirin alone was 1.01 and corresponding lower limit of CI was 0.91, which excluded the pre-defined clinically meaningful effect margin of 0.75. APTT was on average 32–33 s in the placebo treatment arm for all time points and was not affected by aspirin therapy. Sugammadex dosing induced an immediate prolongation of approximately 3.5–4 s, which disappeared within 1 h post-dose. The GMR of statistical interaction between sugammadex and aspirin on APTT was 1.01 and corresponding 90% CI upper limit was 1.04, which was below the pre-defined non-inferiority margin 1.50. In addition, the GMR for sugammadex alone vs. placebo alone was 1.06 and corresponding 90% CI upper limit was 1.07, which did not exceed the pre-specified non-inferiority margin of 1.50. Bleeding time was variable and prolonged by aspirin treatment and no additional effect of sugammadex was observed. The GMR of bleeding time for sugammadex with aspirin vs. aspirin alone at 5 min was 1.20 and corresponding 90% CI upper limit was 1.45, which was below the pre-defined non-inferiority margin 1.50. The plasma concentration profiles of sugammadex were comparable for sugammadex alone and sugammadex plus aspirin. Sugammadex, either alone or in combination with aspirin, was generally well tolerated by all treated subjects.

Conclusion: This study showed no clinically relevant interaction between sugammadex and aspirin on platelet aggregation, APTT and bleeding time.

PO 325

A standardized flow chamber model for real-time visualization of whole blood platelet aggregation

Laursen PN[1], Rea C[2] and Sorensen B[2]

[1]University of Aarhus, Aarhus C, Denmark; [2]St. Thomas'Hospital, London, UK

Background: Currently available standard laboratory models for the assessment of the platelet function are all performed in static conditions and may overlook important mechanisms of platelet function in the flowing blood. Standardized flow chamber models are needed for flow based platelet assessment.

Methods: This study aimed to develop a standardized flow chamber model for assessment of platelet adhesion and aggregation using commercially available hardware and disposable assay biochips. The models sensitivity towards shear forces, platelet receptor defects, platelet inhibitors and coating reagent was assessed and the reproducibility of the model was validated.

Results: The model is sensitive to: (i) high vs. low shear stress dependent platelet adhesion and aggregation ($P < 0.0001$), (ii) coating reagent as well as (iii) blockage of platelet receptors GP-IIb/IIIa, GP-Ib-α, GP-VI and inhibition induced by aspirin. Reproducibility: The average%CV declined over time from a mean of 28.7% at 0.5 min to a mean of 12.9% at 7 min.

Conclusion: This flow chamber model produces reproducible, physiologically and pathologically relevant findings, assessing whole blood platelet adhesion and aggregation. It fulfils all recent recommendations of flow chamber development and standardization from the ISTH scientific subcommittee on biorheology.

PO 326

Automation of light transmission platelet aggregation

Lawrie AS[1], Kobayashi K[2], Lane P[1], Mackie IJ[1] and Machin SJ[1]

[1]University College London, London, UK; [2]Sysmex Corporation, Kobe, Japan

Background: The investigation of platelet function disorders by light transmission aggregometry has changed little over the last 50 years, with the use of manually operated instrumentation making the process time consuming and labour intensive. In the current study we have used samples from normal healthy donors to develop the potential of using a high throughput coagulation analyser (CS-2000i. Sysmex Corporation, Kobe, Japan) to automate platelet aggregation.

Methods: We assessed the ability of a CS-2000i with prototype software to perform platelet aggregation, examining the effect of varying reaction cuvette stirrer speed and the platelet count in platelet rich plasma (PRP) using: ADP (0.5–10 μM) and collagen (0.5–10 μg/mL); dose response with ADP (0.5–10 μM), Epinephrine (0.5–10 μM), Collagen (0.5–10 mg/μL), Ristocetin (0.75–1.25 mg/mL), Arachidonic Acid (0.12–1.0 mM); imprecision of response to ADP (2 μM and 5 μM). All platelet agonists were from Hyphen Biomed (Neuville sur Oise, France), and an AggRAM (Helena Biosciences Europe, Tyne and Wear, UK) aggregometer was used as the reference instrument.

Results: CS-2000i reaction cuvette stirrer speed was found to influence reaction sensitivity and was optimised to 800 rpm. There were no clinically significant changes in aggregation response when the PRP platelet count was 150–480 $\times$ 10^9/L, but below this there were changes in the maximum amplitude (MA) and slope (rate). For further experiments a standardised PRP count of approximately 250 $\times$ 10^9/L was then used. Dose response with ADP, Epinephrine, Collagen, Ristocetin and Arachidonic Acid were comparable between CS-2000i and AggRAM. Aggregation imprecision was similar on both systems (CS-2000i: MA for ADP 2 μM cv 5%, 5 μM, cv 12% slope 2 μM cv 6%, μM cv 10%. AggRAM: MA for 2 μM cv 9%, ADP 5 μM cv 6%, slope 2 μM cv 7%, 5 μM cv 3%).

Conclusions: Our preliminary studies with platelets from normal healthy donors indicated that optimal sensitivity using the CS-2000i was obtained with a reaction cuvette stirrer speed of 800 rpm, and that the PRP should be adjusted with autologous PPP to a count of 200–300 $\times$ 10^9/L. Aggregation with a PRP platelet count of less than 150 $\times$ 10^9/L showed poor sensitivity. Aggregation imprecision was comparable between the CS-2000i and AggRAM, with similar aggregation dose response profile from the commonly used platelet agonists. In addition to the advantage of its walk-away technology the CS-2000i also required a smaller PRP sample volume than the AggRAM (140 μL vs. 250 μL respectively). These data are encouraging but further studies are underway using clinical samples from patients with platelet disorders and subjects receiving various anti-platelet drugs.

PO 327

Measuring platelet aggregation integrals to predict thromboembolic complications in patients undergoing pipeline embolization for treatment of cerebral aneurysms

Maier CL, Schneider T, Smith G, Rutledge WC, Guarner J, Duncan AS and Winkler AM

Emory University School of Medicine, Atlanta, USA

Background: Thromboembolic complications remain a significant cause of morbidity and mortality in patients undergoing treatment for

cerebral aneurysms with flow diverting stents such as the pipeline embolization device (PED). While the prevalence of antiplatelet therapy non-responsiveness has been associated with adverse cardiac events in patients with acute coronary syndrome, the role of platelet non-responsiveness in thromboembolic complications after PED has not been fully examined. We recently found that the prevalence of clopidogrel and aspirin resistance in patients treated with PED was 27.6% and 30.3%, respectively, which was similar to that reported in ACS patients, but did not reduce the likelihood of aneurysm occlusion at 6 months. The maximum amplitude of platelet aggregation by light transmittance platelet aggregometry (LTA) has been the gold standard identifier to characterize antiplatelet therapy (clopidogrel and aspirin) non-responsiveness; however, in our experience, discrepancies exist between the maximum amplitude and degree of platelet disaggregation, which also reflects platelet responsiveness.

Aims: Here we sought to examine a role for LTA integrals (area under the curve, AUC) in predicting acute thromboembolic complications in patients receiving antiplatelet therapy prior to PED intervention.

Methods: All patients received clopidogrel and aspirin prior to LTA using 4 agonists (ADP 20 and 5 uM, arachidonic acid (ACA), and U46619). Calculation of the integral of each aggregometric reading was used to determine the AUC, which is a function of both the maximum amplitude and the degree of platelet disaggregation. One-way ANOVA was used to assess statistical significance for any association between AUC and thromboembolic complications. Complications were defined clinically by interventional neuroradiology after the procedure.

Results: Of the 79 patients treated with PED for cerebral aneurysms 15 experienced a major or minor complication. Of those 15 complications 5 were classified as thromboembolic and 10 were classified as non-thromboembolic (3 were hemorrhagic, the remaining were due to other etiologies including device malfunction and vascular stenosis). Although the average AUC generated from ADP 20 μM response curves was increased in patients with thromboembolic complications (17,978AUC ± 8545), as compared to the average AUC generated from the response curves of the patients with non-thromboembolic complications (11,641AUC ± 6567) or those without complications (11,833 ± 7876), the data did not achieve statistical significance ($P > 0.05$). There was no significant difference in the average AUC between any of the groups to the remaining three agonists (ADP 5 uM, ACA, and U46619).

Summary/Conclusion: Developing parameters that more completely assess platelet responsiveness is important for determining the optimal antiplatelet therapy prior to cerebral aneurysm treatment with flow diversion devices. While our study failed to reach statistical significance, we did see a trend showing increased ADP 20 uM aggregation response integrals in patients that went on to have thromboembolic complications, as compared to those patients without complications. We conclude that further investigation with increased sample size is needed to determine whether the AUC from aggregometric readings might be a helpful indicator of thromboembolic complication risk in the setting of flow-diverting stent intervention for cerebral aneurysms.

PO 328

Platelet activation might facilitate the immunogenicity of stressed biotherapeutics

Malisauskas M, Lenk C, Wurz T, Lubich C, Scheiflinger F and Reipert BM

Baxter BioScience, Vienna, Austria

Background: The primary role attributed to platelets has been the support of hemostasis and the initiation of wound healing. Recently, it has become increasingly clear that platelets play an important role in the regulation of the intravascular immune system. Platelets express the IgG receptor FcgammaRIIa, MHC class I molecules, the immune costimulatory proteins CD40 and CD40 ligand as well as a variety of toll-like receptors. Furthermore, platelets can produce important immune modulators such as IL-1 beta, soluble CD40 ligand, serotonin and histamine. Although platelets are unable to transcribe new RNA, they contain a wide range of precursor mRNAs which they can use as templates to synthesize proteins de novo. Activated platelets can also bind to neutrophils and monocytes in circulation and modulate their functional activity.

Aim: We asked if protein aggregates as contained in stressed biotherapeutics might influence the activation status of platelets.

Methods: Flow-cytometric assays were established to analyze platelet activation and the formation of leukocyte-platelet aggregates (LPA) in citrated human whole blood obtained from healthy blood donors. Human monoclonal IgG1 and human polyclonal IgG were either used untreated or subjected to temperature or mechanical stress. Upregulation of CD62P, PAC-1, CD63 and CD154 on platelets and formation of LPAs were analyzed after 15 min incubation of human whole blood at 37 °C with the stressed and unstressed IgG preparations, respectively.

Results: Incubation of human whole blood with human IgG preparations subjected to either mechanical stress or temperature stress induced a marked increase in platelet activation associated with an upregulation of platelet activation markers when compared to the unstressed human IgG controls. Furthermore, stressed human IgG induced a significant increase in leukocyte-platelet aggregates when compared to unstressed preparations.

Conclusion: Based on our results, we believe that the potential role of platelet activation in the induction of unwanted immune responses against biotherapeutics that are given intravenously deserves further attention. Currently, we investigate if the activation of platelets by protein aggregates is restricted to IgG preparations or is a more general phenomenon that is also seen with non-IgG therapeutics.

PO 329

A novel flow cytometry-based platelet aggregation assay

Meinders M[1], De Cuyper IM[1], De Haas M[1], Seeger K[2], Rutell S[3], Kuijpers TW[1], Verhoeven AJ[4], Van Den Berg TKT[1], Gutierrez L[1], Van De Vijver E[5], De Korte D[5], Porcelijn L[5], Eble JA[6] and Pagliara D[3]

[1]Sanquin, Amsterdam, The Netherlands; [2]Otto-Heubner-Center for Pediatric and Adolescent Medicine, Berlin, Germany; [3]IRCCS Bambino Gesu Children's Hospital, Rome, Italy; [4]Academic Medical Center; [5]Sanquin Research and Landsteiner Laboratory, Amsterdam, The Netherlands; [6]Center for Molecular Medicine, Frankfurt, Germany

Background: The main function of platelets is to maintain normal homeostasis. Inefficient platelet production and/or defective platelet function results in bleeding disorders which summon a wide range of genetic traits and acquired pathologies. Several platelet function tests have been developed to date to be used in the clinic and in experimental animal models. In particular, platelet aggregation is routinely measured in an aggregometer, which requires normal platelet counts and significant blood sample volumes, making it difficult to analyze platelet function in thrombocytopenic patients, infants or small rodents.

Aim: To develop a novel flow cytometry-based platelet aggregation assay, in which 10–25-fold lower platelet counts can be used. To optimize the test to be used on either platelet-rich plasma (PRP) or whole blood from human subjects or mice.

Methods: Fluorescent labeling of platelets with 2 different dyes or fluorochrome-conjugated antibodies, and subsequent measurement of double-colored events on a flow cytometer.

Results: With this novel aggregation assay we are able to measure the early onset of aggregate formation which allows us to distinguish between aggregation mediated by αIIbß3 and α2ß1 integrins. This fea-

ture allows us to discriminate between aggregopathy accompanying Glanzmann thrombasthenia andLAD-III.
Further, this assay can be used for mouse platelets, both whole blood, prp and fetal platelets. A great advantage is the small volume which is necessary to perform an assay. This gives us the opportunity to follow platelet function in time in one mouse and embryonic mouse blood can be measured. In a Bernard-Soulier-phenocopying mouse model, we were able to distinguish the specific failure of vWF andCLEC-2 receptor mediated signaling required for proper platelet aggregation.
Summary/Conclusions: The presented principle stands as a promising user-friendly tool, which allows analysis of platelet aggregation in thrombocytopenic patients or infants, and facilitates studies in platelets obtained from experimental animal models without the need of special devises but a flow cytometer.

PO 330

Ex vivo and *in vivo* effect of aspirin on different platelet activity pathways

Montenont E, Michael NA and Berger JS
NYU School of Medicine, New York, USA

Background: While aspirin inactivates the cyclooxygenase-1 (COX-1) enzyme responsible for the conversion of arachidonic acid (AA) in prostaglandin H_2, the *in vivo* and *ex vivo* antiplatelet effects of aspirin in different pathways may not be equal in all subjects.
Aims: We sought to investigate platelet aggregation in response to AA, epinephrine, collage and ADP at different concentrations in healthy controls before and after aspirin, and in subjects with stable coronary artery disease (CAD) on aspirin.
Methods: Fourteen healthy controls had blood collected during 3 consecutive weeks (visits 1, 2 and 3) and after a week of treatment with aspirin 81 mg daily (visit 4), and from 26 CAD patients taking aspirin 81 mg/day. Platelet aggregation from light transmission aggregometry (LTA) was measured in response to arachidonic acid (150 and 1500 μM), adenosine diphosphate (ADP; 1 and 2 μM), and epinephrine (0.4 and 2 μM). LTA was performed with and without *ex vivo* addition of aspirin (final concentration 30 μM) to platelet rich plasma (PRP). Paired samples were compared using paired *t*-test and unpaired samples were compared using standard *t*-test.
Results: Prior to aspirin ingestion in visits 1–3, addition of aspirin *ex vivo* to PRP decreased platelet aggregation in response to AA, ADP, collagen and epinephrine. Following aspirin use for 1-week, a significant decrease in platelet aggregation was observed for each agonist. The response to aspirin *in vivo* vs. aspirin *ex vivo* was similar for platelet aggregation in response to AA (150 μM: 2.5 ± 2.1 vs. 2.8 ± 1.8, $P = 0.8515$; 1500 μM: 7.0 ± 4.8 vs. 4.1 ± 2.4, $P = 0.949$) and ADP (1 μM: 10.2 ± 6.3 vs. 9.2 ± 5.5, $P = 0.243$; 2 μM: 33.7 ± 12.7 vs. 27.1 ± 13.6, $P = 0.065$). However, epinephrine induced platelet aggregation in response to aspirin *in vivo* was higher than aspirin *ex vivo* (0.4 μM: 22.6 ± 9.8 vs. 15.2 ± 6.5, $P = 0.0018$; 2 μM: 41.2 ± 20.1 vs. 25.9 ± 11.4, $P = 0.0019$) suggesting that responsiveness to epinephrine may be dose dependent. A similar pattern was observed in patients with CAD. There was no significant difference between AA- (150 μM: 4.7 ± 3.8 vs. 4.4 ± 4.5, $P = 0.659$; 1500 μM: 19.4 ± 18.6 vs. 15.5 ± 10.7, $P = 0.306$) and ADP- (1 μM: 27.2 ± 21.4 vs. 29.5 ± 20.7, $P = 0.141$; 2 μM: 50.0 ± 25.2 vs. 52.3 ± 21.8, $P = 0.334$) induced platelet aggregation in response to aspirin *in vivo* and *ex vivo*, while epinephrine induced platelet aggregation in response to aspirin *in vivo* was higher than aspirin *ex vivo* (0.4 μM: 26.1 ± 12.2 vs. 20.5 ± 12.4, $P = 0.001$; 2 μM: 41.9 ± 16.1 vs. 34.6 ± 16.6, $P = 0.005$). Not surprisingly, CAD patients had increased platelet aggregation in response to *in vivo* and *ex vivo* aspirin for each agonist compared with healthy controls.
Conclusions: *In vivo* and *ex vivo* aspirin decreases platelet aggregation in response to ADP, epinephrine, and AA. While the response to ADP and AA activation pathways is inhibited to a similar degree with *in vivo* and *ex vivo* aspirin, epinephrine induced platelet aggregation is higher following *in vivo* (approximately 5 μM) than *ex vivo* (30 μM) aspirin. These data suggest that aspirin affects multiple activation pathways and may affect different pathways in a dose dependent manner.

PO 331

Clinical features and bleeding patterns in children with Glanzmann thrombasthenia: single center experience

Ozdemir N, Kutlubay B, Tuysuz G, Apak H and Celkan T
Pediatric Hematology Department, Istanbul University, Cerrahpasa Medical Faculty, Istanbul, Turkey

Background: Glanzmann thrombasthenia is a rare autosomal recessive bleeding disorder characterized by a defect in platelet aggregation. The incidence is high in communities where consanguinity is prevalent.
Aim: To report the clinical features and bleeding patterns of children with Glazmann thrombasthenia at our center.
Material and Method: Patient files were retrospectively reviewed for demographic and clinical data.
Results: Twenty-four patients (12 girls and 12 boys) were diagnosed as Glazmann thrombasthenia at our center. Two patients were excluded because of insufficient clinical data in patient files. Positive family history of bleeding was noted in 8 (36%) patients, no history of bleeding in 4 (18%) and unknown in 10 (45%). Sixteen patients' parents were consanguineous. The median age of onset of bleeding symptoms was 2 months (1 week–7 years). All patients presented with easy bruising, 4 presented with hematoma after vaccination, 2 with gastrointestinal bleeding and 1 with bleeding after circumcision. On follow-up, the most common type of bleedings were; easy bruising (100%), epistaxis (54%), gum bleeding (42%), gastrointestinal bleeding (25%), oral mucosa bleeding (21%), bleeding from tongue (21%) and menorrhagia (4%). The most common indication for hospitalization was epistaxis (n:5). Fourteen patients were treated with thrombocyte transfusion, tranexamic acid, recombinant active factor VII and fibrin glue as a single or combined therapy; none of them had a major bleeding complication. Oral contraceptives were used in two patients with menorrhagia. Four patients had a surgical procedure on follow-up, 3 were circumcised and 1 had a dental operation. Circumcisions were performed with fibrin-glue and transamin, dental extraction was performed with transamin. No major bleeding or complication was noted after the procedures. No patient was lost due to bleeding on follow-up.
Conclusion: Glanzmann thrombasthenia is a se−vere hemorrhagic disease with clinical variability: epistaxis, gum bleeding and easy bruising are the most frequent bleeding types. Patients usually present early in life, 73% of our patients were ≤ 1 year when they first had a bleeding symptom. Although the bleeding problem is lifelong, the disease is associated with a low morbidity and mortality with good supportive care.

PO 332

Influence of angiotensin-(1-7) on the expression of talin 1 induced by angiotensin ?in endothelial cells

Ran W, He X and Wen Z
Central South University, Changsha, China

Background: Renin-angiotensin system (RAS) is one of the most important regulation systems, which has played an important role on regulating physiological function, especially at cardiovascular and cerebrovascular diseases development. Integrin is a major receptor family present in the cell surface, which can induce the conglutination between cells and extracellular matrix, activated integrin $\alpha II_b\beta_3$ is mainly involved in thrombus formation through inducing platelets adhesion and aggregation. Talin 1, as the essential factor in the process of activating $\alpha II_b\beta_3$, is recently specially concerned. Previous work

have proved that angiotensin-(1-7) [Ang-(1-7)] could significantly inhibit the experimental thrombosis induced by angiotensin II(AngII). However, whether Ang-(1-7) and AngII can affect thrombosis formation by means of regulating talin 1 has not been reported. In this study, we will observe the influence of Ang -(1-7) on the expression of talin 1 induced by AngII in endothelial cells.

Aims: To study the effects of Ang-(1-7) on the expression of talin 1 induced by AngII in human umbilical vein endothelium derived cell line (HUVECs).

Methods: HUVECs were cultured in DMEM. Talin 1 antigen was measured by ELISA Kit.Talin 1 mRNA was examined by semi-quantitative reverse transcription polymerase chain reaction (RT-PCR).

Results: (1) Compared with control, a gradual increase in talin 1 antigen ($r = 0.965, P < 0.05$) and talin 1 mRNA ($P < 0.05$), were due to the increasing concentration of AngII(10^{-10}–10^{-6} M) treated in HUVECs, and peak appeared in the 10^{-7} M. (2) When pretreated with Ang-(1-7) (10^{-9}–10^{-6} M), then treated by AngII, it inhibited the expression of talin 1 at antigen and mRNA level in the dose-dependent manner ($r = -0.987$, $P < 0.05$), and 10^{-6} M was the strongest concentration.

Conclusion: The present data suggested that AngII could increase the expression of talin1 in vascular endothelial cells, and Ang-(1-7) could inhibit this effect at mRNA level.

PO 333

Molecular study on the interactions between extracellular fragments of platelet thrombin receptor PAR4 and thrombin exosites and functional effects on platelet activation

Sanchez Centellas D, Selegård R, Enander K and Lindahl T
Linköping University, Linköping, Sweden

Introduction: Thrombin is a potent activator of platelets by the cleavage of the *N*-terminal of its receptors PAR 1 and PAR4 and it is well established its roll in haemostasis, thrombosis and vascular biology, but the detailed receptor mechanisms needs to be further elucidated to improve treatments for cardiovascular diseases. The focus of this project is centered in the details of thrombin interactions with its low affinity receptor PAR4 and how this would affect normal haemostasis or become the basis for new drug design. In this interaction with the PAR4 it is not known in detail the contributions of the different extracellular loops (ECL) of PAR4 or the exosites of thrombin: exosite I is related to PAR1 activation by its hirudin-like binding site, but it has not been experimentally discarded its contribution to PAR4 binding (1), on the other hand, exosite II is the natural binding site for heparin, a highly cationic patch (2) similar to exosite I but in the opposite side of the protein. Its binding to PAR4 would depend upon its electro-negativity and hydrophobic interaction with α-helix chains.

Methods: We propose possible ECL and PAR4 *N*-terminal region as candidates to interact with thrombin at exosite II. The most plausible sequence are: *N*-terminal anionic cluster (A54 to S66), and two amino-acidic sequence in the ECLII (both from S221 to S240).

Our first approach is performed with peptides that mimic the aforementioned PAR4 fragments in order to detect some binding and/or effect on thrombin. To test these peptides we use activation of platelets by thrombin measured, in flow cytometry (P-selectin exposure) and we evaluate an expected quenching of this activation by the presence of the peptides, and additional data from the use of exosite I and II blockers. The hypothetical bindings that result in these mentioned effects are also investigated by Surface Plasmon Ressonance (SPR). The next approach is the evaluation of the PAR4 cleavage by thrombin using Western Blot with monoclonal antibodies against PAR4, and again a parallel quenching effect of these peptides.

Results: Our data seems to confirm a hypothesized contribution of exosites I and II with different strength in the PAR4 activation with exosite II being the most important; moreover the use of PAR1 inhibitors and blockers of the exosite I and II in combination with the designed peptides give us differential results indicating contributions of both thrombin exosites. The results for gamma-thrombin, lacking exosite I, drive us to the conclusion that there is an interchangeable interaction with different extracellular parts of PAR4. The experimental data were confirmed by different methods such as the check of the PAR4 cleavage by Western Blot. These results give us a starting point for the development of further assays in living systems to study these interactions in detail.

PO 334

The influence of neurotropic drugs on platelet aggregation *in vitro*

Shamanskaya M[1], Pradun S[2], Darensky I[3] and Shamanskaya N[1]
[1]Chita Medical Academy, Chita; [2]Cuban Medical University, Krasnodar; [3]Moscow medical university, Moscow, Russia

Background: Neurotropic drugs of different groups are widely used nowadays. Besides the central action they influence other systems-immunity and hemostasis. Although there exist some discrepant data to this.

Aim: the research of influence of some neurothropic drugs on aggregation ability of trombocytes.

Methods: the aggregation of thrombocytes was examined by analyzer 'Biola' (Moscow) with turbidimetric method (Born's method 1962). Adrenalin, ADP (10 mcg/mL, collagen was used as inducers.

For influence of neurotropic drugs examination the plasm, rich of thrombocytes was incubating with diazepam, propranolol, haloperidol, flumazenil, dopamine at a temperature of 37 °C during 2 min. Measuring of drugs in the process of incubation was- for diazepam - 10 mcg/mL, propranolol- 10 and 15 mcg/mL, haloperidol- 10 mcg/mL, flumazenil- 10 flumazenil.

Statistical processing of results of research was conducted by using nonparametric method W-Wilcoxon, Mann Whitney.

Results: It was established that incubation of healthy men's plasm, which is rich of platelets with agonist of benzodiazepine receptors (diazepam 10 mcg/mL) refused the aggregation effect, in spite of adding inducers of aggregation (adrenalin [$P < 0.01$], collagen [$P < 0.01$], ADP [$P < 0.01$]). Adding flumazenil didn't influence on ADP, collagen, adrenalin-induced aggregation of blood platelets ($P > 0.05$) and didn't refuse diazepam effect ($P < 0.01$). Adding to the healthy man's plasm, rich of thrombocytes the blocking agent D2- of dopamine receptors of haloperidol also restrained the aggregation in the setting of inducers of different nature: adrenalin ($P < 0.01$), ADP ($P < 0.01$), collagen ($P < 0.01$).

The blocking agent of ß- adrenoreceptors propranolol also reduced aggregation after incubation with thrombocytes on traditional inducers – adrenalin ($P < 0.01$), ADP ($P < 0.01$) and collagen ($P < 0.01$). It should be mentioned, that propranolol had a dose-dependent effect: with increasing drug dose, the amplitude of curve of aggregation was decreasing.

Conclusion: Inhibiting influence of diazepam is caused by covalent bonding of drug with glycoprotein receptors GP IIb/IIIa, which have a common RGD- consequence for bonding with fibrinogen. Another probable mechanism is connected with metabolism of arachidonic acid. In this case diazepam changes the conformation of thrombocyte membrane, which influence the activity of phospholipase C, phosphoinositid's level, formation of thromboxane A2, brake action of mobilization Ca2+ and phosphorylation of protein P-47. The propranolol's effect can be explained only by it's prevention of dissociation of a to βg- subunit of G-protein, which leads not only to brakeage of response of β adrenoreceptors, but also others, including α- adrenoreceptors. Just only dissociation of subunits of G-protein can be the necessary condition of receptors' activation. As approval of this statement can be the fact of inhibiting of aggregation ability in case of adding not

only adrenalin, but adding ADP and collagen, biological effects of which are connected with other receptors and occur in case of dissociation of a to βg- subunit of G-protein. If this statement is true, we amplified signalling mechanisms in blood platelet in case of agonists adrenoreceptors actions. Similar mechanism is probable for blocking agent D2- of dopamine receptors- haloperidol.

PO 335

Antidepressant suppresses collagen-induced platelet activation

Sugita N, Hirakata H, Kawamoto S and Murai T
Graduate School of Medicine, Kyoto University, Kyoto, Japan

Background and Aims: Selective serotonin reuptake inhibitors (SSRIs) are a class of most frequently prescribed antidepressants in the treatment of a variety of neuropsychiatric disorders as well as depression. Recent epidemiological studies have shown that SSRIs may increase the risk of abnormal gastrointestinal bleeding and may prevent ischemic heart disease events. Additionaly, some *ex-vivo* studies have shown that platelet functions of patients medicated with SSRIs may be impaired. To understanding these findings, it is suggested that SSRIs inhibit serotonin uptake into platelet, as well as into presynaptic neuron, to reduce platelet serotonin content in patients chronically medicated with SSRI. However, probably it is not the sole mechanism of platelet dysfunction. The aim of our study is to elucidate the mechanisms of SSRIs' effects on human platelets.

Materials and Methods: We purchased pharmaceutical ingredients of S-citalopram, paroxetine, fluvoxamine, sertraline, which are marketed SSRIs for clinical use, and those of R-citalopram (the optical isomer of S-citalopram) and metabolites of both citalopram isomers. Each material was resolved in platelet rich plasma (PRP) taken from healthy volunteers and incubated for 90 min at 37 degree Celcius.

(1) Platelet aggregation induced by ADP, collagen, arachidonic acid, epinephrine or STA_2, was measured with a light transmission aggregometer.

(2) Collagen-induced cytosolic calcium increase with/without S-citalopram, R-citalopram or the metabolites, was measured with fluorescent indicator fura-2 and a cytosolic ion analyzing device.

(3) Expression of CD62Pand phosphorylation of spleen tyrosine kinase (Syk) induced by collagen with/without S-citalopram were measured with a flow cytometer.

Results:

(1) All SSRIs and the related materials suppressed platelet aggregation induced by collagen significantly, but did not suppress platelet aggregation by the other agonists.
(2) The both citalopram isomers and the metabolites suppressed collagen-induced cytosolic calcium increase.
(3) S-citalopram suppressed collagen-induced CD62P expression and Syk phosphorylation.

Summary: Our data show that, after only 90-min incubation, SSRIs suppress collagen-induced platelet aggregation specifically, and that the non-SSRI related materials, which do not inhibit serotonin uptake, also suppress similarly. These facts indicate that there are other mechanisms of SSRIs' impairing effects on platelet functions than decrease of platelet serotonin content, above mentioned.

Glycoprotein VI (GPVI) is a major collagen receptor on platelet and forms a complex with an Fc receptor, which has intracellular docking sites for Syk. Following activation of GPVI and Syk phosphorylation, calcium is released from dense tubular system. Our data show that S-citalopram, a typical SSRI, inhibits both of Syk phosphorylation and cytosolic calcium increase induced by collagen. These facts indicate that SSRIs may suppress collagen-induced platelet activation by inhibiting some steps before Syk activation in GPVI pathway.

Conclusion: SSRIs may affect in early steps of GPVI signaling pathway.

PO 336

Platelet aggregation pattern amongst multiracial healthy blood donors performed in National Blood Centre (NBC), Malaysia

Tohit ER[1], Muhsin A[1], Noor S[1], Hassan R[2] and Karim F[2]
[1]UPM, Serdang, Selangor; [2]National Blood Centre, Kuala Lumpur, Malaysia

Background: Platelet aggregation test using light transmission aggregometry is considered as gold standard for assessment of platelet function. Laboratory performing the test is highly encouraged to establish its own reference range, as different population/ethnic background may have different aggregation pattern. Malaysia is a multiracial country comprises of three major ethic groups i.e Malay, Chinese and Indian. National Blood Centre (NBC) is the referral centre for the nation to conduct platelet function study using platelet aggregation test for inherited platelet disorders.

Aims: This study aims to determine the platelet aggregation pattern and subsequently estimate the reference range for platelet aggregation test performed in three major ethnic in Malaysia i.e Malays, Chineses and Indians at Hemostasis Laboratory, National Blood Centre, Kuala Lumpur.

Methods: This study was conducted from September 2012 to January 2013. There were 60 informed consented healthy blood donors of different ethnic group participated in the study. Blood were drawn into 3.2% sodium citrate tube. Subsequently, platelet rich plasma (PRP) was obtained and platelet aggregation test were done using PAP-8E, BioData. Five panel agonists were used i.e. ADP (10 μM), ristocetin (1.5 mg/ml), arachidonic acid (1.0 mM), epinephrine (10 μM) and collagen (5 μg/ml and 0.19 mg/ml) as per mentioned in the guideline. Reference ranges were taken as mean ± 2SD of final aggregation in percentage.

Results: Analysis showed that mean ± 2SD for ADP (10 μM) is 82–92%, ristocetin (1.5 mg/ml) is 98–103%, arachidonic acid (1.0 mM) is 90–97% and collagen (0.19 mg/ml) is 88–95%. About 48% of respondent had 0% aggregation in response to collagen (5 μg/ml) (Median = 3%). We also noticed that 30% of respondent had < 20% aggregation in response to epinephrine (10 μM) which might due to variability in the sensitivity of its receptor among normal person (Median = 86%). Therefore, the reference range for collagen (5 μg/ml) and epinephrine (10 μM) could not be estimated.

There were no differences observed in pattern/percentages of platelet aggregation amongst the three major ethnic groups or amongst different gender for all agonists. However, the percentages of platelet aggregation to all agonists were significantly higher as compared to Caucasian population. These findings could indicate variability in platelet receptors sensitivity amongst different population.

Conclusion: Results obtained from this study could provide an insight for the dedicated laboratory at National Blood Centre when performing platelet aggregation test among the three main races. This estimated reference range can substitute the reference range provided by manufacturer which is based on Caucasian population. Future study may look into variability in sensitivity of receptors seen amongst Malaysians population in particular for epinephrine and collagen agonist.

PO 337

Prasugrel shows less intraday variability in its antiplatelet effect compared to ticagrelor in cynomolgus monkeys

Tomizawa A[1], Ohno K[1], Jakubowski JA[2], Mizuno M[1] and Sugidachi A[1]
[1]Daiichi Sankyo, Tokyo, Japan; [2]Eli Lilly and Company, Indianapolis, USA

Background: Prasugrel is the 3rd generation thienopyridine prodrug while ticagrelor is a direct acting non-competitive $P2Y_{12}$ antagonist. In

phase three studies, both agents reduced the ischemic event rates compared to clopidogrel. A new ELISA-based vasodilator-stimulated phosphoprotein (VASP) phosphorylation assay in whole blood provides a more specific test of $P2Y_{12}$ inhibition than other platelet function tests.

Aims: The objectives of this study included a comparison of the antiplatelet effects of single and 7-day multiple dosing of prasugrel and ticagrelor in cynomolgus monkeys using the human VASP phosphorylation assay and light transmittance aggregometry (LTA).

Methods: Platelet VASP phosphorylation was determined in whole blood by ELISA and expressed as the platelet reactivity index (PRI). ADP-induced platelet aggregation in platelet-rich plasma was determined by LTA. The relationship between PRI and platelet aggregation was evaluated.

Results: Single oral dosing of prasugrel (0.3 and 1 mg/kg, $N = 6$) resulted in potent and significant antiplatelet effects, which were sustained up to 24 h. Each mean PRI was 84, 21 and 16% at 0, 4 and 24 h, and each mean platelet aggregation induced by 20 μM ADP was 57, 24 and 27%, respectively, in 0.3 mg/kg prasugrel group. Ticagrelor (3 and 10 mg/kg, $N = 6$) also showed significant effects with maximum decreases similar to prasugrel, but its effects were diminished at 24 h. Each mean PRI was 82, 13 and 69% at 0, 4 and 24 h, and each mean platelet aggregation induced by 20 μM ADP was 58, 20 and 54%, respectively, in 3 mg/kg ticagrelor group. In this single-dose study, strong correlations between the PRI and platelet aggregation induced by ADP (5 and 20 μM) were observed (correlation coefficient of 0.93 and 0.96, respectively). Multiple dosing of prasugrel (1.8 mg/kg loading dose, 0.3 mg/kg once daily maintenance dose, $N = 10$) showed more rapid antiplatelet effects, that were sustained over 24 h. Each mean PRI was 93, −2, 0, 1, 1 and 3% at 0, 1, 4, 12, 16 and 24 h on Day 1, respectively. Similar low PRI values were observed on Day 7 with mean PRI of 7, 1 and 6% at 0, 4 and 12 h, respectively. Twice a day multiple dosing of ticagrelor (10 mg/kg maintenance dose following a single 20 mg/kg loading dose, $N = 10$) also showed significant antiplatelet effects during the day, but intraday changes in antiplatelet effects were observed. Each mean PRI was 93, 29, 4, 22, 9 and 12% at 0, 1, 4, 12 (12 h = predose), 16 and 24 h on Day 1, respectively. Similar intraday changes in the PRI were observed on Day 7 with mean PRI of 7, 5 and 24% at 0, 4 and 12 h, respectively. The multiple-dose study also showed strong correlation between the PRI and platelet aggregation.

Summary/Conclusion: Prasugrel showed potent antiplatelet effects with longer duration of action throughout the entire day. Ticagrelor also showed potent antiplatelet effects but more intraday variability in platelet inhibition compared to prasugrel was observed. The present study also showed the human ELISA VASP assay can be utilized for monkey studies.

PO 338

Methods for detection ASA resistance *in vitro*

Ulehlova J, Slavik L, Krcova V, Vaclavik J and Kucerova J

University Hospital, Olomouc, Czech Republic

Background and Aim: Acute myocardial infarction (AMI) is frequently also associated with platelet gene polymorphism as platelet enzyme cyclooxygenase 1 (COX-1). Dual antiplatelet therapy is part of the secondary prophylaxis in the treatment includes regularly acetylsalicylic acid (ASA). Polymorphism of COX-1 gene is not the only cause of ASA resistance. By use of the impedance aggregometry after *in vitro* administration of ASA i tis possible to distinguish exogenous (noncompliance or patient problems of absorption of the active substance) from endogenous causes in failure of antiplatelet therapy.

Material and Methods: We examined a group of 90 patients with AMI who were receiving antiplatelet therapy such as aspirin by impedance aggregometry on Multiplate analyzer (MEA). We used as agonist arachidonic acid (1 mM). Patients without adequate response to treatment were subjected to *in vitro* incubation with ASA. The dose was equivalent to a daily dose of 100–500 mg/day. Patients who were not respond on antiplatelet therapy were also selected for *in vitro* measurements. Samples of blood were incubated with an appropriate amount of ASA (18.2 mg/ml, diluted 1:2, 1:4, 1:8 and 1:16 NaCl) for 5 min. Subsequently, the detected change in the aggregation ability after the addition of arachidonic acid by MEA. The DNA samples were examined receptor polymorphism COX-1 (position 842 A/G; rs10306114).

Results: Patients, in the effective treatment, are with ASA inhibition of aggregation under 220 AUC*min. The resulting data demonstrate that the number of patiens (2/3–66%) *in vitro* testing is responding to treatment. Absolute data will be presented in this communication.

Conclusion: With this method, we were able to eliminate the deficiency of platelet receptor, and thereby reveal irregular drug intake or malabsorption. The majority of patients were detected insufficient response to the presence of ASA. We can conclude, that in the above-mentioned causes of failure of antiplatelet therapy it is necessary to change treatment. An ineffective preventive use of ASA may be also caused by aspirin resistance. On the other hand, the cause of aspirin resistance may be due to a number of factors such as low absorption, inadequate dosage of ASA, genetic factors or interactions with other medications in the given cases.

Supported by the Grant LF-2013-004.

PO 339

The influence of different types of TRAP peptides on platelet aggregation, using different light transmission aggregometry devices

Verhezen P, Körver-Keularts IMLW, Van Oerle R, Van Thoor L and Henskens Y

Maastricht University Medical Center, Maastricht, The Netherlands

Background: Light transmission aggregometry (LTA) is the recommended method to assess platelet function. Recommendations for standardizing LTA are advised by the platelet physiology subcommittee of the SSC of the ISTH. One of the recommendations is the use of Thrombin Receptor Activation Peptide (TRAP) as an agonist. Although the concentration (10 μM) is standardized, there is no recommendation for the type of TRAP to use.

Aims: Comparison of platelet aggregation in healthy volunteers with two types of TRAP agonist on three different LTA devices. TRAP aggregations were measured both in adjusted (A) and non adjusted (NA) platelet rich plasma (PRP).

Material and Methods: Citrated blood (3.2%) was collected from 30 healthy volunteers, 18 females (21–58 years) and 12 males (20–54 years) with comparable mean platelet counts $263 \pm 59 \times 10^9$/L and $250 \pm 40 \times 10^9$/L. In part one of this study, 13 healthy donors (7 females and 6 males) were tested using the inhouse method with TRAP14 (10 μM) (Bachem) and the CH490-D (Chronolog). Also tested was TRAP6 (10 μM) (Hart Biologicals) using PAR8 (Hart Biological) and PAP8e (Biodata).

In the second part, 17 healthy donors (11 females and 6 males) were analysed with only one TRAP reagent (TRAP14, 10 μM, Bachem) on all three LTA devices. TRAP aggregation was tested in both adjusted (250×10^9/L) and non-adjusted PRP. The healthy donors didn't use any medication that is known to inhibit platelet function for at least 10 days before blood collection. A normal response is defined as a single monophasic wave with a minimal maximal aggregation of 70%.

Results- The first study ($n = 13$) showed a normal response to TRAP14 in NA and A PRP with the CH490-D in all subjects. In NA PRP, 85% (11) showed a normal response to TRAP6 with the PAR8 and only 60% (7) with the PAP8e. In A PRP, only 55% (7) showed a normal response to TRAP6 with the PAR8 and only 30% (4) with the PAP8E.

In the second study ($n = 17$) TRAP14 was compared on all three devices. In NA PRP, 100% (17) showed a normal response to

TRAP14 using CH490-D and PAR8. Only 65% (11) showed a normal response to TRAP14 using the PAP8e (NA PRP). In A PRP, 94% (16) showed a normal response to TRAP14 on the CH490-D, 70% (11) with the PAR8 and only 40% (7) with the PAP8e.
Conclusions: Although the recommended concentration of 10 μM was used for both types of TRAP, TRAP6 shows more abnormal responses in healthy volunteers as compared with TRAP14 on the PAR8 and PAP8e device. Therefore recommendations should be made on the type of TRAP that is used for platelet function testing. Although there are more healthy volunteers with a normal response on TRAP14 compared to TRAP6 with the PAP8E, there is still a markedly abnormal response when compared with CH490-D and PAR8. Laboratories should therefore standardize and validate there method for TRAP aggregation. Because of the high number of abnormal responses found when using A PRP, it is recommended to perform TRAP aggregation in NA PRP.

PO 340

Platelet aggregation in patients with chronic cerebral ischemia, carried the AGT-174T/M, AGT-235M/T, AGTR1-1166F/C, ACEI/D polymorphisms

Vitkovsky Y, Strambovskaya N and Knyazeva A
Chita State Medical Academy, Chita, Russia

Background: Cognitive dysfunction syndrome is a companion set of brain disorders. The major share of cognitive deficits based on the neurodegeneration of Alzheimer's type, and cerebrovascular disorders.
Aim was to study the platelet aggregation and genetic polymorphism of some proteins of the renin-angiotensin-aldosterone system (AGT-174T/M, AGT-235M/T, AGTR1-1166A/C, ACEI/D) in patients with chronic cerebral ischemia, complicated by cognitive dysfunction.
Methods: Clinical group consisted of 207 (135 women and 72 men) patients aged 66 ± 10 years, with cognitive deficits with chronic cerebral ischemia without signs of decompensation. The criteria for inclusion, as well as the objective of establishing the degree of cognitive decline rating scales were used: MMSE, tracking test, clock drawing test, Khachinsky's scale, Hamilton's test. The vascular nature of the lesion was confirmed by neyrovizulizatsion and scale ischemia NINDS-AIREN. The PCR method in real time to identify of genetic polymorphism was applied. ADP-, collagen- and adrenalin-induced platelet aggregation was measured.
Methods: Among all patients, cognitive deficits bore signs of mild dementia (MMSE (M ± δ) – 20.2 ± 2.7 points), without of depression (Hamilton (M ± δ) – 7.99 ± 2.4 points) against chronic cerebral ischemia (Khachin (M ± δ) – 6.27 ± 0.9 points, neuroimaging data). The study found all the desired mutations in the homo-or heterozygous. To assess the effect of the mutant allele carriers on platelet aggregation, all patients were divided into 5 groups: 1) homo-and heterozygous (AGT-174M | | AGTR1-1166C | | ACE-Del, $n = 12$); 2) homo-and heterozygous (AGT-174M | | ACE-Del, $n = 15$); 3) homo-and heterozygous (AGTR1-1166C | | ACE-Del, $n = 68$); 4) ACE-Del, $n = 68$); 5) patients carried of the 'wild' alleles studied polymorphisms in the homozygous state ($n = 32$). It was established that in all patients the slight platelets hyperaggregation on low doses of ADP. Spontaneous platelet aggregation ranged from 1.22 ± 0.39 to 1.56 ± 0.35 optical units and did not differ between groups of observation. When comparing the average size of the aggregates formed in making inductors (ADP, adrenalin), marked the lowest platelet aggregation in patients – carriers of the three 'unfavorable' alleles. Severe induced hyperaggregation observed in patients carriers of wild-type alleles for all studied polymorphisms (*U*-test, $P < 0.05$) with a maximum radius of aggregates on ADP- induction. When comparing the average size of the aggregates formed in making inductors marked the lowest platelet aggregation in patients – carriers of the three 'unfavorable' alleles.
Summary. In patients with chronic cerebral ischemia, the wild-type allele carriers studied genetic polymorphisms of angiotensin-aldosterone system registered a high platelet aggregation with the same radius of aggregates (resistance) with a decrease in the ADP concentration. The patients – carriers of the mutant allele aggregation properties of blood platelets relatively pronounced.

PO 341

Reduced platelet reactivity in critical limb ischemia patients

Wisman PP, Teraa M, De Borst GJ, Moll FL, Verhaar MC and Roest M
UMC Utrecht, Utrecht, The Netherlands

Objective: Despite aspirin therapy a substantial amount of patients will experience cardiovascular events (CVE). In the current study, we tested baseline platelet activation and platelet reactivity in critical limb ischemia (CLI) patients, a patient population with a particular high cardiovascular risk, hypothesizing that platelets from CLI patients display increased baseline activation and are hyperreactive. Furthermore, we investigated the effect of aspirin therapy and the presence of high-on-aspirin platelet reactivity (HAPR) in patients with CLI with a novel platelet reactivity assay.
Methods: Baseline platelet activation and platelet reactivity in response to five major platelet agonists were determined, in 23 CLI patients (11 on aspirin, 9 on oral anticoagulant and 3 on aspirin + clopidogrel) included in the Juventas-trial (clinicaltrials.gov: NCT00371371) and in 17 healthy controls. Platelet activation was quantified with flow cytometric measurement of platelet P-selectin expression and fibrinogen binding. Aspirin effectiveness was measured by the additional stimulatory effect of arachidonic acid (AA) stimulation to convulxin (CVX) stimulation (AA-effect).
Results: CLI patients not on aspirin compared to healthy controls, showed higher baseline platelet activation: P-selectin expression was 59.4 ± 4.8 vs. 40.3 ± 8.6 ($P < 0.001$). Platelet responsiveness to the tested agonists was not different between cases and controls, except for responsiveness of fibrinogen binding to CVX with or without AA, which was lower in cases than in controls ($P = 0.009$ and $P = 0.037$, respectively). Presence of cardiovascular risk factors was inversely correlated with *in-vitro* reactivity of circulating platelets of CLI patients. Use of aspirin did not substantially modulate platelet responsiveness in CLI patients, except from the effect of AA, while a profound effect of clopidogrel was observed. Furthermore, the AA-effect seemed to properly identify the effect of aspirin and HAPR in CLI patients.
Conclusions: Baseline platelet activation in CLI patients is increased compared to healthy controls, while the *in-vitro* response to stimulatory agents was either not different or decreased.. Additionally, several cardiovascular risk factors were inversely correlated with *in-vitro* reactivity of circulating platelets. HAPR was observed in a substantial proportion of the CLI patients.

PO 342

The use of a rapid, whole blood platelet factor 4 clotting assay for the early detection of hypercoagulability and guide to heparin therapy in equines

Yin ET[1], Sousa C[2], McCarroll DG[3], McCarroll J[3], Morgan D[4] and Rozin T[5]
[1]Heptest Laboratories, St. Louis; [2]Equine Medical Associates, Aubrey; [3]Interstate Equine Services, Goldsby; [4]Hemaxa, LTD., Valley View; [5]Heptest, Inc., St. Louis, USA

Background: Hemostasis research using animal models has significantly influenced clinical, diagnostic and pharmaceutical advance-

ments in human coagulation, thrombosis and drug therapy. Platelet Factor 4 (PF4), a protein primarily secreted from within the platelet, is a strong contributor to the coagulation status of the patient and is a specific heparin antagonist. It is released from the alpha granules of platelets when the latter are activated by trace thrombin insufficient to clot plasma fibrinogen. As a result, PF4 provides a means for determining the degree of a hypercoagulable state, defined here as a state in which activated products and intermediates normally absent from circulating blood are detected intra-vascularly or are released from tissues.

Aims: This study describes the utility of PF4 testing in the treatment of equine patients admitted to veterinary clinics with clinical diagnosis of acute laminitis, an equine disease that is caused by inflammation of the sensitive soft-tissue, or laminae, of the foot, and is a major cause of lameness and death if not medically treated immediately. Methods.

Patients were diagnosed with acute laminitis as evidenced by abnormal sensitivity, pain, heat and significantly decreased circulatory status in the hoof capsule by radiograph and venogram. Subjects were tested using a rapid PF4 assay using citrated whole blood with a < 3-min turn-around time to determine hypercoagulability. A 500 μL of blood was added to the PF4 reagent vial, containing co-lyophilized calcium chloride and unfractionated heparin, and clotting was measured in a semi-automatic coagulometer. Based on the results of the PF4 assay, where it is known the clotting time is inversely related to the PF4 level, heparin therapy was modified in subjects where a hypercoagulable state was determined.

Results: Over 30 horses suffering with laminitis secondary to colic, endotoxemia, sepsis, EHV-1 and colitis were successfully treated with simultaneous conventional therapy and heparin. These animals, destined for euthanasia, were subsequently spared and recovered fully. Conclusions.

The use of heparin as an adjunct to traditional therapies results in better therapeutic outcomes than traditional therapies alone. Heparin dosing will depend on the PF4 level and clinical condition of the patient. The availability of an easy, whole blood functional PF4 assay is a significant step toward the rapid detection of a patient's hypercoagulable state. Current commercial PF4 assays are either radioimmuno or ELISA methods that are labor intensive and require 45 min to h to perform. It is the intent that studies using a rapid PF4 assay will transition to human applications, providing timely and clinically useful information that has never before been possible.

PO 343

Evaluatyion study of a new, direct whole blood platelet function assay and its application

Zhao Y, Zhang Y, Yao S, Ji S and Ruan C

The First Affiliated Hospital of Soochow University, Suzhou, China

Background: Platelet function assay is not only helpful in the diagnosis of certain congenital and acquired platelet defects which leads to bleeding disorders, but also plays a key role in the study of thrombotic disease pathological machanism, clinical diagnosis, antithrombotic therapy, monitoring the responseness of anti-platelet drug, etc..

Aims: The purpose of this study is to develop a method using a continuous automatic platelet counting assay based on the Coulter principle to test platelet aggregation function by PL-11 platelet function analyzer (Nanjing Sinnowa Medical Science & Technology Company, Nanjing, China) and also to evaluate its performance in clinical application.

Methods: Whole blood sample anticoagulanted with sodium citrate were taken from 247 healthy volunteers (125 men, 122 women, between the ages of 18–82 years), from June to December 2012 at the First Affiliated Hospital of Soochow University, China. The study conformed to the ethical guidelines of 2004 Declaration of Helsinki and was approved by the institutional Ethics Committee at the First Affiliated Hospital of Soochow University, China. The informed consent was obtained from all healthy donors. Platelet aggregation in 0.5 ml of whole blood was induced with ADP or collagen by PL-11 using a continuous automatic platelet counting assay based on the Coulter principle. The intra-assay and inter-assay coefficient of variation (CV), carry-over rate, accuracy, linearity of PL-11 were also evaluated, respectively. The correlation of platelet aggregation was detected between the PL-11 and MPG-3E photoelectric turbidimetry.

Results: All the parameters were conformed to the standard of Clinical Laboratory Improvement Amendment 88. Both of the intra-assay and inter-assay CV values were less than 5%; carry-over rate was less than 1%; the accuracy and the linearity was excellent ($r > 0.99$). The correlation between the PL-11 and MPG-3E was $R^2 = 0.9439$. The maxium of platelet aggregation induced by ADP or collagen using PL-11 was 17.7–54.3%, or 19.8–61.1%, respectively.

Conclusion: Analytical results of the PL-11 platelet analyzer are accurate and reliable. It has a potential in clinical application.

PO 344

Evaluation of 195 referral cases with suspected hereditary platelet function disorders using platelet aggregometry and ATP release

Ahmadinejad M, Rajabi A, Mashkooli M, Tabatabaei MR, Seyed Mortaz SL, Balooch S and Mokhtari M

Iranian Blood Transfusion Organization Research Center, Tehran, Iran

Background: Although hereditary platelet function disorders (PFDs) are common in the general population but in our country except for severe cases, they are not well recognized due to limited diagnostic tools for these problems.

As a reference coagulation laboratory in Iran, after being equipped with lumi-aggregometer during recent 2 years, we have started to check our referral patients suspected to PFDs for light transmission platelet aggregometry (LTA) using different dilutions of agonists (instead of one dilution which was used in the past) and check ATP release in highly suspicious cases for platelet secretion abnormalities.

Aims: To evaluate our cases suspected to PFDs with new panel of platelet function assays especially for finding the prevalence of platelet secretion abnormalities which has never been diagnosed or classified in our hemophilia centers.

Methods: During a 7-month period from November 2011 until May 2012, we have investigated 195 patients with bleeding problems who referred for platelet aggregation test to our special coagulation laboratory of Iranian Blood Transfusion Organization. Twelve normal healthy controls were also evaluated for determination of reference ranges of dilutions of agonists for LTA. Platelet secretion and LTA were measured in platelet rich plasma using Crono-log Lumi-aggregometer (model 700X). We have applied four platelet commercial agonists including ADP (5.10 and 20 μM), arachidonic acid (0.5 mM), collagen (2 and 5 μg/ml) and ristocetin (1.5 mg/ml) for the aggregation test. Due to high expenses of Luciferin-Luciferase reagent, ATP release was investigated only in patients with suspicious secretion abnormality in LTA. Results were analysed by SPSS version 16, Polar Engineering.

Results: Among 195 referred patients (66 male and 129 female), 91 patients were abnormal (quantitative and/or qualitative platelet defects) and 104 cases were quiet normal in platelet count and function. Abnormal cases laid on the category of Bernard Solier Syndrome (BSS) (4 cases) (2% of 195 cases), Glanzman thrombastenia (GT) (9 cases, 4.6%), platelet secretion abnormality (13 cases, 6.7%), low platelet count with normal function (14 cases, 7.7%), unclassified PFDs (46 cases, 23.6%), drug-affecting abnormalities (3 cases) and PFD due to afibrinogenemia (one case). Six cases of GT (5 new and 1 known case) and 3 cases of BSS (2 new and 2 known cases) were confirmed by flowcytometric analysis. Bleeding score (Tosetto et.al) was ≤ 2 in 62% of 195 cases, 3–5 in 28.4% and ≥ 6 in 9.6%. Interestingly

two cases that previously diagnosed as GT and BSS several years ago, laid on the platelet secretion defects category.

Conclusion: It seems that the two rare and severe platelet function abnormalities (GT and BSS) have a relatively higher incidence in Iranian patients. About 8% of patients were classified as platelet secretion abnormality. We guess if we did platelet secretion test in all patients with abnormal platelet aggregation pattern, it's prevalence was higher than 8%. Since this study is the first evaluation of ATP release in Iran, reevaluation of registered patients with PFDs and comprehensive studies should be done to find patients with platelet secretion disorders.

PO 345

The efficacy of anti-Rh D, and vincristine sulphate in immune thrombocytopenic purpura

Akarsu S[1] and Kurnaz E[2]

[1]*University of Firat, Faculty of Medicine, Elazig;* [2]*Sirnak State Hospital, Pediatrics, Sirnak, Turkey*

Background: Immune thrombocytopenic purpura (ITP) is a benign disease prevalent in infancy, and pediatric age. The critically important complication is related mortality secondary to intracranial bleeding. The therapeutic objective is to decrease its treatment-related side effects, while maintaining platelet counts at a safe level.

Aims: In this study we wanted to investigate the effects of anti-Rh D immunoglobulin in acute, and vincristine sulphate therapy in chronic ITP. We intended to determine the time to the onset of treatment effect.

Methods: Anti-Rh D immunoglobulin (Win Rho SDF®, 300 mcg, 1500 IU, Cangene Corporation, Winnipeg, MB, Canada) was administered to the patients with diagnoses of acute (n = 26), and chronic (n = 14) ITP, while 6 cases diagnosed as acute ITP received vincristine sulphate therapy. Anti-Rh D immunoglobulin was administered at a dose of 50 μg/kg given as a 5-min IV infusion. Chronic cases with ITP who were not responsive to any treatment modality as corticosteroids, intravenous immunoglobulin (IVIG) and Anti-Rh D immunoglobulin received a vinca alkaloid, i.e. vincristine sulphate at weekly IV doses of 0.02 mg/kg (max. 2 mg/dose) for 4 weeks. WBC measurements were performed at the end of 24, and 48 h, and on 5., 7., and 14. days, and at 1. months of the treatment to determine platelet counts. Side effects of the drug therapy were closely monitored. Informed consent forms were obtained from patients and/or their parents. Statistical analyses were performed using 11.5 Statistical Package Program (SPSS v. 11.5). For intergroup comparisons Student-t test, and for comparisons between genders *chi*-square *test* were used. $P < 0.05$ was considered as statistically significant.

Methods: Anti-Rh D administration increased platelet counts within the first 24 h of therapy in cases with acute ITP, and in those with chronic ITP paltelet counts increased only after 48 h of therapy. Even though Anti-Rh D immunoglobulin is not recommended in cases with emergency, in our cases diagnosed as acute ITP, it was found to be effective within the first 24 h of therapy. In our cases we didn't observe any potential adverse effects of Anti-Rh D immunoglobulin (which exerts its effects via blockade of Fc receptors of the reticuloendothelial cells) when given to Rh-positive patients.

Our cases with a diagnosis of chronic ITP responded to vincristine sulphate at a lower extent within the first week of therapy when compared with anti-Rh D immunoglobulin treatment. However especially at 2. weeks, a marked increase in platelet counts was observed. None of our cases experienced any treatment-related adverse effect.

Summary/Conclusions: Anti-Rh D immunoglobulin raised platelet counts to higher levels in acute ITP, rather than chronic ITP. Anti-Rh D immunoglobulin is an efficient, cost-effective, and safe drug to be used in the treatment of acute ITP.

In chronic ITP, vincristine sulphate induced an increase in platelet counts in the long term i.e. 2 weeks. Vincristine sulphate should be used as a last resort in cases of need for its long term effect, and only with a short-acting drug like anti-Rh D immunoglobulin.

PO 346

Thrombotic complications in patients with adult chronic immune thromobocytopenic purpura

Colovic NR[1], Djunic I[2], Suvajdzic N[1], Vidovic A[1], Miljic P[1], Tomin D[1] and Colovic M[1]

[1]*Medical Faculty University of Belgrade;* [2]*Clinic of Hematology, Clinical Center Serbia, Belgrade, Serbia*

Background: Immune thrombocytopenic purpura (ITP) is autoimmune disease characterized by platelet destruction and decreased platelet production. Occasionally in ITP a life-threatening hypercoagulable state may develop. There are reports of thrombotic events after splenectomy or management of ITP with intravenous immunoglobulin (IVIg). There are also rare reports of intracranial thromboses and ischaemic heart strokes. We present 5 adult chronic ITP patients with different thrombotic events during the long course of ITP hystory.

Material and Methods: We present five patients (4 female and 1 male), with median age 56 (range 43–60), suffering from ITP for median 10 years (range 3–32), four of them were splenectomized, but in all of them with transient response to splenectomy. In further disease course in four patients different treatment modalities were used at the tine of low number of platelets and in one patient the prednisone was the only therapeutic modality. In a-53-year-old woman after splenectomy the number of platelets normalized but on 21st day after splenectomy a portal vein thrombosis developed. She was on LMW heparin and recovered completely. In the second patient after viral infection when platelet count dropped to 1×10^9/L IVIg 0.400 mg/kg/day for 5 consecutive days was given. She responded to the therapy with normalization of platelet count but after 5 days she developed acute anterolateral myocardial infarction with creatin kinase of 2260, troponin 27,8. She was treated with IV heparin and she completely recovered. The other three patients (aged 56, 60 and 56 years) developed cerebral vascular insult (CVI) confirmed by CT in two and MRI in one patient. Two patients were without treatment and one patient was with corticosteroids treatement. At the time of CVI the number of platelets was 21×10^9/L, 18×10^9/L, and 22×10^9/L respectively. All three patients recovered, one, without sequel and two patients with neurologic sequel.

Conclusion: In the first patient with thrombotic event after splenectomy we advise cautiousness after splenectomy for possible post-splenectomy thrombotic complications in the subset of ITP patients who may have persisting platelet activation. In second patient IVIg have promoted thrombosis by increasing bloodviscosity, activating platelets, or causing vasospasm. In patients with CVI anti-platelet antibodies, which are present in most cases of chronic ITP complement mediated fragmentation of platelets and the release of platelet microparticles was a factor contributing to microthromboses.

Kex words: hypercoagulability, immune thrombocytopenic purpura, ischaemic stroke.

PO 347

Successful use of Recombinant Factor VIIa for menorrhagia control in a patient with Glanzmann's thrombasthenia

Jun S[1], You CW[2], Shin HJ[1] and Han JW[3]

[1]*Pusan National University Hospital;* [2]*Eulji university Hospit, Daejeon;* [3]*Yonsei University College of Medicine, Seoul, South-Korea*

Glanzmann's thrombasthenia is a congenital bleeding disorder caused by defective platelet glycoprotein IIb/IIIa, which is essential for the binding process between platelets and fibrinogen. The standard treatment for bleeding is platelet transfusion but repeated transfusion may result in the development of anti-platelet antibodies rendering future platelet transfusion ineffective.

Menorrhagia is common problem in patients with Glanzmann's thrombasthenia, particularly during first menstruations and may sometimes require blood transfusion.
A 14-year-old girl with Glanzmann's thrombasthenia suffered from menorrhagia monthly. Her menstrual cycle was 28 days and menstrual duration was over 15 days. To control menorrhagia patient need repeated platelet transfusion. Over time platelet transfusions had often had a suboptimal result and were complicated by allergic reactions. Alternative effective agents were needed. Hormonal therapy (oral contraceptives), hemostatic drugs were not helpful and patient needed iron supplement for iron deficiency anemia due to massive monthly blood loss. She could not go to school during menstrual period, her activity was disrupted and normal life stood paralyzed.
We report on a patient with Glanzmann's thrombasthenia with menorrhagia, despite documented suboptimal effectiveness of platelet transfusions and complicated allergic reactions, menorrhagia controlled successfully with monthly use of recombinant factor VIIa.

PO 348

Evaluation of laboratory desmopressin testing and clinical effects in patients with hereditary and acquired thrombocytopathies: results of a retrospective multicenter study

Knoefler R[1], Gneuβ A[2], Franke D[3], Kentouche K[2], Koscielny J[4], Krammer-Steiner B[5], Petros S[2], Platzbecker U[2], Seeger K[4] and Klamroth R[6]

[1]University Hospital Dresden; [2]University Hospital, Dresden; [3]Practice of Internal Medicine and Angiology, Magdeburg; [4]Charité Medical University, Berlin; [5]South-City Hospital, Rostock; [6]Vivantes Hospital Friedrichshain, Berlin, Germany

Background: The necessity of desmopressin testing (DT) in patients with thrombocytopathies (TP) prior to the first therapeutic use is a matter of controversy and the test itself is not standardized. Aim of study was to develop recommendations on a standardized test in patients with TP.
Patients and Methods: Data were collected from patients tested between January 2000 and September 2010 in 13 centres of the 'Competence Network Hemorrhagic Diatheses East' : age, gender, diagnosis, bleeding history, medication, results of coagulation testing, way of desmopressin administration, dose, side effects, time points of blood sampling, coagulation parameters (von Willebrand factor antigen – VWF:Ag, collagen binding activity – VWF:CB, ristocetin cofactor activity – VWF:RCo, factor VIII activity – FVIII:C, activated partial thromboplastin time – aPTT, PFA-100® closure times – CT with collagen/epinephrine and collagen/adenosine diphosphate cartridge – coll/epi and coll/ADP) and clinical applications. Criteria for desmopressin response were defined as follows: increase of basal values of VWF:Ag and VWF:CB or VWF:RCo of at least 1.5-fold and shortening of CT values reaching the reference range (coll/epi: 85–165 s, coll/ADP: 71–118 s) within 120 min after desmopressin administration.
Results: Seventy-five patients (42 children, age range: 3–17 years; 33 adults, 20–83 years) with hereditary TP (aspirin-like defect: $n = 34$; 25 non-classified TP; 9 storage pool defect; 4 MYH9-associated macrothrombocytopenia; 3 receptor defect) and 15 adults with acquired TP (14 medication-induced, 1 essential thrombocythaemia) were included. Desmopressin was administered i.v. in 56 patients (42 children/14 adults), intranasally (i.n.) in 32 (1/31) and s.c. in 2 adults. The i.v. dose ranged from 0.07 to 0.4 μg/kg (median: 0.3 μg/kg); the absolute i.n. dose from 300 to 600 μg. After desmopressin administration blood was collected mainly at 60, 120 or 240 min measuring CT, VWF:Ag, VWF:CB and FVIII:C. In 6 patients (7%) mild side effects such as facial flush were reported. Of 84 patients evaluated for response, 57 (68%) showed a response and 27 (32%) a non-response. Responders were significantly younger than non-responders and the response was dependent on the way of administration (i.v.: 43 responders/11 non-responders; i.n.: 13/15). After desmopressin administration a significant shortening of CT values was observed reaching the reference ranges. The desmopressin-induced increase of mean values of VWF:Ag, VWF:CB, VWF:RCo and of FVIII:C ranged from 1.2 to 2.7fold.
Gender and blood group did not influence the time course of any of the measured parameters. The maximal desmopressin effects were observed between 30 and 120 min after desmopressin application. For 20 patients (7 children, 13 adults), 23 clinical applications were described including mainly dental/oral surgical interventions ($n = 6$), herniotomies ($n = 3$) and menorrhagia ($n = 3$). Three patients who were classified as responders in the DT suffered from bleeding despite desmopressin application.
Conclusion: An i.v. dose of 0.3 μg/kg and the determination of PFA 100® CT coll/epi and VWF:Ag measured before and 60 min after desmopressin application is recommended as test standard for patients with TP. A prospective study is needed for the validation of these recommendations and for the evaluation of clinical relevance of test results.

PO 349

Congenital amegakaryocytic thrombocytopenia – the first case diagnosed in the Czech Republic and successfully treated by means of hematopoietic stem cell transplantation from matched unrelated donor

Kuhn T[1], Blazek B[1], Keslova P[2], Cmejla R[3], Kovarova P[1] and Ballmaier M[4]

[1]Teaching Hospital, Ostrava University, Ostrava; [2]Teaching Hospital Motol, Prague; [3]Chambon Laboratory, Prague; [4]Hannover Medical School, Hannover, Germany

Background: Congenital amegakaryocytic thrombocytopenia (CAMT) is a rare recessively inherited disorder characterized by severe thrombocytopenia with a reduction or absence of megakaryocytes in the bone marrow and the development of progressive bone marrow failure. It manifests mostly in the neonatal and infant period. Level of endogenous thrombopoietin (TPO) is high, but platelets or progenitor cells do not respond to it due to mutations of thrombopoetin receptor – c-mpl. In some patients additional anomalies (heart defects, CNS anomalies and orthopedic anomalies) have been reported. The only causative cure for CAMT is hematopoietic stem cell transplantation (HSCT).
Methods: A case of a female baby born in 33 week of gestation is described. The child presented at birth with hematomas and petechiae on the body. Severe thrombocytopenia (14×10^9/L) was recognized. No serious structural congenital anomalies were detected. Intravenous immunoglobulin application as the first treatment attempt had no effect on the level of thrombocytes. Platelet concentrates had to be repeatedly administered in the span of 7 to 8 days once the number of thrombocytes fell below 20×10^9/L. Because of recurrent drop of hemoglobin level red blood cells had to be transfused every 3 weeks. Immunological cause of thrombocytopenia was excluded by serological testing and genotyping of human platelet antigens. Trephine biopsy revealed hypocellular haematopoiesis. A few dysplastic megakaryocytes were found, no other significant features of hematopoiesis dysplasia were observed. TPO level was significantly increased. Other causes of congenital thrombocytopenia (Fanconi anemia, Shwachmann -Diamond syndrome and Dyskeratosis congenita) were systematically examined and ruled out. Molecular genetic testing was performed, mutation in the c-mpl gene was not however revealed. At the age of 6 months the child underwent successful allogeneic bone marrow transplantation from matched unrelated donor. Peri and post-transplant period was without major complications or signs of severe graft vs. host disease (GVHD). Patient has been nowadays surviving 4 years after transplantation without immunosuppression in a good quality of life. Platelet count does not fall beyond normal ranges.

Summary: CAMT is a rare cause of congenital bone marrow failure syndrome. Even though the diagnostic testing (c-mpl gene mutation) is known, cases with not proven mutation were observed. In those affected, bone marrow failure ensues usually within the first 5 years.
The excellent results of the allogeneic HSCT can be achieved only if highly specialized laboratory techniques are at disposition, matched donor is available and transplantation is performed by experienced transplant unit team at early stage of disease.

PO 350

Haemostatic management of pregnant women with platelet function disorders: utility of PFA-100

Lentaigne CE[1], Sodhi V[2], Usman N[2], McCarthy A[2] and Millar CM[1]
[1]Imperial College London, London; [2]Imperial College Healthcare NHS Trust, London, UK

Background: Defects in platelet function are a common cause of mucocutaneous bleeding, however characterisation of this heterogeneous group of disorders is hampered by the limitations of currently available tests. Consequently, there is little available guidance on monitoring of women with platelet function disorders during pregnancy and labour. Diagnostic uncertainty leads to variable management of these patients between centres and frequently leads to infusion of pooled platelet concentrates. The PFA-100™ is a rapid, global test of shear-dependent platelet function that may be sensitive to quantitative and qualitative defects in platelets and VWF and may provide clinically useful information.
Aims: To evaluate the use of PFA-100™ in informing haemostatic management of delivery in a cohort of pregnant women with platelet function disorders.
Methods: The course, management and outcome of pregnancy and delivery in a tertiary obstetric unit were evaluated retrospectively alongside haemostatic parameters including PFA-100™ analyses.
Results: Nine pregnancies in eight women were evaluated. Prolongation of both collagen/epinephrine and collagen/ADP closure times were demonstrated by PFA-100 analysis outwith pregnancy in all cases, in association with abnormalities of platelet light aggregometry, normal platelet counts, VWF levels and function. All were uncomplicated, singleton pregnancies and delivered at term. Antifibrinolytic therapy (tranexamic acid) was used routinely prior to and/or following delivery. Serial PFA-100 analyses were performed during pregnancy; correction to normal values was demonstrated in four cases, while remaining abnormal throughout pregnancy in five cases. Five of the nine deliveries were vaginal, with two requiring episiotomy and forceps delivery; there were two cases of emergency Caesarian section (C-section) and two planned C-section. Of the five cases with persistently prolonged closure times, three received treatment with desmopressin during labour, two of whom went on to receive combined spinal and epidural anaesthesia (CSE) and C-section uneventfully with no additional haemostatic measures. Further doses of desmopressin were administered as necessary, including prior to epidural catheter removal. The third, in whom desmopressin did not result in correction of PFA parameters, had an uncomplicated vaginal delivery. The remaining two cases with prolonged PFA closure times had vaginal deliveries with no bleeding complications, using alternative forms of analgesia. Of the four cases with normalised PFA-100 closure times, two were vaginal deliveries without CSE, one of which was forceps with episiotomy. One patient required emergency C-section with CSE anaesthesia in her first pregnancy and CSE and elective C-section in her second, which was complicated by uterine atony and significant haemorrhage. No patients in our cohort received prophylactic pooled platelet concentrates.
Conclusions: Our data suggest that PFA-100 analysis may be useful in monitoring selected patients with platelet function disorders during pregnancy: PFA-100 analysis was shown to directly influence haemostatic management of delivery in at least six of the nine cases studied. We propose that women with previously demonstrated abnormalities in PFA-100 that fully correct during pregnancy (or following DDAVP) be considered for regional anaesthesia and delivery without routine use of platelet concentrates. Therefore, PFA-100 may be useful in tailoring haemostatic support and avoiding unnecessary use of platelets in these patients.

PO 351

Spontaneous duodenal hematoma in a patient with Glanzmann's thrombasthenia

Tokgoz H and Caliskan U
Necmettin Erbakan University, Meram Medical Faculty, Konya, Turkey

Background: Glanzmann's thrombashtenia (GT) is a rare congenital disorder of platelet function associated with a prolonged bleeding time, a normal platelet count, abnormal clot retraction and defective platelet aggregation. Mucocutaneous bleedings including gastrointestinal bleeding are common in GT patients but spontaneous intramural duodenal hematoma is extremely rare (1–2).
Aim: We report a child who had GT presented with signs and symptoms of duodenal obstruction. We aimed to pay attention a rare presentation of GT patients.
Case and Methods: A 5-year-old boy with a known GT was brought to the pediatric emergency room by his parents. The patient had been complainting of the acute onset of periumblical and right upper quadrant pain and vomiting. There was no melena and hematemesis in admission. No history of trauma was present. The abdomen was flat with tenderness in the midepigastrium and right upper quadrant without evidence of peritoneal irritation. Rectal examination reveled black stool.
Results: Abdominal ultrasonography revealed appearent intramural duodenal hematoma and ileoileal invagination. Invagination was resolved via rectal barium application. Intramural hematoma was resolve recurrent administration of thrombocyte suspension. Erythrocyte suspension was given because of deep anemia. The patient did not need further surgical intervention. Intramural hematoma completely regressed on day 10.
Discussion: Intramural duodenal hematoma is generally seen after abdominal trauma. It has been reported spontaneous intramural duodenal hematoma in coagulation disorders such as Von Willebrand disease, immune thrombocytopenic purpura, polyartheritis nodosa, hemophilia A (1–3). Only one report about GT and intramural duodenal hematoma was found in the literature and GT (1). The diagnosis of duodenal hematoma should be considered in any patient who has abdominal pain and a coagulation disorder. İntramural hematoma may be abundant even requiring blood transfusion. Nonoperative management of an obstructing duodenal hematoma was successful and potentially life-threatening surgery was avoided.

PO 352

Use of recombinant factor VIIa in the management of 3 bleeding episodes in a patient with Bernard-Soulier syndrome

Messaoudi R[1], Hadj T[1] and Zahia B[2]
[1]University hospital Oran, Oran; [2]University hospital sidi Bel Abbés, Sidi Bel Abbés, Algeria

Introduction: Bernard- Soulier syndrome (BSS) is a rare congenital platelet autosomal recessive disorder characterized by defective platelet adhesion and manifested by spontaneous and often profuse bleeding.
Objective: To report the efficacy of recombinant factor VIIa (rFVIIa) in the management of bleeding episodes in a patient with BBS refractory to platelet transfusions.

Report: We reported the case of a 20 year-old woman with BBS. Born from a first degree consanguineous marriage. Family history: 10 siblings, five of them suffering from BBS and 3 died in early infancy by severe haemorrhage. The patient was admitted twice for severe melena and once for menorrhagia scored 150 (Higham et all (1990) British Journal of Obstetrics and Gynecology). Despite oral contraception and Platelet transfusion, bleeding persisted with severe anaemia. She was administered Intravenous rFVIIa (NovoSeven®) (90, 56 μg/Kg, 3doses at 2 h). She was administred parenteral iron supplement which corrected anaemia.
Conclusion: Considering the refractory to platelet transfusion and platelet alloimmunization risk in our patient, we administered rFVIIa which permitted to stop the haemorrhage.This case highlights the potential benefits of rFVIIa in helping to control severe bleeding episodes in patients with BBS.

PO 353

Availability of a microchip flow chamber system as a screening test of platelet storage pool disease

Minami H[1], Nogami K[1], Ogiwara K[1], Sakurai Y[1], Yada K[1], Kashiwagi K[2], Suzuki H[3], Hosokawa K[4] and Shima M[1]
[1]Nara Medical University, Kashihara, Nara; [2]Graduate School of Medicine, Osaka University, Osaka; [3]Nippon Medical School, Tokyo; [4]Fujimori Kogyo Co., Ltd., Kanagawa, Japan

Background/Aims: Platelet storage pool disease (SPD) is platelet disorders characterized by a reduction in the number or content of α-granules, δ-granules or both. SPD is diagnosed with electronic microscopy and quantitative measurement of platelet ADP/ATP, which need specialists. Although SPD presents prolonged bleeding time, a standard screening test, its accuracy depends on individual technique and sometimes it shows false-negative. We hypothesized that an automated microchip flow-chamber system, Thrombus-formation Analysis System (T-TAS, Fujimori Kogyo), which has been reported to be useful for evaluations of antiplatelet therapy (Hosokawa, Thrombosis and Haemostasis 2013), might be available as a screening test for platelet functional disorders. We evaluated a family-case of α/δ SPD with T-TAS.
Case: A 6-year-old boy presented with intracranial bleeding after a head injury, and postoperative ruptured suture. His mother and the elder brother also repeated subcutaneous hemorrhage and a nasal bleeding since childhood. They had no clinical symptom except for bleeding.
Methods: In T-TAS, hirudin-added blood was injected to a microchip which surface was coated by collagen, and platelet thrombus formation was monitored with a pressure sensor. The blood flew through the duct in microchip at the shear rate of 1000 s. Flow pressure curve was visualized for 10 min and the time when the pressure in the microchip reaches 10 kPa (T_{10}) was evaluated. Platelet aggregation was further evaluated with standard assays using platelet aggregometer, PRP313M (IMI) and Multiplate (Verum Diagnostica).
Results: Platelet count and size was normal in all cases. His bleeding time was 15 min and his mother's was 6 min, while other common coagulation tests were normal. In PRP313M using platelet rich plasma, their platelet response to 5 μg collagen and 1.7 μg ristocetin were 48.6%-58.3% and 27.3%-55% compared to normal control, respectively. In Multiplate using whole blood added hirudin, response to ristocetin, ADP and collagen were within normal range. In T-TAS, however, thrombus formation was not observed during measurement time (T_{10} > 10 min, reference 2.4–6.6 min) in all cases. Farther investigations for definite diagnosis were performed. Electronic microscopy revealed few α-granules. In quantitative analysis of ADP/ATP released from washed platelets stimulated by convulxin or PAR1P, ADP was 0–1.09 μM at 1.0×10^6/μL platelets (reference 11.7–13.7 μM) or 0–1.55 μM (10.5–12.0 μM), respectively, and ATP was 0 μM (14.0–16.3 μM) or 0 μM (13.7–14.8 μM), respectively.
Conclusion: In this α/δ SPD family case, standard platelet function tests were nearly normal except for prolonged bleeding time in the propositus, but T-TAS could show abnormal platelet aggregation in all cases. Therefore, T-TAS might have high sensitivity to platelet disorders and be a candidate as a screening test for platelet functional disorders including SPD.

PO 354

Features of patients with immune trombocytopenic purpura south-east of Turkey

Soker M, Akyüz F, Kelekci S, Sen V, Karabel M, Üzel H, Yolbas I and Günes A
Dicle University School of Medicine, Diyarbakir, Turkey

Background and Aim: Acute immune (idiopathic) thrombocytopenic purpura (ITP) is characterized by thrombocytopenia, spontaneous formation of purpura, petechiae, ecchymoses and mucosal bleedings and it is also a disease which can be diagnosed with exclusion of other thrombocytopenia symptoms. However, the disease is important in aspect of severe organ bleedings and risk of becoming chronic. In this paper, clinical and sociodemographical features of cases with ITP evaluated in South-East of Turkey.
Materials and Methods: Total 151 patients, who were diagnosed with ITP, were evaluated. The patients' male/female ratio was 1/1.06. The average age was between 5.1 ± 3.4. Seventy-five percent of the patients were diagnosed as acute ITP and 25% of the patients were diagnosed as chronic ITP.
Result: Tendency to chronicity was highest in the 2–10 years age group ($P = 0.01$). The most frequent presenting symptom was skin findings in both the acute and the chronic group. A 64.6% of the cases with insidious onset had become chronic. It was determined that season and gender had no effect on chronicity of ITP (< 0.05). A 68.4% of the acute cases had history of infection and seropositivity was demonstrated in 1%. Bone marrow aspiration findings did not alter the diagnosis in any patient. In the first treatment, the patients responded partially positive against steroid; the ratio of becoming chronic and, in the acute ITP group the ratio of positive response against steroid was higher and this difference was found significant ($P = 0.001$ and $P < 0.05$).
Conclusion: The preference of economical and effective treatment methods for the ITP patients will prevent morbidity and mortality deaths relating to ITP.

PO 355

Successful IVF and pregnancy in Glanzmann's thrombasthenia under cover of recombinant factor VIIa

Staritz P[1], Zimmermann R[2], Domschke C[3], Strowitzki T[4], Sohn C[3] and Huth-Kuehne A[5]
[1]SRH Kurpfalzkrankenhaus Heidelberg; [2]Hemophilia Care Center Heidelberg; [3]University of Heidelberg; [4]University of Heidelberg; [5]SRH Kurpfalzkrankenhaus, Heidelberg, Germany

Case Report: A 35 year-old woman with glanzmann's thrombasthenia (GT) with no further conservative treatment options for primary infertility underwent *in vitro* fertilization (IVF). Ultrasound guided follicle aspiration was performed under cover of recombinant factor VIIa (rFVIIa). The patient became pregnant during the first treatment cycle.
Pregnancy itself was uneventful. During pregnancy, the frequency of epistaxis increased significantly and could be treated successfully by local application of tranexamic acid and bipolar coagulation during one episode.
In 38 + 1 weeks of gestation, primary caesarian section was performed due to the elevated risk of peripartal bleeding again under cover of

rFVIIa. Four HLA compatible platelet concentrates had been prepared as stand by therapy. An apparently healthy child was delivered. Despite no evidence for increased intraoperative bleeding, postoperative hemoglobin concentration decreased to 6.7 g/dl, necessitating transfusion of two erythrocyte concentrates. Recombinant FVIIa was reduced successively and discontinued on day 10 after delivery. Under this regimen including tranexamic acid 1000 mg tid p.o.), no further relevant bleeding complications occurred and lochia were even below average.
The decision for rFVIIa over platelet transfusions was guided by the idea to prevent alloantibody formation against the GPIIb/IIIa complex.
This case report demonstrates feasibility and safety of IVF in women with GT under specific treatment.

PO 356

Course of pregnancy, labour and perioperative management of a patient with Bernard-Soulier Syndrome – case report and literature review

Teliga-Czajkowska JH[1], Sikorska A[2], Bykowska K[2], Maslanka K[2], Kopec I[2], Schubert W[1], Dmoch-Gajzlerska E[1], Windyga J[2] and Czajkowski K[3]

[1]Medical University of Warsaw, Faculty of Health Sciences; [2]Institute of Hematology and Transfusion Medicine; [3]Medical University of Warsaw, Warsaw, Poland

Background: Bernard-Soulier syndrome (BSS) is a rare hereditary thrombocytopathy characterized by large platelets, thrombocytopenia of variable degree, and bleeding symptoms. The disease is caused by dysfunctional GPIb/IX/V heterocomplex or its absence.
We present the course of pregnancy, delivery and postpartum period of a patient with a grave Bernard-Soulier syndrome complicated by a history of VTD and epilepsy.
Case Report: A 39-year-old patient was admitted to the Clinic in 15th gestational week of her second pregnancy (one miscarriage) due to grave anemia and thrombocytopenia (Plt = 3G/L). She had a history of chronic ITP treated with corticosteroids since infancy, splenectomy performed at the age of 25 and was first diagnosed with Evans' syndrome 6 years ago. The diagnosis was then discarded following negative Coombs' test. After skull injury in early childhood she developed grand mal epilepsy at the age of 14. Since the age of 25, the patient experienced numerous mucosal bleeding episodes from GI tract, epistaxis, easy bruising and gingivial bleeds. She also suffered from viral hepatitis C and had a history of deep venous thrombosis. During pregnancy she was administered several platelet, FFP and RBC transfusions, she was treated with corticosteroids and immunoglobulins as well as argon coagulation procedures. Immunological tests confirmed BSS diagnosis (decreased expression of GP Ib/IX by 58% and GP Ib – by 63.5%).
The course of pregnancy was uneventful except for severe thrombocytopenia. The patient was admitted to the II Ob/Gyn Dept in 37th completed week of gestation. Cesarean section was performed and the male fetus from the breech position was born weighting 2780 g, 53 cm, 1st min Apgar score – 10. The postoperative period was complicated by wound and mucosal bleeds in spite of extended treatment. Perioperative and anesthetic management included platelet, FFP, RBC transfusions, corticosteroids and a selection of appropriate drugs and techniques.
Conclusion: The case of BSS pregnant woman highlights the need for establishing both hematological and obstetrical care standards for management of this rare disease.

PO 357

RFVIIa inhalation for life threatening pulmonary hemorrhage in a case with refractoriness to platelet transfusion

Almomen AK, Aleem A and Saad H

King Saud University, Riyadh, Saudi Arabia

Background: Refractoriness to platelet transfusion is a common complication of repeated platelet transfusion in relapsed acute leukemia, stem cell transplantation, aplastic anemia, and thrombasthenia. It is associated with high mortality rate due to massive intracranial, intrapulmonary or internal bleeding, despite aggressive treatment with platelet and red cell transfusion, high dose steroids, immunoglobulin, anti-fibrinolytic agents and intravenous recombinant factor VIIa (i.v. rFVIIa).The aim of this presentation is to indicate that localintra-pulmonary administration of rFVIIa may be more effective than the intravenous route. We present a 51 years old male with resistant acute lymphoblastic leukemia who who failed to respond first line and second line induction chemotherapy and became refractory to platelet transfusion. On day 17 after receiving a third line induction chemotherapy he developed rapidly progressive cough, shortness of breath and hemoptysis. He was febrile, severely neutropenic with WBC 0.5×10 ⑩/L, Hb 85 g/L, platelets 7×10 ⑨/L despite repeated platelet transfusion. Coagulation profile and chemistry tests were normal. He was transferred to the intensive care unit, intubated and given single donor platelet transfusion along with rFVIIa 90 mcg/kg i.v. every three h in addition to red cell transfusion, fresh frozen plasma, methyl prednisolone, tranexamic acid and immunoglobulin. Pulmonary hemorrhage continued despite a rise in platelet count to 28×10⑩/L and consumption of four doses of single donor platelets and rFVIIa. At this point, same dose of rFVIIa was put in 5 ml normal saline and given intrapulmonarily by nebulizer.
Results: Pulmonary hemorrhage was stopped almost immediately and platelet count continued to rise. He was extubated 5 days later and transferred back to the ward on day 10 with WBC 5×10 ⑨/L, Hb 107 g/L, and platelets $117 \times 10$⑨/L.
Conclusion: rFVIIa inhalation may be more effective in cases with pulmonary hemorrhage.

PO 358

Time dependent effect of aspirin intake on circadian rhythm of platelet reactivity: a pilot study

Bonten T, Snoep JD, Zwaginga JJ, Rosendaal FR, Eikenboom HCJ and Van Der Bom JG

Leiden University Medical Center, Leiden, The Netherlands

Background: Hemangioma, most common benign vascular tumor, has natural history of proliferation in the first year of life followed by spontaneous resolution. The treatment is not universal standard with indication as following: impaired organ function and Kasabach Merritt syndrome (KMS). Alpha-interferon inhibits angiogenesis, endothelial cell migration and proliferation.
Objective: To evaluate the outcome of alpha-interferon for the treatment of hemangioma.
Methods: We recruited 35 patients with hemangioma receiving alpha-interferon followed at hemangioma clinic between January 2001- January 2011.The patients' data including sex, age, type and location of hemangioma, indication, duration, outcome and complications of treatment were reviewed.
Design: Retrospective descriptive study.
Measurements: We evaluate of the outcomes including improvement of organ function, resolution of Kasabach Merritt syndrome (KMS) and decrease hemangioma size.
Results: the number of patients was 35 patients (female = 21, male = 14) with mean age 3.2 months (range 5 days-15 months), loss follow up in five patients. Hemangioma was divided into cavernous

(9), capillary (10), mixed (7). Location of hemangioma includes head and neck (21), extremities (7), mediastinum (3), intraosseous (1), liver (2), larynx and epiglottis (2), and scrotum (1).Average age of treatment was 4.7 months (range 5 days-18 months). Duration of response in 29 patients was 4.7 months (range 1–6 months). Indications of treatment included KMS (1), KMS with impaired organ functions (2), impaired organ functions (30), infection (2), intracranial (1). Eleven patients were decrease in size of mass > 50%, 14 patients were decrease in size < 50% but 23 patients (82.1%) were improved organ function and resolution of KMS. Complications of treatment were elevation of liver enzymes (3), and fever (6).

Conclusions: The use of alpha-interferon was well response to improve organ function and decrease hemangioma size. Due to spastic diplegia, serious complication of alpha-interferon from previous case report studies, the consideration of this treatment should be discussed with parent in light of pro and cons.

PO 359

Can abnormal high mean platelet volume be used as a screening factor for detection of metabolic syndrome and coronary heart disease?

Braester A, Dorosinsky L, Shturman A, Hershkovitz T, Akria L, Suriu C, Shay M and Atar S

Western Galilee Hospital, Nahariya, Israel

Background: Platelets or thrombocytes are the smallest cells in the blood, heterogeneous with respect to size, density, age and metabolic function, initiating the process of coagulation when a blood vessel is broken.

Mean platelet volume (MPV) is a measurement that describes the average size of platelet cells in the blood. The medical literature abounds with studies of various diseases showing a higher MPV in the affected group than in the control group. This is a confirmation of platelet activation in these disorders. Nevertheless, in these studies, the 'abnormal high' MPV is still within the normal range (7–11 fL) even if it is higher than the MPV control group (also within the normal range).

In fact, in day by day practice, in patients with platelet activation, we cannot guess that the MPV is 'abnormal' (compared to control group) although within normal range.

Aims: A. To select consecutive patients visiting the emergency room with MPV above the upper limit of the normal range, and without any disease supposed to cause an abnormal MPV. B. To perform tests on these patients that may reveal pre-diabetes (PDM)/diabetes mellitus (DM), metabolic syndrome (MS) or coronary artery disease (CAD). C. To decide if a naive high MPV can or cannot be used as a screening test for these diseases.

Methods: During 6 months 792 consecutive patients with MPV higher than 11.5 fL (normal: 7.0–11.0 fL) were checked for every disease known to cause high MPV. One hundred and seventy-seven naive patients (those with high MPV but without a clear etiology) have been selected for our study.

Out of 792 patients, 177 patients were found to be naïve and only 30 were interested in undertaking supplementary tests in order to explore the possibility of DM, MS or CAD.

Results: The MPV was 12.3 ± 0.74 (range: 11.5–15.2 fL).

Study population: 47% were males and 53% females; the age was 41 ± 8 (range: 28 – 58 year); Ashkenazi Jews 10%, Sepharadi 43%, Arab (Muslim, Christian and Druse) 43%.

All the selected patients were tested for fasting glucose, HBA1c, CRP and high sensitivity CRP (HS-CRP), triglycerides (TG), total cholesterol (TC), LDL-cholesterol (LDL-C) and HDL-cholesterol (HDL-C).

Blood pressure and waist circumference were measured. TTE and treadmill tests were performed. BMI was calculated for every patient.

MS was found in 33.3% of patients (in Israel's general population, prevalence is 15–17%) and *P* value was 0.022 – statistically significant.

P-DM was found in 30% of patients (in Israel's in general population ages 35–45, prevalence is 15%), the *P* value was 0.028 – statistically significant.

Treadmill test was negative in all patients and TTE demonstrated diastolic dysfunction ± calcified valve in only 16.6%.

Conclusions: A high MPV in a naive patient can be used as a screening factor for P-DM/DM and MS. It does not predict the presence of CAD.

Limitation of this study: the cohort of patients is low; this study will be continued to make possible a better statistical analysis.

PO 360

Metabolomics response of human platelets to collagen interaction

Bussey A, Griffin JL and Farndale RW

University of Cambridge, Cambridge, UK

Background: Metabolomics is the study of total metabolites in a biological system, these studies rely predominantly on NMR and Mass Spectrometry techniques. This approach is yet to be applied comprehensively to platelets, specifically their response to collagen interaction.

Aims: To identify changes in the platelet metabolome in response to collagen receptor engagement. A focus will be placed on the lipidome, and the use of highly specific ligands for different collagen receptors should allow identification of lipid metabolism pathways which are involved in the different receptor axes.

Methods: Three different methods for total lipid extraction are tested, the most effective extraction method for the lipid species of interest is then utilised. Lipid extracts are analysed on a variety of Mass Spectrometry instruments including a Q Exactive Thermo Scientific spectrometer and a LTQ Orbitrap Velos spectrometer. Data is subjected to relevant multivariate statistical analysis such as PLS and PCA. This form of analysis can also be applied to the study of lipid rafts as some platelet collagen receptors have been shown to localise to rafts such as GPVI.

Results: The most efficient lipid extraction method was selected for the broadest range of lipid species of interest possible. This method has been utilised for successful lipid extraction from platelets stimulated by different ligands.

Conclusions: Metabolomics provides a novel method of studying the platelet metabolome and highlighting responses to collagen interaction. The identification of specific lipid species involved in the platelet response to collagen interaction will shed light on uncharacterised receptor axes.

PO 361

Whole blood aggregometry and platelet derived microparticles enumeration in acute leukemia patients

Costache A[1], Mut Popescu I[2], Angelescu S[1], Barbu D[2] and Lupu AR[1]

[1]Carol Davila University of Medicine and Pharmacy; [2]Coltea Clinical Hospital, Bucharest, Romania

Background: Hemostasis is a complex and efficient system maintaining a delicate balance between a prohemorrhagic and a prothrombotic state. Platelets and platelet derived microparticles (PMPs) resulted from platelet membrane remodeling in response to activation or apoptosis play important roles not only in physiological hemostasis, but also in pathological conditions.

In hematological malignancies, the hemostasis impairment can occur both in terms of bleeding, as well as thrombosis. The prediction of

these complications is difficult because of the lack of laboratory markers.
Aims: This study aimed to assess the platelet function and the circulating PMPs levels in patients with acute leukemia and their possible role in hemorrhagic and thrombotic complication prediction.
Methods: Platelet function testing was achieved through whole blood aggregometry using adenosine diphosphate (ADP), colagen and thrombin receptor activating peptide (TRAP) as agonists.
Circulating PMPs levels were evaluated by flow cytometric method.
We investigated 24 patients with acute leukemia at the moment of diagnosis, prior specific treatment initiation and a control group of 16 healthy subjects.
The study was approved by the Ethics Committee of Coltea Clinical Hospital and informed consent was obtained from every participant of the study in accordance with the Declaration of Helsinki.
Results: The results showed that compared with the control group, patients with acute leukemia displayed reduced platelet aggregation response in 19 cases (79%), increased response in 3 cases (13%) and normal response in 2 cases (8%). The reduced platelet aggregation response was associated with hemorrhagic complications development in 8 patients (42%). The increased response to agonists was associated with major thrombotic events (myocardial infarction and stroke) occurrence in all the 3 cases (100%).
The level of PMPs in 21 out of the 24 patients (88%) was not significantly different from the control group, but in 3 patients the circulating PMPs number was much higher, two out from these three patients (67%) developing major thrombotic events during disease progression.
Conclusions: These findings indicate that platelet hypoaggregability precedes bleeding complications, while platelet hyperreactivity could predict major thrombotic events in patients with acute leukemia. Notwithstanding our study group was too small, this hypothesis requiring further investigations.
Our data suggests that PMPs enumeration doesn't offer significant information on acute leukemia patients hemostasis status, except rare isolated cases.

PO 362
A systems biology study of platelet GPVI signalling

Dunster JL, Mazet F, Fry M, Jones CI, Tindall M and Gibbins JM
University of Reading, Reading, UK

Background: Platelet activation occurs in response to a diverse range of signals from the environment and is critical for haemostasis. The complexity of platelet activation *in vivo,* which results in the engagement of multiple cell surface receptors and intracellular signalling pathways, renders this process difficult to study. Although many of the proteins that participate in these pathways are known, their interactions and stoichiometry are still poorly understood. The interdisciplinary techniques of systems biology can enhance our understanding of such complex biological systems that operate over many space and time scales.
Aims: Through close collaboration between mathematicians and biologists we hope to enhance our knowledge surrounding platelet activation and aggregation. To aid this we build stand-alone mathematical models representing individual signalling pathways that can be closely linked to experimental data. Mathematical models are often difficult to utilise in a laboratory setting so we aim to provide interactive tools that enable experimentalists to quickly generate and test hypotheses automatically comparing numerical simulations to experimental data. Analysis of mathematical models should provide us with an enhanced quantitative understanding of the interactions involved, extending the utility of data sets beyond that solely available through intuition alone.
Methods: We present an initial mathematical model of the early subcellular events following the GPVI receptor complex activation. In order to deveop such a model current biological knowledge of the key components involved needs to be captured. Estimations of protein concentrations, binding affinities and rate constants for the key reactions are essential for an accurate model. Such quantitative data requires different experimental approaches and is currently poorly represented in the platelet literature. We compare numerical simulations of our mathematical model to this experimental data focussing on the changes in the phosphorylation states of specific tyrosine residues or key components within the early stages of the GPVI signalling pathway. Through parameter sensitivity and estimation techniques we determine key aspects of the signalling network that effect its dynamics.
Results: A mathematical model is presented that quantitatively captures the time course of kinase activation that follows ligands binding to the GPVI receptor. Our early experiences and difficulties in trying to determine the precise time and location rich data required to parameterise this model are discussed. To enable use of our model in a laboratory setting we are developing a user interface that allows biologists to compare numerical simulations to experimental data. Mathematical analysis of our model highlighted the importance of platelet shape, structure and protein copy numbers of specific proteins to the regulation of these early events.
Summary/Conclusion: By concentrating on detailed models of subsets of individual signalling pathways we are able to validate current knowledge of individual components, their interactions and stoichiometry before we compile them into a complete mathematical model of platelet signalling following activation via combinations of many agonists.

PO 363
Immature platelet fraction and mean platelet volume in diabetes mellitus

Lee E
Department of Laboratory Medicine, Yonsei University College of Medicine, Seoul, South-Korea

Background: Dysregulated platelet-endothelial interactions have been recognized as an important pathogenic mechanism in the development of atherosclerosis. Accelerated atherosclerosis is the main underlying factor contributing to the high risk of vascular events. In patients with diabetes mellitus (DM) in particular, platelet abnormalities play a pivotal role in the lead up to atherothrombotic events.
Aims: Immature platelet fraction (IPF), absolute IPF and mean platelet volume (MPV) was evaluated to investigate the platelet status in DM subjects.
Methods: We investigated peripheral blood IPF, absolute IPF and MPV of 366 patients with DM, 30 with metabolic syndrome (MetS), and 54 controls. The MPV, IPF, absolute IPF and other blood cell indices were measured using Sysmex XE-2100 (Sysmex, Kobe, Japan) and compared between each groups. That of the DM patients were analyzed according to the presence of diabetic complications and glycemic control ($\leq$ 6.5% HbA1c vs. 6.6–7.9% HbA1c vs. $\geq$ 8% HbA1c).
Results: The DM group had a significantly higher MPV (10.35 vs. 10.00 fL, $P = 0.0118$), IPF (%) (2.20 vs. 1.70%, $P = 0.0201$) and absolute IPF (4.80 vs. 4.60 $x10^9$/L, $P = 0.0429$) than the control group. The MetS patients also had higher those markers than the control, however statistically significant differences were not found. There was significant differences in IPF (%) between DM patients with and without cardiovascular disease ($P = 0.0384$). Among DM patients, IPF(%) and absolute IPF showed significant difference based on the HbA1c concentration ($P = 0.0142$ and 0.0034).
Conclusion: IPF is higher in the patients with diabetes or MetS than the control, moreover, associated with cardiovascular disease and poor glycemic control.

PO 364

Responses of different platelet activation pathways in health volumteers with Aspirin/Clopidogrel administration

Li J, Cao J, Wang C and Cong YL
Chinese PLA General Hospital, Beijing, China

Aim: To investigate the inhibition profiles of aspirin and clopidogrel on COX-1 and P2Y12 receptor, and potential interaction between them.
Method: Twenty healthy male volunteers were admitted and divide into two groups, which take clopidogrel (75-mg loading dose and maintenance) or aspirin (100-mg loading dose and maintenance) in consecutive 7 days. Platelet inhibition (%), CEPI-CT/CADP-CT, and CD62p were observed on the 1st, 3rd, 5th and 7th day after medicine intake and withdraw.
Results: Both CEPI-CT and CADP-CT changed significantly ($F = 27.2$ and 25.3, $P < 0.05$) after clopidogrel use, only CEPI-CT changed statistically after aspirin administration ($F = 36.7$, $P < 0.05$). Inhibition on COX-1 induced by arachidonic acid (inhibitionAA) increased statistically ($F = 35.1$, $P < 0.05$) after aspirin intake. In clopidogrel group, it was P2Y12 inhibition increased statistically ($F = 24.8$, $P < 0.05$), but not inhibitionAA ($F = 1.85$, $P > 0.05$). CD62p expression decreased in both groups (clopidogrel: $F = 28.7$, $P < 0.05$; aspirin: $F = 20.7$, $P < 0.05$) after intake.
Conclusions: COX-1 activation may interact with P2Y12 receptors in clinical settings and POCT in platelet function helps to monitor in dual-therapy informatively.

PO 365

ELISA-VASP assay: preanalytical stability of whole blood samples

Moulard M[1], Beroual D[1], Maguer A[1], Haquette G[1], Barragan P[2] and Bourguet N[1]
[1]BioCytex, Marseille, France; [2]Polyclinique 'Les fleurs', Ollioules, France

Background: Phosphorylation of VASP (Vasodilator Stimulated Phosphoprotein) is the most relevant biomarker mirroring the P2Y12 activation by ADP at a molecular level. P2Y12 antagonists play a major role in cardiology. While the flow cytometry-based assay (PLT VASP/P2Y12) is widely used, a new ELISA-based assay (CY-QUANT VASP/P2Y12) was recently developed at BioCytex.
Aims: To determine the stability of whole blood (WB) samples stored at room temperature (RT) before analysis by ELISA-VASP. Stability of WB samples from healthy donors as well as treated patients was investigated over up to 4 days after blood sampling.
Methods: WB samples from healthy subjects and patients undergoing antiplatelet treatment were collected and stored in the dark at RT. Aliquots were taken out using a syringe and needle from the unopened tubes each day from D0 to D4 and readily analyzed by ELISA-VASP. Evolution of the Platelet Reactivity Index (PRI) values was examined over time. Five independent series of samples ($n \geq 30$) from presumed healthy donors were respectively analyzed by ELISA-VASP at t = 0 (D0) and after 1 (D1), 2 (D2), 3 (D3) and 4 days (D4) of storage at RT.
Methods: Platelet Reactivity Index (PRI) values at each time were compared using the non parametric ANOVA on ranks test (Kruskal-Wallis). Although a statistical discrepancy between t = 0 and the following days was detected, the difference was minor and did not interfere with the interpretation of test results. Results from patients will be discussed as well.
Conclusion: The whole blood stability of samples stored at room temperature prior to analysis using the CY-QUANT VASP/P2Y12 is acceptable for at least 48 h or even longer for samples from healthy subjects.

PO 369

The participation of gamma/delta and alfa/beta T- lymphocytes in coagregates forming with platelets in patients with coronary artery disease

Solpov A, Tereshkov P, Avetisyan M, Bolshakova O, Romanyuk S, Topolev I and Vitkovsky Y
Chita Medical Academy, Chita, Russia

Background: Recent studies accumulate evidence that platelets, beside their haemostatic activity, participate in inflammation, immunity and atherosclerosis. In a previous study we demonstrated that CD4 + lymphocytes interacted with platelets and formed heterotypic aggregates. We also found that platelets support CD4+ lymphocyte adhesion to the subendothelial extracellular matrix under flow conditions by formation of heterotypic clusters that are dependent on platelet adhesion and aggregation and mediated by CD40L, PSGL-1 and $_1$-dependent integrins.
Aim: Aim was to investigate the participation of gamma/delta and alfa/beta T- lymphocytes in coagregates forming with platelets in healthy individuals and patients with coronary artery disease.
Methods: In this study, we used the blood of twenty healthy men and thirty-two patients with coronary artery disease (as anticoagulant sodium citrate 3.8% were used). Blood samples were pre-incubated with specific antibodies for platelets, T-cell and gamma/delta and alfa/beta T- lymphocytes detection (Beckman Coulter). The monoclonal antibodies anti-CD3-FITC (Beckman Coulter, Brea, CA, USA), anti-TCR PAN alfa/beta -PE (Beckman Coulter, Brea, CA, USA), anti-TCR PAN gamma/delta -PC5 (Beckman Coulter, Brea, CA, USA), anti-CD41-PC7 (Beckman Coulter, Brea, CA, USA), anti-CD45-ECD (Beckman Coulter, Brea, CA, USA), and their negative controls were used to label gamma/delta, alfa/beta T- lymphocytes and platelets, respectively. Counting of cell aggregates and the definition of lymphocytes phenotype in the composition of these aggregates was performed using flow cytometry FC 500 (Beckman Coulter, Brea, CA, USA). A minimum of 5000 lymphocytes was counted per test.
Methods: It was observed that in the normal whole blood the number of lymphocyte-platelet aggregates were $3.37 \pm 0.8\%$ of the total number of leukocytes. The percentage of T-cell-platelet coagregates were $72.15 \pm 5.7\%$ of the total number of lymphocyte-platelet aggregates. In total T cell-platelet aggregates T gamma/delta were $6.27 \pm 2.4\%$ and T alfa/beta $85 \pm 6.4\%$. Patients with coronary artery disease and progressive atherosclerosis have increased number of lymphocyte-platelet aggregates (LPA) compared to healthy donors ($P < 0.001$). Administration of aspirin (cyclooxigenase-1 inhibitor) corrected the number of LPA to the values in healthy individuals. Conclusions. So in whole blood of healthy donors T gamma/delta – cells interact with platelets, but in T cell-platelet adhesion alfa/beta T-lymphocytes take a greater role. Perhaps it is important for T-cell migration and participation of platelets in the immune response and atherogenesis. Our data point on lymphocyte-platelet interaction in atherosclerosis with coronary artery disease. This process depends on cyclooxigenase-1 related platelet function.

PO 370

Guideline for diagnosis of inherited diseases of platelet function: interdisciplinary S2K guideline of the GTH (e..V.); AWMF-Registry Nr. 086-003

Streif W[1], Eberl W[2], Schulze H[3] and Knoefler R[4]
[1]Innsbruck Medical University, Innsbruck, Austria; [2]Klinikum Braunschweig, Braunschweig, Germany; [3]Charite, Berlin, Germany; [4]University Hospital Dresden, Dresden, Germany

Background: Congenital disorders of platelet function are a heterogeneous group of disorders which are often not detected until bleeding

occurs. In clinical settings only a few methods have proven to be useful for identification and classification.

Aims: The THROMKID quality project was aimed to obtain information on the means of investigating platelet function employed by clinical centres in German-speaking countries.

Methods: A patterns-of-practice survey was conducted from 2005 to 2007. Consensus conferences were held 2009 and 2011. Results were summarized in the guideline AWMF-Registry Nr. 086-003 (http://www.awmf.org/) 2012.

Results: For a rational diagnostic approach, a stepwise algorithm is recommended. Patient history and clinical investigation is mandatory. Von Willebrand disease and other coagulation disorders should always be ruled out prior to specific platelet testing. Platelet count, size, volume (MPV) and morphology may guide further investigations. The PFA-100® CT is suited for screening for severe platelet defects. Platelet aggregometry allows assessment of multiple aspects of platelet function. Flow cytometry enables diagnosis of thrombasthenia Glanzmann, Bernard-Soulier syndrome and storage pool defects. Molecular genetics may confirm a putative diagnosis or pave the way for the identification of new defects.

Conclusion: Consensus guidelines that reliably guide clinicians may improve diagnostic and therapeutic approach to affected patients.

PO 371

Lymphocyte-Platelet Adhesion in patients with chronic viral hepatitis C

Vitkovsky Y, Sakharova D and Petrov A

Chita State Medical Academy, Chita, Russia

Background: In the works of many researchers shows the significant role of the immune system in the pathogenesis of chronic viral hepatitis C. It is now widely studied intercellular interactions, especially between hemostasis and immunity. It is established, that the platelets are relevant to inflammatory reactions: adhesive interaction between platelets and leukocytes are important links in the mechanisms for migration of leukocytes to zone of damage, and, consequently, the inflammation and the development of immune and reparative reactions (Vitkovsky Y.A. et al., 1999–2011). At the same time, many aspects of the immune response with hepatitis C remains unknown, although this is important both in the theoretical aspect to understanding immunopathogenesis, and in practical terms, to forecast the course of the disease.

Aim: The Aim was to study the performance adhesion of lymphocytes with platelets in patients with chronic viral hepatitis C.

Methods: Thirty-two persons with chronic viral hepatitis C were examined. Group included 10 women (31.3%), 22 men (68.7%), in age 37.68 ± 2.0 years old. Duration of the illness up to 5 years was revealed at 59.1%, over 5 years – at 40.9%. The first degree of the biochemical activity was determined at 59.1% of patients with chronic viral hepatitis C, the second – at 40.9%. LTA was studied by Vitkovsky's method (1999). Indicator of LTA expressed number of units of lymphocytes with platelets on 100 cells (norm – 13–15%). Degree of adhesion (LTD) defined as number of platelets, formed contact on lymphocyte surface (norm – 3.0 ± 0.3).

Methods: It is established that at patients with chronic viral hepatitis C the LTA-index decreased to 10.0 ± 1.32%. The average LTD reduced to 2.46 ± 0.29. Thus at the persons had illness HCV less than 5 years ago, LTA consisted 10.23 ± 1.81%, LTD – 2.35 ± 0.24; at the patients who had diseases more than 5 years ago – 9.67 ± 2.01% and 2.58 ± 0.61 respectively. At patients with the first degree of biochemical activity of process had minimal LTA-index – 8.62 ± 2.48%; LTD – 2.48 ± 0.40. Patients with the second degree of HCV activity showed 12.0 ± 1.68% of LTA-indicies; an 2.39 ± 0.39 of LTD.

Summary: Thus, in the case of chronic viral hepatitis C the adhesion of lymphocytes with platelets decreased. This decrease was more in persons with a longer duration of the disease.

PO 372

Comparison of TRAP-stimulated platelet releasate between children and adults using two dimensional-Differential-In-Gel Electrophoresis (DIGE)

Yip C[1], Karlaftis V[2], Attard C[2], Linden M[3], Mongale P[4] and Ignatovic V[1]

[1]University of Melbourne; [2]Murdoch Children's Research Institute; [3]University of Western Australia, Perth; [4]Royal Children's Hospital, Melbourne, FL, Australia

Background: Platelets play important roles in hemostasis and thrombosis. In response to physiologic stimuli such as thrombin, platelets release their granular contents that mediate both thrombosis and vascular repair. Recent studies of the platelet proteome demonstrated that secretion of platelet proteins is increased in patients with cardiovascular disease and that these secretory proteins play potential roles in the inflammatory process. Hence the study of platelet releasate or secretory proteins has become important.

Aims: This study aimed to characterise the differences in platelet releasate from healthy children and adults upon activation with thrombin receptor activating peptide (TRAP).

Methods: Blood samples were collected from adults (n = 4, age 22–41 years old) and children (n = 4, age 2–6 years old). All participants were healthy, with no family history of haematological disorders and had not taken any antiplatelet medication 10 days prior to sample draw.

Washed platelet suspensions were prepared and activated with 0.5 U/L TRAP. Protein released from the activated platelets was isolated and stored at −80 °C until analysis by 2 dimensional Differential-In-Gel Electropheresis (DIGE). Releasate protein from each individual was randomized for labeling with either Cy 3 or Cy 5 cyanine dyes. Equal amount of protein from all the samples were pooled and labeled with Cy2 acting as internal standards. The internal standard was included in all gels to minimize variation between gels. Labeled proteins were separated on 7 cm-immobilized pH gradient (IPG) strips (pH 4–7) as first dimension isoelectric focusing. The strips were then electrophoresed on 4–12% Bis-Tris zoom gels.

Gel images were scanned by Typhoon Trio Imager and analyzed for differentially expressed proteins using DeCyder software v7.0. The biological variation analysis module was used for matching multiple gels and calculating the relative abundance of protein spots comparing children to adults. The filtering parameters were set to select protein spots that had a P-value of < 0.05 and a 1.5 fold difference in relative abundance.

The differentially expressed protein spots were excised for future identification of differentially expressed proteins by mass spectrometry.

Results: On average, 245 protein spots were detected on each gel. The DeCyder analysis identified twenty protein spots that showed at least 1.5 fold differential expression, of which seven protein spots were significantly different (P value < 0.05). Quantitative changes in protein abundance were mainly observed in proteins related to platelet activation and signaling pathway.

Summary/Conclusion: This study demonstrates that there are some differences in the platelet releasate of children and adults following activation with TRAP. Future studies are required to further characterise the age-specific differences in platelet releasate across the spectrum of age. Such studies will contribute to the understanding of the normal platelet physiology across age.

PO 373

Platelet-derived growth factor (PDGF-BB) and platelets in myeloproliferative neoplasms

Rosc D, Boinska J, Stankowska K, Drela E and Gadomska G
Nicolaus Copernicus University in Torun, Collegium Medicum in Bydgoszcz, Poland, Bydgoszcz, Poland

Background: Platelet-derived growth factor, first discovered 30 years ago, is a small molecule belonging to the heparin-binding family of polypeptide growth factors. There are four isoforms of PDGF: PDGF-A, PDGF-B, PDGF-C, and PDGF-D, which in active forms are present as dimers. PDGF-BB is released from activated platelets, however, numerous studies have shown that it is also produced by endothelial cells, fibroblasts, smooth muscle cells of blood vessels, astrocytes, neurons, monocytes, cytotrophoblast cells and tumor cells. Platelet-derived growth factor is involved in angiogenesis, embryogenesis, as well as cancer development and progression. The studies in a variety of pathological conditions indicate that tumor cells by secreting cancer procoagulant, induce platelet activation and PDGF release from the platelets alpha-granules.
Aims: The aim of this study was to evaluate the concentration of platelet-derived growth factor (PDGF-BB) and platelet count in patients with myeloproliferative neoplasms.
Methods: The study involved 69 patients with myeloproliferative neoplasms (mean age 62.42), hospitalized and diagnosed at the Clinical Ward of Hematology of the Dr. J. Biziel University Hospital No. 2 in Bydgoszcz, Poland. These patients were enrolled in the study at the time of the diagnosis of MPNs and prior to the implementation of appropriate treatment. The study group included 40 patients with essential thrombocythaemia (ET), 18 with polycythemia vera (PV), 5 with chronic myeloid leukemia (CML) and 6 with the primary myelofibrosis (PMF). The control group consisted of 31 healthy volunteers to correspond to the age (the mean age of 58,22) and gender to the study group. In blood samples was determined PDGF-BB concentration using ELISA test (R&D Systems, USA). Platelet counts were measured using an automated hematology analyzer. The study was approved by the Bioethics Committee of Collegium Medicum in Bydgoszcz, the Nicolaus Copernicus University in Torun, Poland.
Results: In the current study, there was a significantly higher concentration of PDGF-BB in all patients with MPNs, as compared to the control group (Me = 253,84 pg/ml vs. 118,78 pg/ml, $P = 0.001097$). There was also significantly higher number of platelets (PLT) in patients with myeloproliferative neoplasms compared to the controls (Me = 713,42 $\times 10^9$/L vs. Me = 250,39 $\times 10^9$/L, $P < 0.000001$). Furthermore, a detailed analysis of the results in four subgroups revealed that the concentration of PDGF-BB was significantly higher only in ET (Me = 244,53 pg/ml) and PV (Me = 322,94 pg/ml) patients, compared to the control group (Me = 118,78 pg/ml). Moreover, platelet counts were significanlty higher in ET (X = 955,49 $\times 10^9$/L), PV (X = 397,29 $\times 10^9$/L) and CML (X = 598,20 $\times 10^9$/L) patients in comparison with controls (X = 250,39 $\times 10^9$/L). Analysis of correlations revealed statistically significant, positive correlations between PDGF-BB and PLT count ($R = 0.602941$, $P = 0.010407$), PDGF-BB and red blood cell count (RBC) ($R = 0.632353$, $P = 0.006454$), and PDGF-BB and hematocrite (HCT) ($R = 0.534314$, $P = 0.027140$) in PV patients.
Conclusions: Coexistence of high PDGF concentrations and an increased platelet count in patients with MPNs indicates a platelet-derived source of PDGF. Significant correlations between PDGF and platelet count as well as the number of red blood cells may suggest an increased cells proliferation dependent on angiogenesis in PV patients.

PO 374

Biomarkers for post thrombotic syndrome: a systematic review and meta-analysis

Bouman AC[1], Atalay S[2], Ten Cate H[1], Ten Wolde M[2] and Ten Cate-Hoek AJ[1]
[1]*Maastricht University Medical Centre, Maastricht;* [2]*Flevohospital, Almere, The Netherlands*

Background: Post thrombotic syndrome (PTS) is a serious condition that occurs in 20–50% of patients following deep vein thrombosis (DVT). Currently, no curative treatment options are available. Biomarkers can be of use in both exploring PTS etiology and developing risk stratification tools for PTS. Potentially, this could increase the options for preventive or therapeutic measures according to the individual risk profile.
Aims: This review gives an overview of the current knowledge on biomarkers in relation to PTS.
Methods: A systematic search was executed in Pubmed, Embase/Medline, and Cochrane Central Register of Controlled trials to identify all publications on biomarkers in relation to PTS. Where possible, results of studies were pooled and a meta-analysis was performed using Review Manager 5.1 (The Cochrane Collaboration).
Results: A total of 24 papers were included in this review. In patients after DVT, increased D-dimer appeared to be associated with the development of PTS, according to meta-analysis of three studies [OR 2.04 (95%CI 1.02–4.08)] $P = 0.04$. Neither thrombophilia nor increased Factor VIII (FVIII) was associated with PTS in patients after DVT [OR 0.93 (95%CI 0.72–1.18)] $P = 0.54$, [OR 1.78 (95%CI 0.88–3.57)] $P = 0.11$ Factor V Leiden (FVL) was associated with post thrombotic ulceration [OR 11.42 (95%CI 6.37–20.48)] $P < 0.00001$. Due to extensive heterogeneity, meta-analysis could not be performed for markers of inflammation and tissue remodelling in relation to PTS.
Conclusion: Based on the findings of this review, we pose that D-dimer as well as FVL are associated with an increased risk for PTS and post thrombotic ulceration respectively, most likely explained by either prolonged clotting, or impaired clot lysis. Hypercoagulability as such appears not to be associated with PTS. The role of inflammation still has to be elucidated. More standardized research methods are needed, to increase comparability of future studies.

PO 375

Diagnosis and prevention of post-thrombotic syndrome (PTS)

Utne KK, Wik H and Ghanima W
Østfold Hospital, Fredrikstad, Norway

Background: Up to 50% of the patients develops PTS after deep venous thrombosis (DVT). PTS has negative impact on thequality of life and DVT-related costs. The Villalta and CEAP clinical scores are most frequently used tools for the diagnosis of PTS. To prevent PTS, it is recommended to wear compression elastic stocking (CES) for 2 years.
Aims: To determine the: 1- rate of PTS after DVT, 2- agreement between Villalta and CEAP scores, 3- association between PTS and duration of use of CES.
Methods: This cross-sectional study included patients treated for DVT in Oestfold Hospital-Norway 3–9 years prior to recruitment. Villalta and CEAP scores were assessed by the investigators. PTS was classified into four categories by Villalta score: severe (> 14), moderate (10–14), mild (5–9) and absent (< 5), and into eight categories by CEAP scale. The duration of use of CES was retrospectively registered. The study was approved by the Regional Ethics Committee and written informed consent was obtained from all patients.
Results: Median duration of observation after first DVT in 128 patients [median age 61 years; males 89 (67%)] was 5.5 years (range 3.5–8.7 years). Twenty-five patients had recurrence in ipsilateral

extremity and 13 in contralateral extremities after the first episode. In the Ipsilateral extremity 72 patients (56%) had no PTS, 38 (30%) had mild 12 (9%) had moderate and 6 (5%) had severe PTS assessed by the Villalta score.
The distribution of CEAP classes in ipsilateral extremities were C0 (38%), C1 (17%), C2 (15%), C3 (10%), C4a (16%), C4b (2%), C5 (2%) and C6 (0%).
There was a weak correlation between continuous Villata score and CEAP classes ($r = 0.27$, $P < 0.000$). Of 126 patients with both scores only 67 had concordant results regarding the presence or absence of PTS (kappa 0.09, $P = 0.2$).
CES was worn for 3, 6, 12 or 24 months by 31%, 34%, 29% and 6% respectively. Median durations of using CES in patients with no, mild, and moderate PTS (Villalta) were 6, 6 and 12 months and for C0-1, C2-3, C4a-b were 6, 6, 6 months respectively.
Summary/Conclusions: The proportion of patients having PTS according to Villalta in the ipsilateral extremity (44%) was comparable to other studies. Higher proportion of patients was deemed to have PTS in according to CEAP (62%). There was no very week correlation and absolutely no agreement between the two scores. Although, it is unknown which of two tests more accurate diagnose PTS, however, the International Society of Haemostasis and Thrombosis recommend Villalta score as a standard for diagnosing PTS. Interestingly, the grade of PTS does not seem to be affected by the duration of using CES. Further studies are needed to determine the optimal duration for using CES.

PO 376

Spontaneous acute serebral hematoma in a child with F XIII deficiency

Bay A, Sirikci A and Dogan A
Gaziantep University, Gaziantep, Turkey

Background: Factor XIII deficiency is a very rare bleeding disorder with an estimated incidence of one in 3–5 million individuals. The clinical manifestation of factor XIII deficiency are neonatal haemorrhage and lifelong bleeding diathesis. The incidence of intracranial haemorrhage (ICH) is higher in factor XIII deficiency than any other congenital bleeding disorders.
Aim: We are reporting here the clinical outcome of a young child with intracranial bleed due to factor XIII deficiency.
Results: Five years old boy was admitted to emergency room with vomiting, headache and poor feeding. His symptoms had started 3 days prior to the admission. There was no history of trauma and bleeding. The patient had been followed up by haematology department with diagnosis of factorXIII deficiency since 10 days old (his factor XIII levels was% 2). On physical examination, he was lethargic and disorientated, and plantar reflexes was extensor bilaterally. Also there was no motor dysfunction, facial asymmetry, fever and neck stiffness. Computed tomography showed a right periventricular haematoma and ventriculer dilatation due to foramen monro obstruction. The patient was managed successfully with fresh frozen plasma transfusion and supportive treatments.
Conclusion: Early diagnosis is crucial due to risks associated with ICH, commonly experienced during childhood.

PO 377

Major surgery in emergency in a patient with deep factor X homozygous deficiency: use of the thrombin generation test for management

Bellucci S, Appaplazza P, Lubrano S and Drouet L
Hopital Lariboisiere, Paris, France

Background: Factor X (F.X) deficiency is a rare, severe bleeding disorder, recessively inherited. Although haemorrhages are frequent and often life-threatening there are few reports on its handling in emergency conditions.
Aim: In surgical procedures, since there is no specific F.X concentrate available, PCC concentrates containing F.X but also the other vitamin K dependent factors are administered with a theoretical risk of thromboembolic complications. We assessed in emergency condition whether monitoring of thrombin generation concomitantly to plasma F.X was helpful for adjusting the dosages.
Patient and methods: Our patient, a 30 years old female presented with pelvic and abdominal violent pain due to intraperitoneal rupture of a large ovarian cyst with intracystic haemorrhages. The deficiency in F.X (at 2%) was diagnosed at 6 years because of frequent ecchymoses post mild traumas. She also presented previous post tonsillectomy haemorrhages and abundant menorrhages. At basal level, during surgery and post -surgery period, plasma F.X level was monitored chronometry, Stago, Asnières, France) concomitantly to Endogenous Thrombin generation Potential (ETP) with a calibrated automated thrombography (CAT) (Stago, Asnières, France) allowing also to measure the Lag time (LT), the Peak Height (PH), the Time to Peak (TTP) and the Velocity index (VI); fibrin monomers (FM) (Stago, Asnières, France) were measured too in order to detect any coagulation activation.
Results and discussion: At basal level F.X was at 2%, but ETP was in the normal range: 1771 nM/min vs. 1419–2060 nM/min in controls, PH and VI were decreased at 188 nM and 52 nM/min vs. 282–388 nM and 114–196 nM/min in controls respectively, LT and TTP were prolonged at 7.2 min and 10.8 min vs. 1.43–2.13 min and 3.33–4.73 min in controls respectively. Before surgery (cystectomy with cure of hemoperitoneum), the patient received 20 IU/kg of F.X (present in CONFIDEX ®, CSL Behring SA, France) in order to obtain a F.X level at 50%. Then she received 10 IU/kg/day during 5 days followed by 7.5 IU/kg/day/2 days of F.X to obtain a residual plasma F.X level at about 30–35%.With this procedure, ETP was only slightly increased (1.5 fold vs. the basal level), PH and VI remained in the normal range, LT and TTP were improved. There was no coagulation activation since FM remained undetectable during 6 days. Neither haemorrhages nor thrombotic complications were observed.
Conclusion: This observation illustrates that toraise F.X plasma level at 50% in pre-surgery followed by a residual plasma level at 30–35%, in agreement with the normalisation of the generation of thrombin parameters data, allowed a surgery with high haemorrhagic risk. Such conclusion must be confirmed by future cases reports.

PO 378

The rare coagulation disorders in the west Algeria: diagnosis and screening

Benlaldj D, Mouadene A, Messaoudi R, Moulasserdoun K, Rahal Y, Rahal MC, Touhami H and Seghier F
University hospital of Oran, Oran, Algeria

Background: The rare coagulation disorders present significant difficulties in diagnosis and management and her frequency in the general population is low.
Aims: Diagnosis and screening of rare coagulation disorders in west Algeria.
Method: This study was conducted from 2008 to 2012 in west Algeria on All the subjects with bleeding tendency without any acquired causes, were selected for further investigations.
Screening tests including platelet counts, prothrombin time (PT), activated partial thromboplastin time (aPTT), and fibrinogen assay.
Patients with prolonged aPTT were tested for factor VIII, IX, XI and von Willebrand factor (antigen and Ristocetin cofactor activity).
Patient with prolonged PT and aPTT were tested for factor II, V, VII, and X.
Patient with low factor V level were tested for factor VIII.
Result: Out of 127 patients diagnosed with inherited bleeding disorders, 47 (37%) subjects had rare bleeding disorders. Among them,26

were male and 21 patients were female. Median age of all the patients was 14 years, (range 6 months to 65 years).
The rare bleeding disorders that were found in our population included deficiency of factor II:{n = 04 (3.14%)}, factor V:{n = 07 (5.51%)}, factor VII: {n = 16 (12.60%), factor XI: {n = 5 (3.94%)}, Combined deficiency of factor V and VIII: {n = 12 (9.45%)}, fibrinogene dificiency {n = 3 (2.36%)}.
In 47 patients withe rare coagulation disorders, the mean bleeding score (Tosetto,2006) was 2.3 (range 0–13).
Conclusion: The diagnosis of rare bleeding disorder is dificult in our contries (lack of reagent). this results dont reflect the real frequency of rare coagulation disorders in west Algeria. The perspective is to organise and develop the diagnosis and management of rare coagulation disorders.

PO 379

Prenatal diagnosis for rare bleeding disorders

Dai J[1], Lu YL[1], Xin ZF[2], Ding Q[1], Wang LH[1] and Wang X[1]
[1]Shanghai Jiao Tong University School of Medicine Ruijin Hospital; [2]Shanghai Jiao Tong University School of Medicine, Shanghai, China

Background: Inherited deficiencies of blood coagulation factors are usually associated with lifelong bleeding tendency. Rare bleeding disorders (RBDs) represent 3–5% of all inherited coagulation deficiencies, and are usually transmitted as autosomal recessive traits. Congenital factor VII deficiency is one of rare bleeding disorders with prevalence of around one individual per 500,000. Severe bleeding manifestations tend to occur mainly in homozygous or compound heterozygous individual. It is an autosomal recessive disease.
Aim: To avoid patient was born, prenatal diagnosis is a very good method for the disease history positive family. A women asked for prenatal diagnosis for her second conception. She have a congential factor VII deficiency baby-boy, who was diagnosed at his 2-age.
Methods: Coagulation activity was assessed by one-stage clotting method detected on IL coagulation analyser. The gene of facotor VII, including all exons and intron boundary, was amplified by PCR and seqenced.
Results: Biological assessment for this proband showed significant prolonged prothrombin time and the activity and antigen of factor VII were 2.8% and 3.62% respectively. Other factors of haemostasis (V, II and X) were in the normal range for age. Molecular diagnosis was performed by direct sequencing analysis of the factor VII gene. It revealed one homozygous missense mutation which is Gly360Asp substituation. Both parents were totally asymptomatic of blood disorders, but had partial FVII deficiency, with factor VII levels of 38.8 and 40.6% for the mother and father respectively. Family investigation show that this couples are consanguineous marriage. Gene diagnosis results indicated that they were all heterozygous missense mutation carrier. So theoretically this couples will have another congenital factor VII deficiency patient with 25% probability. To avoid conceive another patient fetus, fetal DNA was extracted from 10 to 15 ml amniotic liquid obtained by amniocentesis at 16–21 weeks gestation. Gender detection shows it is a femal fetus and gene analysis for F7 indicated that this fetus have homozygous Gly360Asp missense mutation which is as same as its brother.
Conclusion: To a conclusion, this fetus is a congenital factor VII deficiency female. Use gene diagnosis can help the women from inherited disease family.

PO 380

Inherited factor VII deficiency in three Moroccan pedigrees

Guedira C[1], Giansily M[2], Benkirane S[1], Jeddi D[1], Messoudi N[3], Mikdame M[3] and Schved J-F[2]
[1]Ibn Sina Hospital, Rabat, Morocco; [2]CHU, Montpellier, France; [3]Mohamed V instruction military hospital, Rabat, Morocco

Background: Severe inherited factor VII deficiency is a rare autosomal recessive disorder. The clinical features are variable and there is no relationship between FVII activity and the bleeding tendency which can vary from a modest bleeding to life-threatening hemorrhages.
Many mutations have been already published which are often single base pair substitution.
Aim: To analyze the clinical and biological findings in three Moroccan pedigrees of inherited coagulation factor VII (FVII) deficiency.
Methods: The coagulation function and coagulation factors activity of probands were detected for phenotype diagnosis, all exons and junctions of FVII gene from the family members' genomic DNA were amplified using polymerase chain reaction (PCR), and detected the gene mutation by direct sequencing.
Results: The proband 1 was 37 years old, the proband 2 aged 6 and the proband 3 was 64 years old. They all had consanguineous parents. Proband 1 and 2 had a history of spontaneous bleeding such as epistaxis, menorrhagia and gingival bleeding while proband 3 was asymptomatic.
They all had prolonged prothrombin time (PT) with normal activated partial prothrombin time (aPTT): PT of proband 1 was 45s, for proband 2 it was 33s and proband 3 had a PT of 40s.
The FVII activity was 2% in proband 1, 13% in proband 2 and 10% in proband 3. Homozygous mutation was identified in the proband 1, who had a severe quantitative deficiency, resulting in Arg413Gln. The molecular analysis of proband 2, who carries a moderate qualitative deficiency, showed a homozygous mutation resulting in Arg364Gln. The molecular data aren't available yet for proband 3.
Conclusion: Congenital FVII deficiency is a bleeding disorder that requires optimal hemostatic management for each case due to its wide variety of bleeding symptoms.

PO 381

Effect of social factors on high prevalence of factor XIII deficiency in southeast Iran

Naderi M[1], Dorgalaleh A[2], Eshghi P[3], Alizadeh S[2], Tabibian S[2] and Sanei Moghaddam E[4]
[1]Research Center For Children Health[RCCAH], Zahedan University Of Medical Science, Zahedan; [2]Hematology department, Allied Medical School, Tehran University of Medical Scien; [3]Pediatric Hematology &Oncology Research director of Mofid Research Center for Co, Tehran; [4]Manager of Blood Transfusion Center of Zahedan, High Institute for Research and, Zahedan, Iran

Background: Inherited factor XIII (FXIII) deficiency is a rare bleeding disorder that can present with significant bleeding complications such as umbilical cord Bleeding and life-threatening intracranial haemorrhage. Precise prevalence of the disease is not clear but in countries where consanguineous marriages are relatively high This disorder occur frequently. In Sistan and Baluchistan due to the high rate of consanguineous marriage prevalence of factor XIII deficiency is increased.
Aims: The aim of this study is to assess the role of relatives, ethnicity and residence in prevalence of factor XIII deficiency.
Methods: This study performed on 205 patients with severe factor XIII deficiency. The clot stability test in order to asses the suspected patients was done and in some patients also molecular analysis and factor assay were done. Data of patients was collected by survey of

patient records, designed questionnaire and family tree. Eventually Statistical analysis was done by SPSS software.

Results: The mean age of patients was 12.7 ± 8 years and 47.8% patients were men and 52.2% patients were women. Ninety-three and seven-tenths percent of patients were baluch and a minority of them were Afghan immigrants (1.5%). More than 70 percent of parents of patients were close relative and 11.8% were distant relative while just 10% of parents no family relatives.

Summary/Conclusions: Factor XIII deficiency is rare bleeding disorder in general population while the prevalence of disorder is significantly higher in Sistan and Baluchistan province, southeast of Iran. It seems that ethnicity, religion, residence and consanguineous marriage have crucial role on this high prevalence of factor XIII deficiency.

PO 382

Rare inherited clotting factor deficiencies (RICFD) in pediatric population: King Faisal Specialist Hospital and Research Centre Riyadh Experience

Saleh' M, Jamil R, Al Musa A, Zahrani H, Owaidah T, Hassan TH, Mohammed V, Abu-Riyash M and Siddiqui K

King Faisal Hospital & Research Center, Riyadh, Saudi Arabia

Background: The rare inherited coagulation factor deficiencies (RICFDs) are deficiencies of factor I, II, V, VII, X, XI, XII, XIII and contact factors.They are generally autosomal recessive disorders or present in homozygous states. Heterozygotes have approximately half-normal levels of coagulation factors and are usually asymptomatic. They have a prevalence of about 1: 500,000 to 1: 2,000,000 in general population. Factor VII and Factor XI deficiencies are the most prevalent world wide. The most typical symptoms in the RICFDs are the occurrence of excessive bleeding at the time of invasive procedures as well as mucosal bleeding. Menorrhagia and postpartum bleeding often occurs in these patients if replacement therapy is not administered.

Aims: To determine the prevalence, clinical profile and treatment outcome of RICFDs in pediatric patients seen at King Faisal Specialist Hospital and Research Centre, Saudi Arabia from 2002 to 2012.

Methods: We are presenting results of a descriptive study where we retrospectively reviewed the charts of the pediatric patients treated at our facility from 2002 to 2012.

Results: Of 22 pediatric (≤ 14 years) patients profiles reviewed, 59% (13) were females. Median age at diagnosis was 5.3 years (0.2–14). Ninety-one percent (20) had a positive family history of RICFD and parents with consanguineous marriages. Family history of RICFD was most common in Factor XIII deficiency (35%). A 27.3% of our patients were from the Northern Region, 18.2% from Western, 13.6% from Eastern, 27.3% from Southern and 13.6% from the Central Region. Median HgB at diagnosis was 119.7(12.3–166), MCV 78.9 (67.2–93) and ferritin 37.9(9–80). Factor XIII deficiency was seen in 8 cases (36.4%), followed by Factor II Deficiency in 4(18.2%) and Factor VII in 3(13.6%). Hepatitis B and C screening was done in 63.6%, all were found to be immune/non reactive. Echymosis was most common bleeding (11.50%) followed by oral in 8(36.4%) and intracranial hemorrhage in 6(27.3%). Eighty-three percent (n = 5) of ICH was seen in patients with Factor XIII deficiency, resulting as the most common serious morbidity. Developmental delay was seen in 2(9%) cases. Five ICU admissions were recorded. Primary reason to ICU admissions was ICH. Treatment modality included topical thrombin in all cases, followed by FFP (17), tranexamic acid (7) and iron supplementation (6). Three were given hormonal contraceptives. All of patients reviewed were alive at the time of last contact.

Conclusion: InSaudi Arabia, the RICFDs are uncommon coagulation problems probably due to under diagnosis of the patients living in remote areas. However in our cohort of pediatric patients, FXIII was the most common presenting with serious bleeding manifestations. Precise knowledge about RICFDs, their clinical presentation, diagnostic work-up and treatment options is vital to accurately diagnosing these patients and providing optimal treatment in pediatric patient population.

PO 383

Handling of a neonate with severe congenital factor VII deficiency and severe bleeding episodes

Wiegand G[1], Rauch R[2], Icheva V[1], Auerswald G[3] and Hofbeck M[1]

[1]University Children's Hospital, Tuebingen; [2]Rems-Murr-Klinikum, Children's Hospital, Waiblingen; [3]Professor-Hess-Kinderklinik, Klinikum Bremen-Mitte, Bremen, Germany

Congenital factor VII (FVII) deficiency is a rare bleeding disorder, which manifests with a high phenotypic variability. It seems that the bleeding disposition in patients with FVII < 25% depends more on the variable genetic defect than on the degree of FVII level reduction. Treatment has traditionally involved FVII replacement therapy using fresh frozen plasma, prothrombin complex concentrates or plasma derived FVII concentrates. Recombinant activated FVII (rFVIIa) is actually considered the first-line therapy for replacement therapy in patients with FVII deficiency.

We report the case of an infant with severe congenital FVII deficiency (< 1%). One day after birth, he presented with marked paleness and hemoglobin levels were in the range of 4–5 g/dl. He required phototherapy because of severe icterus based on a severe cephalohematoma. In the context of this bleeding, the diagnosis of a severe FVII deficiency was made. At the age of 6 weeks he suffered from an intraventricular hemorrhage. The administration of rFVIIa stopped the bleeding immediately and the patient survived without any neurological deficit. At the age of 4 month, the infant was referred to our hospital because of a pyelonephritis with macrohematuria, again repetitive dosages of rVIIa (40 μg/kg every 6–8 h) stopped bleeding instantly. Over the course of the next weeks, the child suffered from spontaneous facial and subcutaneous hematoma of the back of his right hand. Based on the several severe bleeding episodes in combination with FVII levels < 1% we started prophylactic therapy with rVIIa 65 μg/kg every second day. No further bleeding episodes were encountered since the initiation of this therapeutic regimen.

Congenital FVII deficiency is a rare autosomal recessive bleeding disorder with an incidence of about 1/500.000. There are only few reports on neonates with intracranial hemorrhage. Lee et al. reported a case of severe intracerebral and intraventricular hemorrhage (IVH) in a neonate with congenital FVII deficiency. At the beginning rFVII was administered in a dose of 20 μg/kg every 4 h. A brain CT 7 days after admission revealed the regression of the IVH. Severe and life threatening hemorrhages are rare (5%) and occur most frequently in the first 6 months of life. In patients with severe hemophilia A prophylactic therapy with factor concentrates is currently the most effective intervention. In patients with severe congenital FVII deficiency prophylactic therapy is uncommon because of the very short half life of infused FVII. Moreover there are no specific guidelines concerning the frequency and dosage of the factor substitution. Authors report about dosages of 20–30 μg/kg once or twice weekly. Other reports have described dosing regimes of 15–90 μg/kg by bolus injection from twice daily to twice weekly. Complicating is that the smallest package available on the market is 1 mg, leading to wastage of a large amount of the very expensive drug.

Congenital VII deficiency is a rare bleeding disorder. NovoSeven is now being used for the treatment of clinically significant bleeding. Despite the low incidence of this illness, further studies are needed for optimizing therapy.

PO 384

Congential afibrinogenemia

Yakovleva E, Tentsova I, Balandina A, Konyashina N, Soboleva N and Zorenko V

National Research Center for Hematology, Moscow, Russia

Introduction: Congential afibrinogenemia is a rare bleeding disorder with an estimated prevalence of 1:1,000,000 in the general population. There are about 250 cases reported in the world literature. In department of coagulopathy of Russian National Research Center for Hematology we are observing two patients with this diagnosis.

The aim of investigation: A complex assessment of coagulation system in patients with a different bleeding phenotype of afibrinogenemia.

Materials and Methods: A 22-year-old woman suffers from ecchymosis appearance each 1–1.5 months; twice she has surgery for hemoperitoneum after corpus luteum rupture. A 17-year-old man suffers from intensive epistaxis each 3 months. Clotting tests included: clotting time (CT), activated partial thromboplastine time (APTT), prothrombin time (PT), thrombin time (TT), fibrinogen (Clausse) assay, factors of prothrombin complex and venom tests (echitox time, lebetox time, ancistrodon time). Electrophoresis and immunofixation were used for fibrinogen identification. Global hemostatic tests embrased thrombin generation assay (TGA), thromboelastography (TE), thrombodynamics (TD).

Methods: In both cases CT, APTT, PT, TT, echitox time, lebetox time, ancistrodon time are infinitely prolonged. Fibrinogen is undetectable by Clauss assay. Factors of prothrombin complex are normal. The fraction of fibrinogen is absent by electrophoresis method; there is a trace band of fibrinogen in a γ1 zone by immunofixing. According to TE, TD the clot is not formed. Results of TGA show increase of endogenous thrombin potential (2018 and 3582 nM/min for patients respectively) and thrombin peak (277 and 205 nM) in comparison with controls (1020 nM/min and 150 nM, respectively).

Conclusion: Coagulation system in patients with a different bleeding phenotype of afibrinogenemia is characterized by identical changes according to clotting tests, electrophoresis and immunofixation, global hemostatic tests: TE and TD. TGA shows different increasing of thrombin generation that is individual distinction of patients.

PO 385

Dysfibrinogenemia and pregnancy – a case report

Remotti L, Vera Morandini P, Ingratti MF, Sánchez Luceros A, Grosso SH, Woods AI, Meschengieser S, Blanco AN and Lazzari MA

Academia Nacional de Medicina, Buenos aires, Argentina, CABA, Argentina

Background: Congenital abnormalities of the fibrinogen (afibrinogenemia, hypofibrinogenemia, dysfibrinogenemia) have been associated with obstetric complications.

Hereditary dysfibrinogenemias are characterized by the biosynthesis of structurally and functionally abnormal fibrinogen molecules, resulting in decreased clotting activity, despite normal circulating levels of fibrinogen antigen. The obstetric complications observed in dysfibrinogenemias include first-trimester pregnancy loss, haemorrhage, placental abruption, and thrombosis.

In patients with afibrinogenemia and hypofibrinogenemia, it is recommended to maintain fibrinogen levels above 150 mg/dL to achieve a postpartum haemorrhage risk similar to that of healthy women without a fibrinogen deficiency. Management of pregnancy in women with dysfibrinogenemia needs to be individualized, taking into account the fibrinogen level and personal and family history of bleeding and thrombosis. No specific treatment is required in asymptomatic women.

Aims: The aim of this report is to present the case of a patient with diagnosis of hereditary dysfibrinogenemia, without replacement therapy or any treatment to increase her plasma fibrinogen level during pregnancy; she was monitored up the 34th week of gestation without any obstetric complication.

Case report and Results: The patient is a 31-year-old woman with previous personal history of obstetric complications (two anembrionic pregnancies), bleeding after curettage that required transfusion of red blood cells and fresh frozen plasma.

The diagnosis was based on the discrepancy between low fibrinogen clotting activity (C, Clauss Method 145 mg/dL) and normal level of fibrinogen antigen (I, Laurell immunoelectrophoresis: 235 mg/dL). Laboratory tests showed prolonged activated partial thromboplastin time (APTT) (ratio 1.2; RV: 0.87–1.13), that was corrected by the addition of normal plasma (ICA 2; control < 10); prolonged thrombin time (TT) (ratio 2; RV: 0.75–1.25) that was not corrected by the addition of normal plasma (1.6; control 1.2) and borderline value of prothrombin time (PT) (ratio 1.13; RV: 0.82–1.13). Apart from the fibrinogen, other coagulation factor activities were normal; von Willebrand disease was also ruled out.

Hereditary defect was assumed because both her mother (C:110 mg/dL, I: 354 mg/dl) and her brother (C: 60 mg/dL, I: 240 mg/dL), had a previous diagnosis of dysfibrinogenemia.

Five months after the diagnosis she became pregnant. Fibrinogen levels were tested between 12th and 34th weeks of gestation. No significant increase of coagulant activity (range: 140–160 mg/dL) was observed; fibrinogen antigen values changed between 230 and 425 mg/dL, with a maximum at 30th week of gestation.

Due to her previous history of bleeding and the fact that fibrinogen concentrates are not commercially available in Argentina, 6 units of cryoprecipitates were indicated to be infused before delivery and another 6 units if a bleeding complication occurred.

Conclusion: We present a case of congenital dysfibrinogenemia without any fibrinogen replacement therapy; only a frequent control of the fibrinogen was carried out. No obstetric complication was detected up to the 39th week.

PO 386

The laboratory profile of the thrombotic Antiphospholipid Syndrome- Experience from a North Indian tertiary care referral centre

Ahluwalia J, Masih J, Bose SK and Neelam V

Postgraduate Institute of Medical Education & Research, Chandigarh, India

Background: The antiphospholipid antibody syndrome (APS) is an autoimmune disorder characterized by thrombosis and/recurrent pregnancy losses and positivity for antibodies directed against phospholipids or the proteins attached to them. It may be associated with recurrent arterial or venous thrombosis and is the commonest acquired cause of thrombosis. There is limited data available on the laboratory testing for this disorder in the thrombotic presentation from the Indian subcontinent.

Aims: We attempted to determine the prevalence of APS in patients with thrombosis and to study the pattern of positivity of the lupus anticoagulant (LA), Anticardiolipin antibodies (ACA) and anti beta 2 Glycoprotein 1 (anti β_2 GPI) antibodies in this group of patients.

Methods and patients: Patients with confirmed thrombosis (arterial or venous), referred for workup of the hypercoagulable state were included in the study. Citrated plasma samples were screened and confirmed for LA by the diluted Russel Viper venom time and in- house Kaolin clotting time. Serum samples were screened for ACA and anti β_2 GPI antibodies by EIA. Results of repeat testing after 12 weeks for a positive result, where available, were noted.

Results: In a period of 3 years, 991 cases were tested for the APS. Eight hundred and eighty-nine cases were available for analysis. In 186 (20%) of these, any one of the APS antibodies were positive at least once. In 30 (3.3%) cases, the antibodies persisted for at least 12 weeks

and they qualified for the APS. Eight cases were children. Fifty-four percent cases had venous thrombosis. Fifty percent cases had intracranial thrombosis. A 6.6% cases had recurrent thrombosis. In 21(70%) cases there were no risk factors other than the antibodies tested. Only 3 cases had persistent positivity for all 3 antibodies. In 22 (73%) cases, only 1 antibody was positive. Anti β_2GP 1, ACA and LA antibodies were positive in 28, 9 & 5 cases respectively. Positivity for IgG isotype of anti- β_2GP 1 antibodies were common (70% cases).

Conclusions: APS affects young patients and children form a significant proportion. A majority of APS patients had no other risk factors. Transient antibody positivity was frequent. Positivity for all three antibodies is rare and there is a need to have a wide antibody panel. Anti β_2GP1 antibodies were the commonest ones encountered. Positivity for LA was the lowest among all antibodies studied and this was possibly due to the inability to reconfirm an initially positive positive LA result, if the patient had commenced oral anticoagulant therapy. LA was always positive along with anti β_2GP1 antibodies and this effect was possibly a subset of the anti β_2GP1 antibodies. Anti β_2GP1 antibodies were instrumental in increasing the yield of APS in our population and are a useful addition to the test panel.

PO 387

Anti-annexin V antibodies and clinical manifestations of antiphospholipid syndrome

Ben Said M, Ellouze R, Sfar I, Kallel H, Gorgi Y, Ben Abdallah T and Guermazi S

Hôpital Charles Nicolle de Tunis, Tunis, Tunisia

Background: The antiphospholipid syndrome (APS) is diagnosed in patients with thromboembolic events and/or recurrent unexplained fetal loss associated with persistent so called antiphospholipid antibodies (aPL). Laboratory diagnosis of APS includes the detection of positive aPL validated by The International Society on Thrombosis and Haemostasis (ISTH): anticardiolipin antibody (aCL) and/or anti-β2 glycoprotein I antibody (anti-β2GPI) of IgG or IgM class, and/or lupus anticoagulant. Some authors have described a potential role of other aPL in the onset of clinical manifestations of APS and in particular anti-annexin V antibodies (AAV), but studies are few and often conflicting.

Aims: In this work, we investigated the place of the detection of AAV in the plasma of patients with thrombosis and/or foetal losses associated or not to positivity for biological markers of APS.

Patients and Methods: We have studied 123 patients (43 males, 80 females) aged 1–81 years (mean 39 years), with confirmed thrombosis: venous (65 cases), arterial (22 cases) or recurrent unexplained fetal loss (36 cases). The control group consisted of 80 healthy subjects. We evaluated aCL, anti-β2GPI and AAV (IgG and IgM isotypes) by an enzyme-linked immunosorbent assay (Orgentec) and for the lupus anticoagulant as recommended by the ISTH.

Results: All normal controls were negative for aCL, anti β2GPI, and AAV. Twenty-three patients (18.7%) had one or more aPL required for the diagnosis of APS. The incidence of isolated positivity for anti-β2GP1, LA and aCL was 9%, 2.4% and 0.8% respectively. The combination of two or three antibodies was observed in 6 (4.9%) and 2 (1.6%) patients respectively. Among these 23 patients, there are two who were also positive for AAV. The presence of AAV was significantly associated with positivity for biological markers of APS ($P < 0.05$). Among 100 patients without conventional biological markers of APS, 4 women (2.5%) had isolated positivity for AAV: 2 thrombotic events (1 arterial and 1 venous) and 2 obstetric events. However there is not a significant association between AAV and clinical manifestations suggestive of APS ($P > 0.05$) in patients with negative classic markers as compared to normal control.

Summary/Conclusion: Our results corroborate those of other studies which report the presence of AAV in patients with thrombosis or obstetrical complications. AAV are not recognized as markers of APS by the ISTH, however their presence associate with classic markers of APS, or isolated in patients with arterial or venous thrombosis, and in women with obstetrical complications suggest a possible diagnosis interest, perhaps in second line when classic markers are negative particularly in case of a strong suspicion of APS. The exact role of AAV in the APS remains uncertain. The results of this study support the complexity of the pathophysiology of APS. Clinical manifestations reflect the interaction of a mix of antibodies. The diagnostic value of AAV deserves to be confirmed on larger studies.

PO 388

Hemolytic anemia and chronic non-healing ulcer on the right foot in a 27-year old female: a case of SLE antiphospholipid antibody positive responsive to cyclophosphamide therapy

Calatrava JBA, Santos-Estrella PV, Villamin MA and Esposo EA

St. Luke's Medical Center, Quezzon City, Philippines

Background: Our patient in discussion was from the Social Service who was asked to sign a consent form that their case can be used as clinical material towards the enrichment of medical education.

SLE is an autoimmune disease in which organs and cells undergo damage initially mediated by tissue-binding autoantibodies and immune complexes. The most common presentation of which are skin and joint manifestations and cardinal symptoms however there are a few who presents differently. The mainstay of therapy is glucocorticoids but to a few who are refractory or resistant, the use of cytotoxic agents can be utilized.

Aims: To present a case of SLE with an atypical presentation.

To present a case of steroid-refractory hemolytic anemia that responded to cyclophosphamide therapy.

Case Report: This is the case of a 27 year-old female who presented with 7-month history of intermittent fever, rash and chronic non-healing right foot ulcer. The right foot ulcer did not improve with regular wound cleaning with Guava leaves and Hydrogen Peroxide. She later on had episodes of dizziness, generalized body weakness and dyspnea on exertion. Consult done showed anemia and thrombocytopenia however diagnosis was unrecalled. Blood transfusions were done but later had ABO incompatibility. A few weeks after discharge, she had muscle and joint pains, discomfort in swallowing, productive coughing and fever with progressive shortness of breath and weight loss of 15Kg over 2 months.

Patient was admitted with anemia of 5.6 mg/dL and thrombocytopenia of 90,000. Peripheral Blood Smear showed hypochromic anemia, slight anisocytosis, and few schistocytes. Coomb's test Direct and Indirect was positive, C3 = 29.8 mg/dL, Anti dsDNA, Anti-Smith, Anti-RNP were strongly positive, ANCA IgM negative, SCL70 Antibody negative, Crossmatching was positive for warm auto-antibodies, both Lupus Anticoagulant and Antiocardiolipin antibody IgG were positive and Duplex Scan of lower extremities was normal for the right lower extremity. She was started on Prednisone 20 mg/tab once daily and was later shifted to Hydrocortisone 40 mg IV once daily then to Pulse Therapy with Methylprednisolone. After 3 days of pulse therapy, her symptoms of fever, easy fatigability, shortness of breath and the thrombocytopenia was improved however the anemia and the right foot ulcer persisted. Patient was started with Hydroxychloroquine 200 mg tab once daily, Prednisone 25 mg after breakfast and 20 mg after lunch and Cyclophosphamide 500 mg IV twice a month for six doses. Anemia was resolved after three doses of Cyclophosphamide and the right foot ulcer completely healed after four doses of Cyclophosphamide.

Conclusion: We presented an SLE patient with antiphospholipid antibody who presented with hemolytic anemia and chronic non-healing ulcer on the right foot who responded to pulse cyclophosphamide therapy.

PO 389

Antyphospholipid syndrome and arterial thrombosis

Ibañez F, Harberth F, Nuria B, Maria Jose A, Carolina M, Fernando C, Maria Luisa M, Helena B, Juan B and Raul S
Hospital San Pedro de Alcántara (Cáceres), Caceres, Spain

Background: Antiphospholipid syndrome (APS) is an acquired autoimmune condition of thrombophilia which predisposes to the development of venous, arterial, microvascular thrombosis and pregnancy complications that have persistently antiphospholipid antibodies (aPL). Arterial thrombosis is the most serious complication of APS and not well known at present that risk factors associated with the development of arterial thrombosis.

Aim: The aim of the present study was to assess the association between risk factors for cardiovascular disease (age, hypertension, dyslipidemia, diabetes, snuff, family history of thrombosis), inherited thrombophilia, oral contraceptives and the presence of arterial and venous thrombosis in patients with APS.

Methods Forty-seven APS consecutive patients were enrolled in a retrospective observational study by San Pedro de Alcántara Hospital (Haematology's Department) between 2000 and 2012. Of them, 22 were men and 25 women aged between 24 and 85 years, classified in multiple or single positive antiphospholipid antibody and obstetric APS. Potential clinical and laboratory risk factor for arterial and venous thrombosis were evaluated. Patients' characteristics were analysed using descriptive statistics in SPSS (Version 19). The level of statistical significance was set to 0.05 (SPSSstatics19).

Results: We observed 23 patients with venous thrombosis, 20 with arterial thrombosis and 4 with obstetrical APS. Lupus anticoagulant present in these patients is the most common (55.3%) being the most prevalent venous thrombosis (57.7%) (OR = 0.38, 95% CI:0.06–2 0.34, $P = 0.001$) compared with arterial thrombosis that is slightly lower (42.3%). Multiple aPL positivity (23.4%) is associated with a more severe course of the disease, increasing significantly the rate of arterial thrombosis (54.5%) compared to venous thrombosis (45.5%) (OR = 1.54, 95% CI:0.3–6.1, $P = 0.001$), whereas the frequency of positive anticardiolipin and ß$_2$glycoprotein-I (4.3% and 8.5% respectively) was the same respectively (50%). Analyzing the distribution of arterial thrombosis in our center a total of 42.6% of APS was observed (25.8% stroke, 9.4% myocardial infarction, 4.7% thrombosis of the central retinal artery, 6.9% peripheral arterial disease) being the most frequent stroke. There wasn'nt a significant relationship between arterial thrombosis and the presence of classic stroke risk factors, inherited and acquired thrombophilia risk factors.

Conclusions: In our group of patients the multiple aPL positivity is associated with a more severe course of the disease, increasing significantly the rate of arterial thrombosis. The most common form of arterial thrombosis in our case series stroke was as described in the literature.

PO 390

Comparison of six dilute Russell viper venom time lupus anticoagulant screen/confirm assay kits

Fritsma GA[1] and McGlasson DL[2]
[1]Fritsma & Fritsma LLC, Trussville, AL; [2]Wilford Hall USAF Medical Center, Lackland Air Force Base, TX, USA

Background: The normalized dilute Russell viper venom time (DRVVT) ratio provides a robust assay methodology for lupus anticoagulant (LA) detection.

Aims: We evaluated six normalized DRVVT LA screen and confirm systems for inter-method consistency. Reagents were purchased from Diagnostica Stago, Precision BioLogic, Siemens, TCoag, Instrumentation Laboratories, and Sekisui.

Methods: For all assays, we employed the STA-R Evolution® automated coagulometer, adhering to manufacturers instructions. LA-positive and LA-negative plasma controls were purchased from Diagnostica Stago and pooled normal plasma (PNP) was purchased from Precision BioLogic Inc. We computed the mean of the reference interval (MRI) and action limits for all kits using LA-negative aliquots from locally sourced normal subjects ($n = 42$). We then assayed locally sourced LA-positive plasmas ($n = 43$) and using ANOVA compared uncorrected screen/confirm ratios and screen/confirm ratios that were normalized using MRI and mean PNP results.

Results: The grand mean action limit, MRI + 3 SD, derived from the local normal plasmas, was 1.2, confirming the manufacturers' recommended limits; however, limits must be locally computed. The all-sample P value was < 0.001, indicating heterogeneity among ratios. When Sekisui ratios were excluded, the P value was 0.14, thus indicating that this method introduced the major difference among methods. Mean screen/confirm ratios computed from LA-positive specimens were 1.91–2.04 for reagent systems other than Sekisui, which instead yielded a mean ratio of 1.198, indicating that this method was relatively insensitive to LA. A negative bias was recorded by two lots from the Sekisui system for LA-positive specimens. Screen/confirm ratios from combined LA-positive and LA-negative samples generated a combined range of 1.59–1.67 for all reagents except Sekisui, which instead yielded 1.09. All within-run coefficients of variation (CV%) were $< 5.0\%$ using all samples. Between-run CV% using Diagnostic Stago LA-positive and LA-negative controls was $< 5.5\%$.

Conclusion: DRVVT screen/confirm ratios discriminate between LA-positive and LA-negative samples and generally provide acceptable reproducibility. Ratio results may vary among reagent-instrument combinations. In this study, normalization added little to the clinical result interpretation.

PO 391

Prevalence of antiphospholipid antibodies in adults with ischaemic stroke

Nwogoh B, Awodu A and Ogunrin O
University of Benin Teaching Hospital, Benin City, Nigeria

Background: Antiphospholipid antibodies are autoantibodies with procoagulant activities. They include lupus anticoagulant, anticardiolipin and glycoprotein I. Their presence is frequently associated with thromboembolic phenomena including ischaemic stroke. The frequency of occurrence of these antibodies in stroke patients in our environment has not been investigated.

Aim: The aim of this study is to investigate the prevalence of antiphospholipid antibodies in adult patients with ischaemic stroke.

Methods: This is a cross sectional case control study. Consecutive established ischaemic stroke patients between 18 and 60 years were recruited as cases and non stroke subjects as controls. Antiphospholipid antibodies were assayed using dilute Russel viper's venom (DRVV) Lupus Anticoagulant kits (LA screen and confirm kits) by TECHNOCLONE DIAGNOSTICS GmbH, Vienna) and total anticardiolipin antibody (ACA) enzyme linked immunosorbent assay (ELISA) based assays (Bioquant Diagnostics, San Diego, USA). Haematological parameters were analyzed with haematology automated analyzer MODEL SYSMEX KN21, Japan.

Data was analyzed using SPSS version 16. The prevalence of antiphospholipid antibodies of the study group and controls were compared using chi-square and Fisher's Exact test. The means of the haematological parameters of both groups were compared using Student T test. P-values < 0.05 was considered significant.

Results: A total of 60 ischaemic stroke patients and 30 controls were recruited. The mean age for the ischaemic stroke patients and controls were 48.5 ± 9.4 years and 42.9 ± 9.5 years respectively. The stroke subjects comprise 36 males and 24 females while the controls included 16 males and 14 females.

Six (10%) of subjects with ischaemic stroke were positive for LA and none of the controls had LA. Twelve (20%) of the stroke subjects were positive for ACA while two (6.7%) of the controls were positive. The prevalence of APLA in ischaemic stroke patients was 28.3% as against

6.7% in the controls. This was statistically significant with a P value of 0.026 and an odd ratio of 5.53. There was no age or sex preponderance in APLA positivity in the ischaemic stroke group and there was no significant difference in the platelet counts of the study groups.
Conclusion: There is a high prevalence of APLA in patients with ischaemic stroke in our environment. Because the presence of these antibodies has therapeutic implications, routine evaluation of APLA is therefore recommended in patients at risk of ischaemic stroke.

PO 392

Incidence of antiphospholipid antibodies in women with preeclampsia seen at the Universty of Benin Teaching Hospital

Nwogoh B, Awodu A and Aziken M
University of Benin Teaching Hospital, Benin City, Nigeria

Background: Antiphospholipid antibodies (APLA) are heterogeneous group of circulating antibodies against anionic phospholipids. They have been associated with a number of obstetric complications however their role in the pathogenesis of preeclampsia has remained an issue of controversy. There is a dearth of information on APLA in preeclamptic women in our environment.
Aims: The aim of this study is to determine the prevalence of antiphospholipid antibodies in preeclampsia among women presenting to the University of Benin Teaching Hospital (UBTH) Benin City; to determine pregnancy outcome in APLA positive women with preeclampsia. This is with a view to recommending screening for APLA to women at risk of preeclampsia.
Methods: This is a cross sectional case control study. Consecutive pregnant women diagnosed of preeclampsia and age-parity matched normal on-going pregnant women were recruited as participants for the study. Antiphospholipid antibodies were assayed using dilute Russel viper's venom (DRVV) Lupus Anticoagulant (LA screen and confirm kits) and total anticardiolipin antibody (ACA) enzyme linked immunosorbent assay (ELISA) kits.
Results: A total of 100 women were studied comprising 50 pregnant women with preeclampsia and age-parity matched 50 normal ongoing pregnant women as control. The mean ages of the study participants were 31.6 $\pm$ 4.7 years and 30.9 $\pm$ 5.4 years respectively. Thirty of the preeclamptic women were booked in UBTH and twenty were unbooked. Eleven of the preeclamptic women had mild preeclampsia while thirty-nine had severe preeclampsia. The prevalence of APLA in preeclampsia was 10% while none (0%) of the controls was positive. This was not statistically significant P value = 0.056 however the odd of detecting APLA in preeclampsia is infinite. There were no significant differences in the obstetric history, pregnancy complications, maternal and birth outcomes between APLA positive and APLA negative women with preeclampsia. However APLA positive preeclamptic women are at increased risk of abruptio placenta and low birth weight with odd ratios of 5.83 and 1.71 respectively.
Conclusion: The prevalence of APLA though increased in women with preeclampsia there is no association between APLA and preeclampsia in the study participants. Therefore a routine assay of APLA in women at risk of preeclampsia may not be justified however women with preeclampsia with other clinical features of antiphospholipid syndrome should be investigated for APLA.

PO 393

Frequency of antiphospholipid syndrome in 600 of Czech females with venous thromboembolism in association with oral contraceptive use

Sadílek P[1] and Dulícek P[2]
[1]University Hospital Hradec Králové; [2]University Hospital and Medical Faculty of Charles University, Hradec Králové, Czech Republic

Background: Among women in their reproductive age, pregnancy and oral contraceptive use (OC's) are common risk situations of VTE. Because the baseline risk of VTE is low in young healthy women, the absolute risk remains low (3–4 VTE/10,000 women per year using OC. Thirty-three percent of Czech women in their reproductive age are taking oral contraceptives.
The aim of the study: We assessed presence of antiphospholipid syndrome (APS) in a group of 600 women with VTE in association with combined oral contraceptive use (COC's) seen at our clinic since 1997 till the end of 2012. VTE was clinically manifested and objectively documented in all cases. We focused on laboratory work-up of APS. Timing of the detection of lupus anticoagulant (LA) is troublesome, because of influence of many factors: the persisting effect of COC on coagulation, influence of acute thrombosis and also anticoagulation therapy. Diagnosis APS is important for clinical practise, because has impact on: the strategy of anticoagulation therapy, management of further pregnancy, possibility of the onset of autoimmune disease etc.
Methods: LA was examined in all samples at least twice, once at the time of diagnosis and again after anticoagulant therapy. In the case of suspected LA after the cessation of anticoagulation, the examination was repeated after 8 weeks.
Citrated blood samples were centrifuged twice for 15 min at 2700 g and then filtered through a filter with a pore size 0.2 μm. Platelet-free plasma was either analyzed immediately or stored at −70 °C. The laboratory screening of lupus anticoagulant antibodies was examined by following laboratory tests: PT, aPTT, aPTT with high sensitivity to LA, dilute Russell's Viper Venom Time. Thrombin time was done with the aim to rule out the presence of heparin in plasma sample. In the case of a prolongation of one or more of these tests (except TT), the mixing tests were done. As confirmatory tests were used: dilute PT, aPTT and test with hexagonal phospholipids. Anticardiolipin antibodies (ACA) were determined using enzyme-linked immunosorbent assay, as well as beta-2 glycoprotein I antibodies. In the case of positivity, the second evaluation was done again after 6–8 weeks.
Results: The mean age of the females was 26 years, and the average duration of use was 45 months at the onset of thrombosis. APS has been found in 30 females (5%) and in the additional 6 females was combined with F V Leiden mutation in heterozygous form. In 16 females we have found positivity of ACA or beta-2 glycoprotein antibodies, in 10 females only LA and four females were positive both.
Conclusion: APS as single thrombophilia has been found in 5% of females on COC's. The result corresponds to other, mostly smaller studies. We can consider this laboratory work-up as useful for further management of those females.

PO 394

Lupus anticoagulant and anticardiolipin antibodies in polytransfused beta thalassemia major

Weng TF[1], Wu KH[1], Peng CT[1] and Shen MC[2]
[1]China Medical University Hospital, Taichung; [2]Changhua Christian Hospital, Changhua, Taiwan

Background: The presence of anti-phospholipid antibodies (lupus anticoagulant, LA and anti-cardiolipin antibody, ACA) has recently been reported in polytransfused patients of beta thalassemia. Moreover,

high prevalence of hepatitis C virus (HCV) infection and thrombotic risk is described in thalassemia.
Aims: We aimed at investigating the prevalence of ACA, LA, and their relation with HCV infection in patients with thalassemia major.
Methods: Presence of anti-HCV antibody, IgG ACA, IgM ACA and LA activity was determined in 36 patients with thalassemia major (male/female: 17/19 aged 12–37 years) registered at China Medical University Hospital, Taiwan. Two patients had thromboembolic events.
Results: LA was seen in 25% (9/36) of cases. The number of transfusions but not age was slightly higher in LA positive patients as compared to LA negative patients, however the results were not statistically significant. Anti-HCV antibody was positive in 15 (41.6%), IgG ACA in 7 (19.4%), IgM ACA in 21 (63%), and LA activity in 9 (25%) patients. A 71.5% of patients positive for IgM ACA had a low titer of ACA. Strong positive IgM ACA were detected in 16.6%(6/36) of patients but no statistically significant correlation was found with age, number of transfusions, and coagulation parameters. No statistically significant difference in the prevalence of LA or ACA was found between HCV-infected and non-infected patients.
Conclusion: A high prevalence of LA and ACA, also the majority in low titers, was detected in patients with polytransfused thalassemia major in Taiwan irrespective of previous history of blood transfusion and presence of HCV infection.

PO 395
Lupus anticoagulants sensitivity of Siemens APTT reagents

Wissel T and Wagner C
Siemens Healthcare Diagnostics Products GmbH, Marburg, Germany

Background: Several studies investigating lupus sensitivity of APTT reagents produced conflicting results with regard to the sensitivity of ellagic acid-based reagents.
Aims: Demonstrate that the activator *per se* does not determine the lupus anticoagulant sensitivity of an APTT reagent.
Methods: The internal study included different APTT methods on the BCS® XP System. One hundred and fifty-four frozen plasma samples from healthy donors (considered negative for LA) and 100 commercially available frozen plasma samples characterized by a positive dRVVT test were investigated. Three samples with prolonged thrombin time were excluded, leaving 97 true dRVVT positive samples for evaluation. All samples were tested by LA1 Screening Reagent, LA2 Confirmation Reagent, LA1 mixing, Pathromtin® SL reagent (PSL); Dade® Actin® FSL reagent (AFSL, low phospholipid content); and Dade Actin FS reagent (AFS, with high phospholipid content). Furthermore, mixing studies with a 1:1 mix of sample pooled normal plasma were performed for PSL and AFSL. While PSL and AFSL were used as screening tests, AFS, with its known low lupus sensitivity, was used as a confirmation test; screen to confirm ratios were calculated for PSL (PSL/AFS) and AFSL (AFSL/AFS). Additionally, the anti-ß2GP1 IgG and IgM and anti-Cardiolipin IgG and IgM antibodies have already been determined.
Results: For the APTT tests, the highest sensitivity was seen for AFSL, with 83% applying the 99th percentile cutoff (96% with 97.5th percentile cutoff), whereas for PSL, the reagent compliant with the SSC recommendation, sensitivity was only 60% (72%). For AFS, the low lupus sensitivity was again confirmed (21%/40%).
In the APTT mixing studies, sensitivities in general were even higher than in the APTT test, as the more narrow distribution of the reference samples and consequently low cutoff resulted in slightly abnormal results for several samples just below cutoff in the initial APTT. In the mixing study, AFSL again showed higher sensitivity than PSL.
The APTT ratio AFSL/AFS shows more moderate sensitivity at 69% (79%) than the APTT mixing with AFSL. For PSL, the corresponding sensitivities are even lower, at about 45%.
The APLA profile shows that one sample of the reference panel was anti-ß2GP1 positive. All 97 dRVVT positive samples included were anti-ß2GP1 positive and 39 of the samples exhibiting strong dRVVT were also anti-Cardiolipin antibody positive (triple positive) and one of the weak dRVVT positive sample.
Summary/Conclusion: The APTT comparison using different activators revealed a significantly higher sensitivity for the ellagic acid-based reagent AFSL vs. the silica-based reagent PSL. Similar results have already been described by others, which demonstrates that the lupus sensitivity of APTT reagents is not determined by the activator used, but by the phospholipid source and content, as well as other ingredients. This fact is further underlined by the difference in lupus sensitivity seen for AFSL and AFS, which both use the same activator but employ phospholipids of different source and concentration. Among the APTT reagents tested in this study, AFSL clearly showed the highest sensitivity, and only slightly lower sensitivity than dRVVT.

PO 396
Overweight, obesity and body composition and risk thrombotic complications

García-Raso A, Ene G, Miranda C, Mata R, Vidal R and Llamas P
Fundación Jiménez Díaz, Madrid, Spain

Background and Aim: WHO estimates 700 million adults will be obese in 2015 at least. There is evidence that obesity and overweight suppose a prothrombotic state associated with greater activation of coagulation and/or less fibrinolysis. Several studies link obesity and overweight with increased VTE recurrence. This has been the aim of our study.
Methods: We included 99 patients with VTE in the study, mean age 51.6 ± 15.8 years. The patient group consisted of 54% female and 46% male. Thrombotic risk factors previously described (PRETE-MED Guide) were collected for each patient. All patients underwent a study of body composition by bioelectrical impedance (Tanita, TBF300a. Arlington Heights, IL) obtaining data for fat mass (FM%) and body mass index (BMI). We apply Fisher's test to assess differences between groups.
Results: The distribution by type of thrombosis was: DVT in legs (48%), PE (17.5%), DVT + PE (12.5%), DVT in arms (0.7%), TV surface (11, 3%) and TV-unusual localization (10%). The distribution by BMI was 1% underweight (BMI < 18.5), 23.3% normal weight (BMI = 18.5–24.9), 50.5% overweight (BMI = 25–30) and 25, 2% obese (BMI > 30). A 54.5% of patients suffered recurrent thrombosis, of whom 80% had BMI > 25, and 70% FM% abnormal. A 38.4% developed post-thrombotic syndrome, of which 79% had BMI > 25, while 68% had abnormal FM%. We studied a possible association of these variables with the risk of recurrence and the post-thrombotic syndrome, by sex and age (< 50 or ≥ 50 years). Men with higher FM % have more recurrent events than those FM% within normal limits ($P = 0.0048$). We do not find differences in FM% in women, but if any in BMI. Women with BMI > 25 have an increased frequency of recurrent events ($P = 0.0001$). In patients < 50 years, recurrence ($P = 0.0001$) and PTS ($P = 0.005$) are more frequently when BMI ≥ 25. In patients ≥ 50 years, recurrence are more prevalent when BMI ≥ 25 ($P = 0.0001$) and FM% are higher ($P = 0.002$).
Summary: In our group being male, aged ≥ 50 years and have a higher FM% relates significantly with thrombotic recurrence. In women BMI ≥ 25 was associated with a higher recurrence of VTE regardless of age. Besides BMI ≥ 25 was associated with post-thrombotic syndrome in young patients (< 50 years). The results of our study support a relationship between obesity and venous thrombosis.

PO 397

Measuring quality of life in acute venous thromboembolism

Hogg K[1], Shaw J[2], Fallah P[1], Coyle D[2], Carrier M[1] and Wells P[1]
[1]Ottawa Hospital Research Institute; [2]University of Ottawa, Ottawa, ON, Canada

Background: Future funding of new diagnostic and therapeutic technologies will be guided in large part by economic analyses where quality of life is combined with survival in a single unified outcome. We recently completed the largest study estimating quality of life in acute deep vein thrombosis and pulmonary embolism, using the 'gold standard' measurement technique: the standard gamble. The results showed high degree of variation which suggested further exploration of the use of the standard gamble technique in this area.
Aims: To explore the validity, reliability, reproducibility and acceptability of the standard gamble (SG) measurement tool for quality of life (QoL) in acute pulmonary embolism (PE) and deep vein thrombosis (DVT).
Methods: Thrombosis clinic patients who had been diagnosed with either DVT or PE in the last year were eligible to participate in the study. After consent, the participants were interviewed by one researcher using multiple techniques: the SG technique, the short form-36 (SF-36), disease specific questionnaires (Veine-Qol and PembQol) and a visual analogue scale. These were performed in random order. The SF-6D score was calculated. Participants were asked to return for a repeat interview 4 weeks later.
Results: Forty-five patients consented to participate. The mean age was 54, 28 (64%) were men, 8 (18%) had cancer and for 32 participants (73%) it was their first diagnosis of DVT or PE. Median time since diagnosis was 86 days (IQR 30–169). Sixteen participants returned for a repeat interview.
Acceptability: 24/44 classified the SG method as 'acceptable' and 10/44 as 'pleasant and comfortable', but 5/44 as 'uncomfortable'. One patient declined to perform the SG.
Responsiveness: The SG QoL estimates increased in 4/16 participants on repeat interview. The visual analogue score increased in 12/16, and the EQ-6D score increased in 7/16.
Test-retest reliability: Initial and repeat SG QoL measurements correlated well (Spearman's Rho = 0.664).
Criterion validity: The only SF-36 scale associated with SG QoL was Role Emotional. The SG estimates correlated poorly with the SF-6D (Spearman's Rho = 0.18). There were no significant associations with the dimensions of the Veine-Qol or the PembQol.
Construct validity: Participants with PE gave SG QoL estimates which were lower than participants with DVT (median 92.5, IQR 81.6–1.0 vs. 98.9 IQR 85.0–1.0) although this was not statistically significant. There was no correlation with days since diagnosis, age, chronic illness and immobility.
Discriminant validity: Participant sex, education and number of dependents did not influence the SG QoL results.
Significantly higher SG QoL scores were found in those who said they had ingested harmful substances ($P = 0.04$) and wear what they choose to ($P = 0.05$). Nonsignificantly lower scores were seen with depression, 'glass half empty' outlook and lack of social support.
The SG technique demonstrated a ceiling effect with 16/44 giving estimates of 1.0.
Summary/Conclusions: Measurement of quality of life in acute thrombosis using the standard gamble technique does not correlate well with the SF-36 or disease specific questionnaires, and may be influenced by lifestyle factors such as risk taking, confidence and depression.

PO 398

Initiation of evidence-based guidelines in hemostaseology in a local hospital in southern germany

Kessler A, Bickeboeller-Friedrich J, Knoeller J and Fischer G
Oberschwabenklinik, Ravensburg, Germany

Background: In our academic hospital center (530 beds)- attached to the university of Ulm – with several disciplines like neurosurgery, stroke unit, neonatology, hematology, obstetrics and several other disciplines use of antithrombotics and other drugs was historically dependent on personal experience and preference. Knowlegde concerning treatment and prophylaxis of various hematologic diseases was very different both concerning doctors and nurses. We started in 2008 to adapt international and german guidelines dealing with hematologic, thrombogenic diseases and bleeding disorders to our specific needs.
Aims: We wanted to establish evidence-based medicine and improve patients outcome and apply best medical care to our patients although financial resources are rather limited. Finally we made proposals in our pharmacologic conference and decided about the drugs used in daily routine in our hospital.
Methods: A group of interested and ambitious physicians (anasthesiologists, obstetricians, surgeons, neurologists, hematologists, cardiologists, pharmacists) has been meeting every 3 months to discuss and adapt external guidelines of medical societies. Advanced training of all staff in different departments were performed and prescription of new drugs like DTI or factor Xa- inhibitors were scientifically prepared and controlled by our department of pharmacy. Our own guidelines were distributed both electronically and in print form.
Results: Several new drugs were reviewed and introduced in our daily practise. Treatment was standardised and the quality of treatment improved. The total number of consultations with hemostatic topics has been rising. Economical improvement and big attention to patient care is continually observed.
Summary: We started in 2008 to implement a hemostasiological quality circle in our hospital as to improve patient safety and we applied evidence-based medicine to our daily routine. The advantage for our hospital is both economically and scientifically measurable. We recommend that hospitals being attached to a universitary institution or not must discuss and adapt guidelines for their own issues to improve their patient care.

PO 399

A rare cause of recurrent and serious venous thromboembolism: Klinefelter's syndrome

Ozdemir N[1], Tuysuz B[2], Evliyaoglu O[3], Avar O[4], Tuysuz G[1] and Celkan T[1]
[1]Istanbul University, Cerrahpasa Medical Faculty; [2]Genetics Department, Cerrahpasa Medical Faculty, Istanbul University,; [3]Pediatric Endocrinology Department, Cerrahpasa Medical Faculty, Istanbul University; [4]Istanbul, Turkey

Background: Klinefelter's syndrome (KS) is characterized by XXY karyotype, gynecomastia, small testis and hypogonadism with a prevalence of 1/500–1000 in man. There is an increased risk of venous thromboembolism (VTE), arterial thrombus and postthrombotic venous ulcerations. The relatively high serum estrogen concentrations and low androgen levels may be the cause of hypercoagulable state. Obesity that is common in KS patients may serve as an additional risk factor however the exact underlying mechanism is not completely understood yet. Here we report a 14 year old boy who presented with serious and recurrent venous thromboembolism and was found to have Klinefelter's syndrome on follow-up. To our knowledge this is the youngest KS patient reported to have VTE so far.
Case: A 14 year old presented with a sudden swelling and pain in his left leg. There was no family history of venous thrombosis and the

parents were non-consanguineous. On Doppler ultrasonographic evaluation of his lower extremity, there was a large, acute thrombosis starting from proximal saphenous vein spreading to the popliteal vein. D-dimer level on admission was 5.6 mg/L (Normal range: 0–0.5). The patient was diagnosed as deep vein thrombosis and anticoagulant therapy was started with low-molecular weight heparin (LMWH) for 14 days and prophylaxis was given afterwards. On physical examination, he was obese, mildly retarded and had a thickened neck, low neck-line and gynecomastia. He had social and psychiatric problems and was using medication for attention deficit. He was transferred to genetic department for further investigations. One and half month later, he presented again with thrombosis this time at the right leg when he was still on LMWH prophylaxis. Doppler USG showed acute thrombosis from the right iliac vein protruding to the popliteal vein. D-dimer level was 11 mg/L. LMWH dose was increased to the treatment dose. Coagulation tests, plasma FVIII, protein C, protein S and homocystein levels were normal. Genotype analyses for factor V Leiden and MTHFR C677T mutations revealed negative results however, he was heterozygous for G20210A mutation of the prothrombin gene and homozygous for the A1298C mutation of the MTHFR gene. Cytogenetic analysis showed 47, XXY phenotype consistent with KS. The patient is still on LMWH prophylaxis without recurrence.

Conclusion: We want to emphasize the hypercoagulable state and increased risk of recurrent and serious thrombosis in patients with KS. Most patients with KS remain undiagnosed due to heterogenous clinical presentation and unawareness of medical professionals. Early diagnosis might be life-saving. Optimal management of these patients need to be clarified, life-long anticoagulation prophylaxis may be considered in selected cases.

PO 400

Cancer-related thrombosis shows refractory to anticoagulant treatment

Ye X

Second Affiliated Hospital of Guangzhou Medical University, Guangzhou, China

Background: Three cases with refractory, recurrent deep vein thrombosis who were finally diagnosis with respectively gastric cancer, colon cancer or ovary malignant tumor were analyzed and discussed.

Aims: To stress the distinct clinical features and prognosis of cancer-related thrombosis through analysis of the underlying thrombophilic factors, the clinical features of the above cases.

Methods: Clinical courses, treatment protocols and outcomes of the above cases with cancer-related thrombosis had been recorded. Chromogenic substrate methods were used to detect protein C and antithrombin activities. Clotting method was used to detect free protein S and cloting factor VIII and XII activities. ELISA method was used to detect antiphospholipid antibodies.

Results: All three patients had demonstrated with recurrent deep vein thrombosis in bilateral upper or lower extremeties or both, in mesentery vein. Two of them experienced pulmonary embolism. All three cases were refractory to routine anticoagulant therapy including heparin, LMWH, warfarin and riveroxaban. Deficiencies in all the three anticoagulation proteins, e.g., protein C, protein S and antithrombin were excluded. Antiphospholipid antibodies were negative in them. Symptoms and signs were subsidized after removal of tumors.

Summary: Malignant tumors were the only known underlying factors of their refractory and recurrent thrombosis. Patients with refractory recurrent and extensive thrombosis should be examined for malignant tumors. Appropriate treatment for the cancer itself helps to alleviate the symtoms and signs of thrombosis.

PO 401

Automated assay of plasminogen activator inhibitor-1 (PAI-1) activity on STA-R®

Dunois C, Juif V, Guimbard D, Goulas E and Contant G

Stago, Gennevilliers, France

Background: The proteolytic degradation of fibrin clots is mediated by plasmin, an enzyme activated by the urokinase-type plasminogen activator (uPA) or tissue-type plasminogen activator (tPA). The main function of PAI-1 is the inhibition of fibrinolysis by regulation of uPA and tPA activity. Increase of PAI-1 level is associated with many cases of thrombosis, cancer, liver disease and inflammatory syndromes. In contrast, PAI-1 deficiency is associated with risk factors for bleeding diathesis.

Aim: Automation of Stachrom® PAI kit on the STA-R® (Diagnostica STAGO, Asnières, France) to measure elevated levels of PAI-1 and to detect deficient patients. Development of two protocols: standard range for high levels of PAI-1 and low range for PAI-1 deficiency.

Methods: Calibration and samples were measured using chromogenic method at 405 nm for both protocols. Three calibration points were used to obtain a linear calibration: the three calibrators of the kit were ready to use in the standard range protocol while dilutions of calibrator 2 in calibrator 1 were used in the low range protocol. The working range was 3 to 12 AU/mL using low range protocol (depending on the titer of calibrator 2) and 15 to 44 AU/mL using standard range protocol (depending on the titer of calibrator 3).

Results: Using low range protocol: correlation coefficient of calibration was > 0.990, reproducibility within and between assay through automation on STA-R was found to be 10% and 11% C vs. respectively (mean 9.6 AU/mL). Results of normal and low level plasma samples (normals treated with 5 U/mL t-PA) were in agreement with expected values (range from 3 to 11.4 AU/mL and 0.3 to 7.7 AU/mL respectively with a difference mean of 4.2 AU/mL corresponding to uncomplexed PAI).

Using standard range protocol: correlation coefficient of calibration was > 0.995, reproducibility within and between assay through automation on STA-R was found to be 2.2% and 5.6% C vs. respectively (mean 29 AU/mL). Results of normal samples, from cancer patients and pregnant women were in agreement with expected values (< 15 AU/mL in normals, > 26 AU/mL in patients).

Conclusion: The automated assay of PAI-1 activity using the Stachrom® PAI kit on STA-R® showed good performances and allowed to obtain a high sensitivity at low levels. It is easy to improve the measurement of PAI activity in clinical laboratory.

PO 402

Protective anticoagulation effects of peptide Arg-Pro-Gly-Pro and complex heparin with Arg-Pro-Gly-Pro in conditions of immobilization stress

Grigorjeva ME and Lyapina LA

Moscow State University, Moscow, Russia

Background: Some short proline-containing peptides facilitate the activation of the functional state of the anticoagulative system (ACS) and have anticoagulant, fibrinolytic and antiplatelet effects in the bloodstream. At the same time many regulatory peptides play a key role in the maintenance of normal homeostasis and under stressing conditions. We suggested that these peptides would have an anticoagulation effect under the conditions of hypercoagulation during immobilization stress due to their ability to activate ACS.

Aim: The aim of this research was to study the influence of Arg-Pro-Gly-Pro (RPGP) and complex heparin with RPGP on the anticoagulant and fibrinolytic units of haemostasis system under experimental acute immobilization stress and to compare the antistress effects of these drugs.

Methods: The experiments were carry out on the white rats. RPGP and complex heparin with RPGP (with molar ratio 1/1) were used intranasal prior to lasting immobilization. In the blood samples we determined APTT, fibrinolytic activity (FA), plasminogen activator (PA) activity and ADP-platelet aggregation.
It was demonstrated that lasting immobilization stress activated the blood coagulation and promoted the decrease of fibrinolysis. The intranasal injection of RPGP or complex heparin with RPGP to rats prior to immobilization prevented the hypercoagulation, which appeared after lasting immobilization stress. At the same time FA, PA, anticoagulant and antiplatelet activity were increased. Thus the protective effect against hypercoagulation induced by immobilization was shown after administration of study drugs The complex heparin with RPGP were found to have the most significant effects.
Conclusion: Thus our results showed that as RPGP as the complex heparin with RPGP have protective effect against enhanced blood coagulability resulting from immobilization stress. We confirmed that RPGP and complex heparin with RPGP are capable of ACS activation after their administration.

PO 403

Flow conditions modulate fibrillogenesis of plasma fibronectin

Nguyen H, Huynh KC, Scharf RE and Stoldt VR
Heinrich Heine University Medical Center, Düsseldorf, Germany

Background: Soluble plasma fibronectin (Fn) with its inactive compact structure needs to be unfolded to assemble to active fibrils. As reported, mechanical forces, assessed by atomic force microscopy, could regulate the transformation of Fn from the compact form to the extended fibrillar state by exposing cryptic binding sites in individual Fn type III repeats.
Aims: This study investigates the conformational changes of Fn in response to flow conditions simulating venous or arterial shear rates and resulting biomechanical forces.
Methods: Fn isolated from fresh frozen human plasma was added, at different concentrations (50 and 100 μg/ml), to the plate pre-coated with 100 μg/ml Fn or BSA and subsequently exposed to shear rates (50–5000 s) using a cone plate rheometer (Haake Rheostress 1). Viscosities of Fn solutions were recorded over 10 min. To quantify the amount of fibril formation, DOC solubility assays and Western blotting were performed. Control experiments were conducted under static conditions.
Results: After exposure to shear rates, the viscosities (mPa s) of Fn solutions at concentration of 50 and 100 μg/ml increased from 1.87 ± 0.87 (mean ± SD) to 5.03 ± 1.86 and from 2.03 ± 1.63 to 9.29 ± 6.27 on Fn surfaces; from 1.55 ± 0.11 to 4.31 ± 1.7 and from 1.61 ± 0.7 to 4.92 ± 1.8 on BSA surfaces, respectively. In addition, the ratios of fibrils to soluble Fn increased significantly from 0.018 ± 0.012 (mean of ratio ± SD) to 0.121 ± 0.08 ($P < 0.05$) (Fn surfaces) and from 0.021 ± 0.009 to 0.059 ± 0.022 ($P < 0.05$) (BSA surfaces) when increasing the concentration from 50 μg/ml to 100 μg/ml. Under static conditions, no fibril formation was detected.
Conclusion: Our results indicate that the formation of Fn fibrils can be monitored by changes in viscosity. The formation of fibrils is dependent on the Fn concentration, but not on the type of the coated surface. In addition, fibrillogenesis of Fn is modulated by flow conditions.

PO 404

Functional constituents in Natto: nattokinase, vitamin K2 and polyamine contents

Serata M[1], Naito S[1], Yatagai C[1], Ohsugi T[1], Yanagisawa Y[2], Saito J[3] and Sumi H[1]
[1]Kurashiki University of Science and the Arts, Kurashiki; [2]Chiba Institute of Science, Choshi; [3]Honda Trading Corporation, Tokyo, Japan

Background: Natto is produced through the fermentation of steamed soybeans by using *Bacillus subtilis natto*. In previous papers, we have presented reports on the physiochemical properties of nattokinase, a constituent of natto (Sumi *et al*., *Experientia*, 43, 1110, 1987; Yatagai *et al*., *Pathophysiol. Haemost. Thromb*., 36, 227, 2009). It is now widely recognized in particular that natto is a food rich in polyamine, a substance with anti-aging effects (Soda *et al*., *J. Nutr. Sci. Vitaminol*., 55, 361, 2009).
Aims: We have recently had an opportunity to analyze the natto products that were judged to be superior and received prizes at the official National Awards Ceremony Recognizing Excellence in Natto held over the past few years. For natto products, which are considered to have excellent flavor and aroma, the potency of the constituent nattokinase, the amount of vitamin K_2 produced, and the polyamine content have now been identified.
Methods: Of the 224 natto products entered in the above-mentioned competitions, the 14 types that received prizes were frozen at −30 °C until used in the analysis. The procedures for preparation of rabbit antibody for nattokinase and for double immunodiffusion were carried out as reported previously (Sumi *et al*., ISTH, PP-WE148, Kyoto, 2009; Sumi et al., *New Food Industry*, 54, 12, 2011). Thrombolytic activity was measured by using the fibrin plate method. For vitamin K_2, the following procedures were carried out according to the method previously reported (Sumi *et al., Food Sci. Technol. Res*., 5, 48, 1999). Polyamine was measured through the using HPLC by the on-column method (Saito *et al., Anal. Sci*., 8, 675, 1992).
Results: Nattokinase contained in the 14 types of natto showed strong thrombolytic activity. For each product tested, the thrombolytic activity was neutralized with the antibody for nattokinase. BSB (borate saline buffer) at pH7.8 was used, and the nattokinase showed strong activity for the synthetic substrate I (Bz-Ile-Glu-(OR)-Gly-Arg-*pNA*). Because activity declined to less than half the level of the synthetic substrate II (Suc-Ala-Ala-Pro-Phe-*pNA*) used for comparison, the true enzymatic activity of nattokinase is believed to be at work. Potency was calculated at 1.12 ± 0.46 IU/g. Sublitisins, enzymes produced by *Bacillus subtilis* including ones for such industrial uses as cleaning and textile processing, show particularly strong activity for synthetic substrate II. The measured value of vitamin K_2 content was 12.19 μg/g on average, a little higher than expected. Polyamine content in natto was 4.06 ± 0.86 mg/100 g and in *Bacillus subtilis natto* was 66.53 ± 20.71 mg/100 g.
Summary/Conclusion: The production of nattokinase was shown through the lytic ability for the synthetic substrate Bz-Ile-Glu-(OR)-Gly-Arg-*pNA*. Each natto tested contained a large amount of vitamin K_2. The polyamine content in *Bacillus subtilis natto* was quite high at about 10 times the content in natto. Content as high as this was not observed in soybean paste or soy sauce, which are produced by a different microbe.

PO 405

Thrombotic risk factors in cirrhotic patients

Baccouche H[1], Labidi A[1], Kaabi H[2], Mahjoub S[1], Hsouna K[1], Fekih M[1], Slama H[2], Filali A[1] and Ben Romdhane N[1]
[1]Rabta Hospital; [2]National Blood Transfusion Center, Tunis, Tunisia

Background: Cirrhosis results in a complex pattern of defects in haemostatic functions with reduced synthesis of pro and anticoagulant

factors. As possible complication of coagulation disorders in cirrhosis, could be the development of arterial and venous thromboembolism (AVTE). The purpose of our study was to determine thrombotic risk factors in cirrhotic patients.

Methods: Fifty one cirrhotic patients were enrolled into a case control study. The presence of personal and familial history of AVTE were investigated. White blood cells, platelet count, prothrombine time, INR, albumin, urea, procoagulant factors (VIII, XII, VII, II, V) were determined. Level of antithrombin, protein C and protein S were measured (respectively STACHROM AT, STACLOT PC, STACLOT PS; DIAGNOSTICA STAGO). Search for factor V Leiden and prothrombin gene mutation (G20210A) were performed with PCR-RFLP. Anticardioloipin and antiB2glycoprotein antibodies were also investigated.

Results: Mean age was 56.8 years old (range16–86 years old). Sex ratio was 0.9. Among the 51 cirrhotic patients, 7 patients (13.7%) had experienced AVTE after cirrhosis diagnosis: deep venous thrombosis ($n = 2$), pulmonary embolism ($n = 1$), Budd Chiari syndrome ($n = 1$), portal thrombosis ($n = 3$). They were compared to 46 cirrhotic patients without thrombosis. No patient with AVTE had neither personal nor familial history of thrombosis. In an univariate analysis, white blood cell count and platelet count were significantly higher in patients with AVTE than other cirrhotic patients (respectively, 8795 vs. 5032/mm^3, $P < 0.018$ and 91133 vs. 154375/mm^3, $P = 0.03$) However, In a multivariate analysis only the platelet count was independently predictive of AVTE in cirrhotic patients ($P = 0.05$). White blood count was not an independent predictive factor of thrombosis in cirrhotic patients ($P = 0.07$). Moreover, prothrombin time, INR, albumin, urea, level of pro and anticoagulant factors were not statistically different in both groups. There was no link between the presence of Factor V Leiden, prothrombin gene mutation (G20210A), anticardiolipin and antiB2glycoprotein antibodies to thrombosis.

Conclusions: Approximately 13.7% of cirrhotic patients resulted in a thromboembolic event. Platelet count was predictive of increased risk of AVTE as it was supported by other studies. Understanding the factors predisposing to thrombosis in cirrhotic patients could play a role in identifying a subgroup of patients at high risk of thrombosis and making decisions regarding the utility of anticoagulation therapy.

PO 406

Unusual thrombosis and thrombophilia: a difficult problem to address: 4 years experience

Casas C[1], Buitrago L[2] and Solano MH[1]

[1]Hospital San José; [2]Fundación Universitaria de Ciencias de la Salud, Bogotá, Colombia

There are sites called vascular territories can present unusual thrombotic events: venous sinus, upper limbs and splanchnic with clinical consequences can be catastrophic.

Objective: To describe the frequency of thrombophilia in patients who present with thrombosis in unusual sites treated at the hematology service of Hospital San Jose, between January 2007 and December 2011. They describe the population in terms of demographics, gender, age, recurrence, and complications associated and treatments used.

Methods: This is a descriptive case series, patients older than 18 years with first thrombotic event that involves site vascular unusual, data were extracted of medical records retrospectively.

Results: Seventy-three patients entered the study, most women (65.8%), with a location in venous sinuses (47.9%), splachnic (24.0%), upper limb (27.4%), with risk factors for pregnancy frequently (12.5%), puerperium (4.2%), oral anovulatories consumption (10.4%), smoking (9.6%), thrombophilia was found in 57% of patients with thrombosis in unusual sites, the most frequent diagnosis of antiphospholipid syndrome.

Conclusions: There is a high frequency for thrombophilia in patients with thrombosis in unusual site, antiphospholipid syndrome being the most common in our series.

PO 407

New automated chromogenic assay for Protein C activity in Q Hemostasis Analyzer

Lambea E, Lebrero C, Muñoz M, Chiva A and Martorell D

Diagnostic Grifols, S.A., Parets del Vallès Barcelona, Spain

Background: Deficiency of the Protein C (PC) anticoagulant pathway is associated with an increased risk of venous thrombosis.

It is usually recommended to evaluate PC activity as a first step in the screening for thrombophilia. For this purpose, Grifols has developed a new automated PC chromogenic assay for use in Q *Hemostasis Analyzer*.

Aims: Evaluate the performance, robustness and sensitivity to interfering substances of a new chromogenic PC assay (DG-Chrom PC).

Methods: DG-Chrom PC assay is based on the activation of PC in plasma by a specific activator (extract from the *Agkistrodon contortrix contortrix* snake venom). The amount of functional PC in the sample is determined by the hydrolysis of a specific chromogenic substrate for APC.

Precision, Trueness, Linearity, Limit of Detection, Limit of Quantitation and Interferences have been performed in Q *Hemostasis Analyzer* following CLSI EP5-A2, CLSI EP15-A2, CLSI EP6-A, CLSI EP17-A and CLSI EP7-A2, respectively.

Results: For DG-Chrom PC no clinically significant interference was detected up to 2 IU/mL of heparin, 450 mg/dL of hemoglobin, 990 mg/dL of triglycerides and 30 mg/dL of bilirubin.

Robustness of the test DG-Chrom PC at different incubation times was demonstrated within a range between 150 and 360 s. Moreover, variations at different incubation temperatures (between 35 and 39 °C) did not affect PC results.

Precision (in terms of CV%) was assayed at three different levels ($n = 80$). For normal control plasma (100% PC) a within-lot precision of 2.3%, repeatability of 1.2% and a between-lot precision of 2.3% were obtained. For abnormal control plasma (40% PC) a within-lot precision of 2.5%, repeatability of 2.0% and a between-lot precision of 2.9% were obtained. For very low levels of PC (22% PC) a within-lot precision of 4.2%, repeatability of 3.0% and a between-lot precision of 3.6% were obtained.

DG-Chrom PC showed a good linearity between 0 and 150% of PC activity ($n = 5$) with a mean $r^2 = 0.9995$.

Trueness of DG-Chrom PC was evaluated ($n = 5$) using 2nd SSC plasma analysed at three dilutions. Undiluted 2nd SSC plasma (89% PC) generated a mean of 89.5% PC. At 44.5% PC level, the mean obtained was 47.1% and at 8.9% PC level, a mean of 8.9% was generated.

The limit of detection of DG-Chrom PC determined with a PC deficient plasma (Technoclone) was 2.3%. The limit of quantitation of the method was evaluated using 2nd SSC plasma ($n = 10$). DG-Chrom PC accurately measured PC level at 5.6% of PC.

Conclusion: The results obtained support the intended use of DG-Chrom PC assay in Q *Hemostasis Analyzer* as a valuable tool for measuring PC activity in citrated patient plasma samples.

PO 408

The level of β-thromboglobulin and thrombophilia

Matveeva MA[1], Shelest A[1], Popova LV[1], Patrushev LI[2] and Bokarev IN[1]

[1]I.M. Sechenov First Moscow State Medical University; [2]Shemyakin and Ovchinnikov Institute of Bioorganic Chemistry, Moscow, Russia

Background: B-thromboglobulin – is a protein located in the α-granules of platelets and is released into the bloodstream during platelet activation. β-thromboglobulin is a marker of activation of platelet hemostasis. Thrombophilia is defined as an inherited feature of an organism, which increases susceptibility to intravascular thrombus

formation in the absence of other diseases. It is known that the presence of thrombophilia affect plasma haemostasis. Influence of thrombophilia on platelet part of haemostasis has not studied yet.
The aim of our study was to investigate the effect of thrombophilia on platelet part of haemostasis.
Methods and Results: The study included 41 people with the presence of one or a combination of the following mutations: mutation Leiden, prothrombin gene mutation 20210A, a mutation in the genes of MTHFR and PAI-1. Of these, 29 women and 12 men. The control group included 11 healthy individuals with no of these mutations, including 7 women and 4 men. Mean age 35 ± 7.5 years. Inclusion criteria was the lack of thrombotic history and absence of inflammatory diseases at the time of blood sampling. Blood and urine in all subjects were normal.
All people have been identified β-thromboglobulin level (ELISA method, Stago Diagnostica).
Results: The level of beta-thromboglobulin was increased in 56.09% ($P < 0.05$) of people with thrombophilia. In the control group, increasing β-thromboglobulin was observed in 17.1% ($P < 0.05$).
Conclusion: Thus, thrombophilia affect platelet part of haemostasis.

PO 409

Thrombophilia as a cardiovascular risk factor for acute myocardial infarction in a young patient-case report

Pascalau L[1] and Pascalau A[2]
[1]Institute of Cardiovascular Diseases/University of Medicine and Pharmacy; [2]Emergency Clinical Hospital for Children Louis Turcanu, Timisoara, Romania

Background: Hereditary and acquired abnormalities in blood coagulation (hypercoagulation) may predispose for venous and arterial thrombosis. Arterial thrombotic pathology is currently the most important cause of mortality in adult patient; thrombotic arterial occlusion can involve very different territories: coroanarian, limb vessels, mesenteric arteries, cerebrale arteries.The most common is coronary thrombosis that causes acute myocardial infarction. Etiology is diverse, being hipercoagulability are relatively frequent, but rarely found.
Aim: We report a case of 27 years old male patient, with obesity grade 3, smoker of one packs of cigarettes per day, who was admited in our clinic at 30 h of onset of constrictive chest pain radiating to interscapulo-vertebral and left upper member and dyspnea.
Methods: For this case we use laboratory testes, ultrasound methods and coronary angiography.
Results: At admission:blood pressure 130/80 mmHg, heart rate 120b/min, enzymes of myocardial necrosis elevated, on electrocardiogram sinus rhythm, Q wave in V1-V5, ST segment elevation 3–4 mm in V2-V6 and 1–2 mm in DI, AVL.
Cardiac ultrasound: Left ventricle with normal size and significant changes in kinetics, akinesia of half-apical of interventricular septum, apical third of the inferior and anterior wall, basal hypokinesia of interventricular septum, EF = 40%;mild ischemic mitral regurgitation, left atrium dilated.
Angiocoronarography releved left coronary system dominant, left main coronary artery, left circumflex artery, right coronary artery without significant lesions, occlusion of proximal left anterior descending artery without visualization of distal territory; during intervention we observed massive thrombosis on left anterior descending artery until the apex, on a distance of 15–20 centimetres. Thrombus was aspirated repeatedly with an aspiration catheter, with a small amount of thrombus staying in the proximal left anterior descending artery. Then we stented the proximal left anterior descending artery. After stenting thrombus formation was observed proximal and distal to the stent, for which was performed proximal and distal stenting with good result. After five min we observed thrombus formation in the left main coronary artery, for which we performed thrombus aspiration, without succes, after which we stented from the left main coronary artery to the circumflex artery, with good result, without proximal or distal dissection, without residual stenosis, with miocardial blush grade 3.
Due to massive thrombosis in the left anterior descending artery and subsequent thrombosis occurred during the procedure, in the first day after stenting the pacient was investigated for hypercoagulation status. Screening of thrombophilia related hyperhomocysteinemia (homocysteine level = 19.12 μm/L), heterzozygote mutation of methylenetetrahydrofolate reductase A1298C and low level of antitrombin III.
Summary: Evolution under terapy was very well, wiht significant decrease of the markers of myocardial necrosis after 3 days. The patient was discharged after 8 days with dual antiagregation and oral anticoagulation therapy.
Conclusions: Inherited thrombophilia is a congenital tendency to thrombosis which may be manifested episodically usually in the presence of another predisposing factor. Thrombophilia induce a hypercoagulable state, which, with another cardiovascular risk factors, explain repeatedly arterial thrombosis during the interventional procedure at this young patient.

PO 410

Inherited thrombophilia – accidental discovery at patients with neoplastic diseases from III rd Pediatric Clinic, Department of Hematology Oncology and Bone Marrow Transplantation Timisoara

Pascalau A[1], Arghirescu S[2], Oprisoni A[2], Isac A[1], Ciocirlie O[2], Zoica B[2], Balan AM[2], Jinca C[2] and Serban M[1]
[1]Emergency Clinical Hospital for Children Louis Turcanu; [2]University of Medicine and Pharmacy 'Victor Babes', Timisoara, Romania

Background: Inherited thrombophilia is a genetic tendency to venous thrombosis. Many thrombotic episodes occur in association with other identifiable risk factors (pregnancy, oral contraceptives, surgery, cancer). Screening for thrombophilia is recommended for people at high risk of thrombotic events.
Aim: We report four cases of patients aged 6–19 years with inherited trombophilia and cancer.
Methods: Hypercoagulation status was provided with laboratory testes and imagistics methods (Doppler ultrasound, angio magnetic resonance imaging).
Results: Case 1: Boy,19 years, acute lymphoblastic leukemia phenotype B; during chemotherapy he developed deep vein thrombosis on common femoral vein over a distance of 10–15 centimetres, 3 weeks after insertion of tha central venous catheter on the right femoral vein. Anticoagulant therapy was initiated with heparin sodium. In the present is under oral anticoagulant. Screening for thrombophilia: heterozygous mutation for methylenetetrahydrofolate reductase C677T and A1298C, moderate hyperhomocysteinemia (Homocysteine = 21.74 mM).
Case 2: Girl, 6 years, acute lymphoblastic leukemia phenotype B.Cardiological evaluation showed on electrocardiogram sinus arrhythmia, ST segment depression in V5-V6, T wave negative in DII, DIII, aVF and all precordial leads, EF = 46%, with markers of myocardial necrosis negative. Screening for thrombophilia: heterozygous mutation for methylenetetrahydrofolate reductase C677T and A1298C, moderate hyperhomocysteinemia. (Homocysteine = 12.71 mM). Chemotherapy was initiated and was started heparin therapy prophylaxis. A few h after starting heparin, the massive macular hemorrhage preretinian in left eye appeared. We stopped the heparin; in evolution -without acute thrombotic events, currently maintains branches of the catheter with alternative heparin administration in very low doses, daily.
Case 3:Girl 19 years, Hodgkin lymphoma stage IV, second relapse, with deep venous thrombosis on left subclavian and cephalic vein, under anticoagulation therapy. We performed two apheresis procedures, central venous catheter was mentained on right femoral vein for thirty h, under anticoagulant therapy. After removal of the catheter,

she developed partial thrombosis on the left femoral vein, full thrombosis on the right femoral vein.Screening for thrombophilia: heterozygous mutation for methylenetetrahydrofolate reductase C677T and A1298C, moderate hyperhomocysteinemia. (Homocysteine = 15, 0.27 mM).Therapy was initiated with heparin sodium;in the present she is at six mounths after autologous bone marrow transplantation, under oral anticoagulant therapy, in well condition.

Case 4: Boy,11 years, Hodgkin lymphoma stage III A, second relapse and autologous bone marrow transplantation. Three months he had catheter on right subclavian vein with prophylactic heparin therapy. Fourteen days after removal the catheter, Doppler ultrasound showed partial thrombosis of left internal jugular vein. Screening for thrombophilia:, methylenetetrahydrofolate reductase A1298C heterozigot, moderate hyper homocysteinemia (Homocysteine = 15.27 mM).

Summary/Conclusion: Three of four patients developed deep vein thrombosis and we evaluated the genetic risk for thrombosis. All the patients have hyperhomocysteinemia and heterozygous mutations of methylenetetrahydrofolate reductase and they received anticoagulant therapy. The presence of central venous catheter in all the patients was a risk factor for the occurrence of thrombosis, in association with hypercoagulability status of the neoplastic disease and L-asparaginase.

PO 411

The intensity of the intravascular coagulation and thrombophilia

Popova LV[1], Matveeva MA[1], Shelest A[1], Patrushev LI[2] and Bokarev IN[1]

[1]I.M. Sechenov First Moscow State Medical University; [2]Shemyakin and Ovchinnikov Institute of Bioorganic Chemistry, Moscow, Russia

Background: Intravascular coagulation in the human body is constantly. Change in the intensity of blood coagulation is observed in various pathological conditions. Thrombophilia is defined as a feature of an organism that determines its increased risk of thrombosiss in the intravascular normal situations, in the absence of other diseases and often are inherited. Currently it's unknown what changes are observed intravascular coagulation in patients with thrombophilia.

Aim: The aim of our study was to determine the intensity of the intravascular microcoagulation in healthy individuals with thrombophilia.

Methods: The study included 41 healthy people, including 29 women and 12 men. All people had a mutation or a combination of mutations such as Leiden mutation, prothrombin gene mutation 20210A, a mutation in the genes of MTHFR and PAI-1. The average age was 35 ± 7.5. As inclusion criteria ware the lack of a history of thrombosis and the absence of inflammatory disease at the time of blood sampling. Blood and urine in all subjects were normal.

By studying the intensity of intravascular blood microcoagulation to determine the degree of platelet activation we measured the level of beta-thromboglobulin (ELISA method, Stago Diagnostica). To determine the level of procoagulant activity and fibrin formation we measured the level of D-dimer (ELISA method, Technoclone). Was also investigated ADAMTS-13 (ELISA method, Technoclone) as a possible factor in increasing the intensity of the intravascular coagulation.

Results: All people had a normal ADAMTS-13 and D-dimer levels. As for beta-thromboglobulin, it was increased in 56.09% ($P < 0.05$) of person with thrombophilia.

Conclusion: Thus, we can conclude that thrombophilia increase the intensity of intravascular coagulation, which is manifested by increased activity of platelet hemostasis. The fact that the final link of blood coagulation, in particular D-dimer remained normal, confirms the assertion that for the manifestation of thrombophilia person need to have additional triggers.

PO 412

Plasminogen activator inhibitor type 1 (PAI-1) level and activity at patients with PAI-1 polymorphism

Shelest A[1], Matveeva MA[1], Popova LV[1], Patrushev LI[2], Shuganov EG[1], Gneusheva TY[1] and Bokarev IN[1]

[1]I.M. Sechenov First Moscow State Medical University (MSMU), Moscow, Russia; [2]Shemyakin and Ovchinnikov Institute of Bioorganic Chemistry, Moscow, Russia, Moscow, Russia

Plasminogen activator inhibitor type 1(PAI-1 or SERPINE-1) is an important component of the coagulation system that functions as the principal inhibitor of tissue and urokinase plasminogen activators (tPA, uPA) and hence fibrinolysis that degrades blood clots. It is possible, that PAI-1 plays an important role in determining predisposition to cardiovascular disease.

The PAI-1 gene is located on chromosome 7 (7q21.3-q22). There is a common polymorphism known as 4G/5G in the promoter region. The 5G allele is slightly less transcriptionally active than the 4G. The man has two copies of each gene (one from the mother and one from the father) in a population and as a result three different genotypes are possible: 5G/5G, 5G/4G, 4G/4G. It was found that people with 4G/4G variant has much higher concentration of PAI-1 than people with 5G/5G and 5G/4G, which may increase the risk of blood clots.

Objective: To assess PAI-1 level and activity at healthy patients with PAI-1 polymorphism.

Materials and Methods: The study included 39 practically healthy people. PAI-1 polymorphism was found at 32, among them 8 men and 24 women. The middle age was 32.3 years. The PAI-1 antigen and activity was assessed by ELISA method, Tehnoclone (Austria). The *PAI-1 polymorphism* was determined by polymerase chain reaction (*PCR*).

Results: Thirty-two (82%) of investigated people had PAI-1 polymorphism 5G/4G, 4G/4G, among them 12 homozygotes and 20 heterozygous. There was no high antigen level in both groups. Only three individuals (15%) among heterozygous had high activity of PAI-1. Among homozygotes there was no increasing of it.

Conclusions: It is possible to think, that 5G/4G, 4G/4G PAI-1 polymorphism doesn't increase the antigen level and activity of PAI-1 and doesn't lead to thrombosis. So we think, that some other triggers and conditions influence on the intensity of the intravascular coagulation and increase it.

PO 413

Observational analysis of genetic risk factors in patients with a documented diagnosis of cerebral sinus vein thrombosis

Vaccarella G[1], Napolitano M[1], Saccullo G[1], Malato A[2] and Siragusa S[1]

[1]University of Palermo; [2]Ospedale 'Cervello', Palermo, Italy

Background: In industrialized countries, the cerebral sinus vein thrombosis (SCVT) is most often aseptic and it can be observed in all the following settings: surgery, obstetric-gynecology and medicine. SCVT can particularly occur in postoperative period and puerperium, both contexts characterized by hyperfibrinogenemia and thrombocythemia. In addition, in SCVT the use of birth control pills is often imputed as a risk factor. However, the etiology of this disease remains indefinite in 25–35% of cases.

Aims: The objective of this study was to retrospectively analyze the relationship between factor V Leiden, prothrombin G20210A mutation (PT 20210A), MTHR and the occurrence of SCVT.

Methods: The study has included 20 patients with a diagnosis of SCVT instrumentally performed between 2002 and 2012. We determined the mutational status of factor V Leiden, Prothrombin (PT) G20210A and C677T and A1298C of MetilenTetraHydropholateReductaase (MTHFR) in each enrolled patient. We performed a comparative analysis of mutations found in patients with a diagnosis of cerebral sinus

thrombosis compared with a population of unselected patients without venous thrombosis.

Results: The distribution of mutational status in the genetic analysis performed in the enrolled patients was as follows: Wild type for Factor V Leiden, Factor II and MTHFR: 19%.Factor VLeiden: 15% heterozygote and 0.5% homozygote in cases and only 2- 3% and 0.02% respectively in control group (European unselected patients for venous thrombosis).Heterozygous for PT G20210A mutation: 20% in patients and 3–5% in control group. Mutation of the MTHR C677T and A1298C: 45% heterozygote for C677T and 10.5% double heterozygote for C677T and A1298C in cases. In the control group, the mutation C677T was not statistically different from cases, on the contrary a double heterozygote mutation for C677T and A1298C was 1.5%.

Conclusions: The presence of factor V Leiden and PT 20210A are known risk factors for SCVT. The single mutation of C677T of MTHFR does not represent a risk factor for the disease because it has the same prevalence in the normal population. Instead, the coexistence of a double mutation in MTHFR (C677T and A1298C) can be considered a risk factor, as the mutations of the factor V and factor II. The coexistence of a double mutation of MTHFR is associated an increased relative risk for venous thromboembolism in the examined population.

PO 414

About hemostasis system genes polymorphisms in patients with acute ischemic stroke

Vorobyeva NA and Shemakina N

NSMU, Arckhangelsk, Russia

At the modern stage of clinical medicine development a reasonable view on multifactorial nature of congenital predisposition to rapid atherothrombosis progression is formed.

Materials and methods. The research was performed on group of patients (n = 117) with clinical manifestations of ischemic stroke against the background of multifocal atherothrombosis, who underwent surgical brain revascularization (carotid endarterectomy). SPSS for Windows (13.0) software was used for mathematical processing of the research results.

Methods: Cluster analysis of studied genes was performed to investigate the proximity degree of studied polymorphisms. We have studied different mathematic models describing different combinations of hemostasis system genetic polymorphisms. The first cluster united homozygous polymorphisms PAI-1 -675 4G/4G, FGB 455 A/A and heterozygous polymorphism ApoE 28 L/P. It's important that 72% of patients with acute ischemic stroke in anamnesis belonged to the second cluster which united 5 gene variants: MTHFR 677 C/T, PAI-1 675 4G/5G, FBG 455 G/A, GpIIIa PIA1/A2 and ApoE. The third cluster included 22% of patients with acute ischemic stroke in anamnesis and united 6 genotype variants: MTHFR 677 C/T, PAI-1 675 4G/5G, FBG 455 G/A, GpIIIa PIA1/A2, ApoE and FV 1691 G/A.

Conclusion: We revealed significant spread of prothrombotic polymorphisms against the background of atherothrombotic affection of brachiocephalic artery in MTHFR, PAI-1, APOE and GpIIIa genes. It is associated with high risk of atherothrombosis and its complication (brachiocephalic artery thrombosis). At the modern stage of clinical medicine development a reasonable view on multifactorial nature of congenital predisposition to rapid atherothrombosis progression is formed.

Materials and methods. The research was performed on group of patients (n = 117) with clinical manifestations of ischemic stroke against the background of multifocal atherothrombosis, who underwent surgical brain revascularization (carotid endarterectomy). SPSS for Windows (13.0) software was used for mathematical processing of the research results.

The third cluster included 22% of patients with acute ischemic stroke in anamnesis and united 6 genotype variants: MTHFR 677 C/T, PAI-1 675 4G/5G, FBG 455 G/A, GpIIIa PIA1/A2, ApoE and FV 1691 G/A.

Conclusion: We revealed significant spread of prothrombotic polymorphisms against the background of atherothrombotic affection of brachiocephalic artery in MTHFR, PAI-1, APOE and GpIIIa genes. It is associated with high risk of atherothrombosis and its complication (brachiocephalic artery thrombosis).

PO 415

VKORC1 gen polimorphisms distribution features in native population of European Russia

Vorobyeva NA, Lavrinov PA, Belova N, Rogozina AS and Vorobyeva AI

NSMU, Arckhangelsk, Russia

The aims of the research are: reveal VKORC1 gen polimorphisms distribution features in native population of European Russia Far North; determine incidence of C1173T and G3730A polymorphisms of VKORC1 gen in Nenets Autonomous District; compare received data with C1173T and G3730A polymorphisms of VKORC1 gen incidence in population of European North of Russia.

Materials and methods. The number of investigated samples was 88. The object was genomic DNA received from peripheral venous blood leukocytes. Genotyping was held with the use of polymerase chain reaction with allel-specific primers and electrophoretic detection in agarose gel.

Results and discussion. Polymorph allel 1173T of VKORC1 gen was found in 76.1% of participants and allel 3730A – in 53.2%. VKORC1 gen polymorphisms incidence in native population of European Russia Far North differs from those in population of European North of Russia. The most widely spread allel is 1173T (76.1%). In people with T/T genotype synthesis speed and concentration of vitamin K epoxide reductase are minimal. In people with VKORC1 1173 C/C genotype the enzyme activity is the highest and hypercoagulation risk is increased. Polymorphism 3730 A/A also increase enzyme activity and hypercoagulation tendency.

Investigation of VKORC1 gen polymorphisms incidence in particular populations and thrombosis risk analysis in different regions will allow more efficient prevention of thrombosis-associated diseases and pregnancy problems.

PO 416

The difference of homocysteine plasma in acute myocardial infarction depending on genetic polymorphisms of the enzyme methyltetrahydrofolatreductaza

Vorobyeva NA and Muchina PN

NSMU, Arckhangelsk, Russia

The risk of acute myocardial infarction (AMI) depending on hyperhomocysteinemia (HHC) increases by 3–4 times. The main reason for HHC is a genetic defect of the enzyme MTGFR.

Materials and Methods: To study the difference of HC plasma at the 1th and 14th days of AMI, depending on the genetic polymorphism MTGFR. Patients of 70 years old and younger (n = 40) suffering from AMI. To process the received data the SPSS 18.0 software package for Windows has been used.

The results. The level of HC at the first day of AMI was Me 24.4 [15.7, 28.6] mM. It was higher than normal values at the all patients. A 27.5% of patients had heterozygous polymorphism (GT) in the gene for the enzyme MTGFR, 12.5% of patients had homozygous polymorphism (TT). The level of HC in the group with allele (TT) was higher than that of other patients at the 1th ($P = 0.028$) and at the 14th days of AMI ($P = 0.001$). The correlation was detected between (TT) allelic variant and the level of HC at the 1th day ($r = 0.534$, $P = 0.001$) and at the 14th day ($r = 0.314$, p = 0.048).

Conclusions: Patients with homozygous polymorphisms MTGFR have higher levels of HC in both acute and subacute stage in AMI, which is an additional risk factor for adverse thrombotic events.

PO 417

MTHFR C677T and A1298C as a hyperhomocysteinemia risk factor in native population of Nenets Autonomous District

Vorobyeva NA, Lavrinov PA and Belova N

NSMU, Arckhangelsk, Russia

In the metabolic processes study and many common diseases preventing a human ethnic origin should be taken into consideration. Cardiovascular diseases risk factors study and the development of early preventive measures are of particular topicality.

Aim: to investigate the prevalence of methylenetetrahydrofolate reductase gene polymorphisms MTHFR C677T and A1298C (associated with hyperhomocysteinemia risk), the level of homocysteine in blood and lifestyle of the Nenets Autonomous District (NAD) population.

Materials and methods.

Design: One-moment population-based investigation of native population (nenets) from different settlements. Inclusion criteria: nenets ethnicity; constant residence in NAD; presence of informed consent. The study approved by the NSMU local ethics committee (protocol №6, 8.06.2011). Questioning – data on diet, smoking, alcohol intake from survey respondents ($n = 226$). The homocysteine level in the blood serum ($n = 90$) was determined by solid-phase ELISA using reagents Axis Shield Diagnostics Ltd. Identification of polymorphisms MTHFR C677T ($n = 121$) and A1298C ($n = 90$) was performed in CSRL of NSMU. Genome DNA received from peripheral venous blood leukocytes was used in PCR molecular genetic analysis with allele-specific primers with detection by agarose gel electrophoresis.

Results: The age of the study sample Me = 42 [30;51] years, Me = 46 [35;54] for female and Me = 41 [37;49.5] for male.

Among the modifiable risk factors of hyperhomocysteinemia smoking (25%) and alcohol intake (51%) were present. In smoking men 52% smoke more than one cigarette pack per day. In smoking women 36.7% smoke more one cigarette pack and 41.7% half of a pack per day.

Alcohol is taken more often than once a month by 22% of women and 60.8% of men (average age 42.75 ± 11.59 and 42.91 ± 10.15 years respectively).

Homocysteine level was determined in 90 nenets. By to the results they were divided into three groups according to thrombosis risk (Shmeleva V, 2008): < 10.5 nkM (normal amount), 10.5–13.5 mkM (thrombosis risk increased 1,3–3 times) and more than 13.5 mkM (thrombosis risk increased 3–5 times). The results were following: 8.07 [7.2;9.3] for the 1st group ($n = 28$), 11.5 [11.2;12.0] for the 2nd group ($n = 22$) and 17.2 [14.6;19.8] for the 3rd group ($n = 40$).

Frequency of T677T polymorphism in nenets population significantly less than in Russian population in Tomsk ($\chi 2 = 10.59$, $P = 0.001$). A1298C polymorphism frequency significantly differ in compared populations ($\chi 2 = 6.17$, $P = 0.01$).

Assessment of interlinkages of homocysteine level in the blood serum with different allelic MTHFR gene variants carriage was performed using Kruskal-Wallace test ($P = 0.05$). No significant differences were revealed: 0.066 for MTHFR C677T and 0.531 for MTHFR A1298C.

We revealed a high percentage of hyperhomocysteinemia in nenets population. It should be in connection with external modifiable factors.

PO 418

The value of hyperhomocysteinemia on the severity of acute myocardial infarction

Vorobyeva NA, Muchina PN and Vorobyeva AI

NSMU, Arckhangelsk, Russia

The risk of acute myocardial infarction (AMI) depending on hyperhomocysteinemia (HHC) increases by 3–4 times. The main reason of HHC is genetic defects of enzymes responsible for the metabolism of HC, in particular methyltetrahydrofolatreductaza (MTHFR).

The Objective: To study the impact of hyperhomocysteinemia and genetic polymorphisms in the gene methyltetrahydrofolatreductaza (MTGFR) on the severity of acute myocardial infarction.

Materials and Methods: Patients of 70 years old and younger ($n = 40$) suffering from AMI who were hospitalized at the cardio intensive care unit of the 1stCityClinicalHospital from 09.01.2010 to 31.12.2010. Diabetes, rheumatism, systemic diseases, blood diseases were the exclusion criteria. Plasma levels of HC by enzyme immunoassay were determined at 1 and 14 days of AMI. Genetic polymorphism of the enzyme were identified in the laboratory MTGFR human genom NSMU. To process the received data the SPSS 18.0 software package for Windows has been used. The age span of the examined patients was Me 55 [45.0;60.25].

Methods: The level of HC at the first day of AMI was Me 24.4 [15.7, 28.6] mM. The level of HC at the 14th day was Me 21,4 [15;27]. It was higher than normal values. A 27.5% of patients ($n = 11$) had heterozygous polymorphism (allele GT) in the gene for the enzyme MTGFR, 12.5% of patients ($n = 5$) had homozygous polymorphism (allele TT). The level of HC in the group with allele (TT) was higher than that of other patients at the 1th ($P = 0.028$) and at the 14th days of AMI ($P = 0.001$). The correlation was detected between (TT) allelic variant and the level of HC at the 1th day ($r = 0.534$, $P = 0.001$) and at the 14th day ($r = 0.314$, $P = 0.048$). Long-term results were studed during the period of 1 year after AMI. The end points was: the development of unstable angina, ischemic stroke, re-infarction, recurrent episodes of revascularization, death from coronary heart disease. The correlation was detected between (CT) allelic variant and frequency of repeat stenting in the second half of the observation ($r = 0.453$, $P = 0.003$). The correlation was detected between (TT) allelic variant and frequency of repeat stenting in the first half of the observation ($r = 0.466$, $P = 0.005$). The correlation was detected between (CT) allelic variant and the incidence of unstable angina pectoris in the 2nd half-year of observation ($r = 0.640$, $P = 0.0001$). The correlation was detected between (TT) allelic variant and the development of re-infarction during the first 6 months of observation ($r = 0.466$, $P = 0.002$).

Conclusions: Patients with homozygous polymorphisms MTGFR have higher levels of HC in both acute and subacute stage in AMI, which is an additional risk factor for adverse thrombotic events. Relationship was found between the presence of polymorphism in the MTHFR gene and the incidence of recurrent cardiovascular events. Thus, in patients with allele (CT), there is a high incidence of repeated revascularization, mostly in the 2nd half-year of observation, while having the allele (TT) – in the first half.

PO 419

Allicin inhibits tissue factor expression in thrombin-induced endothelial cells by blocking MAPK and NF-?B

Li J, Gao F, Zhu W and Zhou P

Xiangya Third Hospital, Central South University, Changsha, China

Background: Inflammation and resultant oxidative stress play great roles in cardiovascular disease. Regulation of inflammatory reactants is an important strategy to improve the outcome of cardiovascular patients. Allicin is the major biologically active component of garlic and manifests hypolipidemic, antiplatelet, and procirculatory effects.
Aims: The objectives of this study were to investigated mechanisms underlying the modulatory effects of Allicin on tissue factor (TF) in endothelial cells.
Methods: HUVECs were treated with or without Allicin for 24 h before exposure to thrombin for 4 h. TF gene and protein expressions were determined by RT-PCR and ELISA. Cell viability was determined by methyl thiazoyltetrazolium (MTT) assay. Phosphorylation of ERK, JNK and p38 were examined by western blotting.
Results: Preincubation of endothelial cells with Allicin dose-dependently inhibited thrombin-induced mRNA and protein expression of TF. Thrombin-induced phosprylation of mitogen-activated protein kinase (MAPK), including ERK, JNK, and P38, were mitigated by Allicin. Activation of NF-κB stimulated by thrombin were also suppressed by Allicin.
Conclusions: Allicin can modulate the responsiveness of endothelial cells to thrombin through inactivation of NF-κB and MAPK pathways, which may explain the ability of Allicin to suppress inflammation in cardiovascular diseases.

PO 420

At equivalent biologic units, commercially available prothrombin complexes are not the same: differential generation of thrombin and factor Xa upon tissue factor mediated activation

Only A, Cunanan J, Hoppensteadt D, Kahn D, Sadeghi N and Fareed J

Loyola University Medical Center, Maywood, USA

Introduction: Commercially available prothrombin complex concentrates (PCCs) are used in the management of bleeding in patients with both oral anticoagulant associated and deficiency of the synthesis of Vitamin K dependent coagulation factors (II, VII, IX, X) associated bleeding. Currently, several PCCs such as Beriplex, Cofact, Octaplex, Prothromplex, and Profiline are available. An activated PCC preparation (FEIBA) is also available. The purpose of this study was to compare the TF mediated generation of thrombin and factor Xa in various.
Methods: Commercially available PCCs were diluted in saline and 5% human albumin to obtain working solutions of 1.25–10 U/ml. A recombinant thromboplastin preparation (Innovin) was used to trigger protease generation which was measured using chromogenic substrate and fluorogenic substrate based assays.
Results: Each of the PCCs produced varying amounts of factor Xa and thrombin in a concentration dependent fashion. Cofact and Octaplex produced relatively stronger effects. In the fluorometric assays, wide variations in the generation of thrombin were noted among various PCCs. Both Cofact and Octaplex produced much higher amounts of thrombin (> 500 nM/unit), where as Prothromplex and Profiline produced < 100 nM/unit. Beriplex was also weaker and produced 200 nM/unit.
Discussion: These results demonstrate that despite unit equivalence for factor IX, various PCCs are capable of generating different amounts of factor Xa and thrombin on TF activation. The marked differences in the generation of thrombin may be due not only to composition but also to the presence of adjunctive antithrombin and heparin. Each of the different PCCs exhibits its own homeostatic profile and therefore these homeostatic agents are not interchangeable for such an indication. Each agent should be considered individually and pre-clinical and clinical data may be needed to demonstrate their relative efficacy in bleeding complications.

PO 421

Influence of D-1208I gene polymorphism on tissue factor expression in healthy and influenza

Petrov A, Petrova O and Vitkovsky Y

Chita medical academy, Chita, Russia

Background: Tissue factor (TF) plays the key role in the development of thrombosis. Influence of D-1208I polymorphism on the function of TF is poorly studied.
Aim: Was to study the effect of D-1208I polymorphism on TF expression by blood monocytes and lung macrophages.
Methods: there were 84 healthy volunteers under observation (42 men and 42 women). The mean age was 37 ± 11 years.
To assess the expression of TF by lung tissue macrophages a material of 20 patients who died of influenza A H1N1 in 2009 was used. The mean age of these patients was 40 ± 14 years (6 men and 14 women). Infection was laboratory confirmed by PCR. The cause of death in these patients were pulmonary embolism (8 people) and respiratory distress syndrome (12 people). All subjects of research were Russian, who was born and resident in the Transbaikalia. Genetic polymorphisms were determined by PCR. To study the TF expression the whole blood samples were cultured during 4 h in presence of LPS and without it and their re-calcification time were measured by impedance coagulometer. The TF expression was estimated by the degree of reduction of coagulation time, expressed as a percentage according to the formula: (t1–t2) × 100%/t1, where: t1 – unstimulated blood clotting time; t2 – stimulated blood clotting time. Lung macrophage TF expression was studied The lung tissue, that was obtained at autopsy from patients who died of complications of influenza A (H1N1) in October-December 2009 in the Transbaikalia, was used as a material. Assessment of TF expression by lung macrophages were determined by immunohistochemistry (TF9-10H10, Santa Cruz Biotechnology, USA). The lung tissue, that was obtained at autopsy from patients who died of complications of influenza A (H1N1) in October-December 2009 in the Transbaikalia, was used as a material. Statistical processing was performed using *t*-test and *U*-test.
Results: It was revealed that the prevalence of TF D-1208I polymorphism among healthy individuals and in patients with lethal influenza A H1N1 did not differ. A 27.4% of the healthy volunteers and 35.0% of patients had DD genotype. A 52.2% and 40.0% of healthy patients – DI genotype. A 21.4% and 25.0% of healthy patients – II genotype. It was established that monocytic TF expression was 179.4 ± 66.2% in a group of volunteers. TF expression of heterozygous was a decreased in comparison with homozygous (198.6 ± 72.9% and 160.1 ± 53.0%, respectively, *t*-test, $P = 0.007$). It was revealed that the TF expression by lung macrophages at D-1208I heterozygous and homozygous patients died from influenza complication differed. The average value of TF expression index was 6 points in the group of heterozygous patients, while in the group of homozygous – 11.1 points (*U*-test, $P = 0.016$).
Conclusion: D-1208I polymorphism heterozygous have shown to reduce the levels of macrophagic and monocytic TF expression, compared to homozygous.

PO 422

Mycophenolate mofetil for treatment of relapsed, refractory thrombotic thrombocytopenic purpura

Wang A[1], Wu J[1], Ding K[1], Liu X[1], Sun Z[1], Su J[2], Yu Z[2] and Ruan C[2]

[1]Anhui Provincial Hospital Affiliated to Anhui Medical University, Hefei; [2]Jiangsu Institute of Hematology, Suzhou, China

Background: Thrombotic thrombocytopenic purpura (TTP) is a rare life-threatening disease. Plasma therapy has dramatically decreased the mortality rate from 90% to less than 10% for TTP patients. In many TTP patients, prolonged Plasma therapy and Immunosuppressive agents (corticosteroids, rituximab, and high-dose intravenous immunoglobulin) is required to achieve remission, however, about one-third of acquired TTP patients still relapse with ADAMTS13 deficiency. Mycophenolate mofetil (MMF), an immunosuppressive agent, has been recently reported to treat for relapsed, refractory TTP patients. The efficacy and safety of MMF is still unknown.
Aims: our study is aim to observe the efficacy and safety of MMF for relapsed, refractory TTP patients.
Methods: We present a case of multiply relapsing TTP which was refractory to many of the treatment modalities mentioned above; and failed a course of rituximab. Then mycophenolate mofetil (100 mg per day) was used with plasma therapy for the patient, the patient were continuing 22 monthly follow-up. ADAMTS13 activity, inhibitor of ADAMTS13, platelet counts and LDH levels were monitored at each visit in conjunction with routine laboratory parameters.
Results: Remission was achieved with mycophenolate mofetil aiming to maintain remission. Seven months later, the patient relapsed after reduction in MMF dose (50 mg per day), platelet counts dropped to 48×10^9/L, A second remission was achieved by plasma therapy combination with MMF (100 mg per day). MMF was continued concomitantly with dose of 100 mg per day. Then the patient was again sustained remission. MMF was very well tolerated in the patient. The patient remains relapse-free survival for 1.5 years. However, it is interesting that ADAMTS13 activity is always less then 5%, and an inhibitor of ADAMTS13 is also detected Whether or not the patient is in remission. And platelet counts was always normal when remission.
Conclusions: Our study suggests that MMF may be a choice for relapsed and refractory TTP patients. Further studies are still needed to confirm the efficacy, while the mechanism of long-term remission for MMF in the patient is remain unclear.

PO 423

Diagnosis of Von Willebrand disease: use of bleeding score

Benlaldj D, Khachaa B, Mouadene A, Moulasserdoun K, Rahal MC and Seghier F

University hospital of Oran, Oran, Algeria

Background: The bleeding score was proposed, to standardised a collection of the bleeding history and use them in diagnosis of bleeding disorders.
Aims: The aims were to assess the bleeding score, in patients previously diagnosed with Von Willebrand disease (VWD).
Methods: The bleeding symptoms of 37 patients with VWD and 30 subjects without any bleeding disorders (15 women and 15 men) were assessed retrospectively using a standardised bleeding questionnary (Tosseto, 2006).
The bleeding score ranged from a minimum of -3 (no symptoms) to a maximum of 45 (blood transfusion or replacement therapy).
Results: In normal subjects, the mean bleeding score was 0.7 (range 0 to 3).
In 37 patients with VWD, the mean bleeding score was 6.9 (range 3 to 15).
In 15 patients with VWD type 1, the mean bleeding score was 5.8 (range 3 to 9).
In 13 patients with VWD type 2, the mean bleeding score was 5.7 (range 3 to 10).
In 09 patients with VWD type 3, the mean bleeding score was 9.4 (range 6 to 15).
The use of bleeding score greater than 3 as a screening test for VWD has a sensitivity of 81% and specificity of 100%.
Conclusion: The bleeding score is a useful clinical tool for the identification of a possible VWD and evaluated a bleeding tendency to indicate a prophilactic therapy.

PO 424

A simplified assay for von Willebrand factor multimers analysis

Bonnefoy A, Fontaine A, Lafayette MG, Dubois C, Cormier A and Rivard GE

CHU Sainte-Justine, Montreal, Canada

Background: Von Willebrand Disease (vWD) is the most common bleeding disorder, affecting up to 1% of some selected populations. Analysis of von Willebrand Factor (vWF) multimers is essential to classify vWD subtypes. The procedure remains highly specialized, labour-intensive, and inaccessible to most clinical laboratories.
Aims: Our objective was to develop a simple vWF multimers assay for routine analysis, with no compromise on quality.
Methods: Plasmas from patients with type I, II or III vWD and a pool of normal plasmas were used as qualitative internal controls.
We used 1.1% or 1.4% agarose in TRIS HCl pH 8.8, SDS 0.1% for resolving gels and 0.8% agarose in TRIS HCl pH 6.8, SDS 0.1% for staking gels. Gels were sequentially poured into an horizontal DNA electrophoresis unit, and plasma samples in TRIS buffer, EDTA 8 mM, SDS 1.6% urea 6.4 M, pH 6.8 were subjected to electrophoresis at 35V overnight at room temperature, in TRIS 0.05M, Glycine 0.384 M, SDS 0.1%, pH 8.35). The gels were then washed in TRIS buffer Saline containing Tween 20, and proteins were transferred onto nitrocellulose using a semi-dry high-speed transfer apparatus (Trans-Blot® Turbo[TRADEMARK] Bio-Rad) for 10 min at 12V with ready-to-use transfer packs. vWF multimers were revealed directly on nitrocellulose membranes using a rabbit polyclonal anti-human vWF-HRP antibody and 4-chloro-1-naphthol as substrate in TRIS0.05 M, pH 7.4, ethanol 15%.
Results: The assay was completed within 24 h, including overnight electrophoresis. The use of an inexpensive horizontal DNA electrophoresis system was particularly convenient to promptly cast the gels, and load up to 44 plasma samples (within 2 h). Semi-dry high speed transfer with ready-to-use transfer pack and direct staining of the nitrocellulose membrane further shortened the assay procedure and enabled a surprisingly good recovery of high molecular weight vWF multimers (HMW vWF) on the membrane, with a resolving power of up to 20 mers. Consistent intra- and inter-assay reproducibility was obtained, enabling unambiguous detection of HMW vWF deficiency in the plasma of type IIA and IIB VWD patients and normal distribution but reduced concentration of vWF multimers in Type I vWD patients.
Summary/Conclusions: By choosing simple technical options, we developed a rapid, reliable and cost-effective vWF multimers assay easily transposable to clinical laboratories.

PO 425

A de novo type 2A von Willebrand factor mutation (Ser1517Arg)

Castaman G[1], Giacomelli S[1] and Coppola A[2]

[1]San Bortolo Hospital, Vicenza; [2]University Federico II, Napoli, Italy

Background: De novo heterozygous mutations have been rarely reported in von Willebrand disease (VWD).
Aim: We report here a novel de novo VWF mutation.
Methods: A 3-year old boy was referred for severe bleeding from a tonsil. A severe reduction of FVIII and von Willebrand factor was observed (FVIII:C 15 U/dL; VWF:Ag 15 U/dL; VWF:RCo < 3 U/dL). An abnormal VWF:RCo/VWF:Ag ratio was evident suggesting the diagnosis of type 2. Bleeding promptly stopped after administration of VWF/FVIII concentrate. A few months later a severe post-traumatic epistaxis occurred, again controlled with replacement therapy. The parents were asymptomatic and had clearly normal FVIII and VWF measurements. All exons and intron-exon boundaries of VWF gene were sequenced in the propositus and a novel heterozygous c.4551 C>A mutation was identified predicting a Ser1517Arg mutation in the A2 domain of VWF protein. This change was not present in the parents, although the coinheritance of VWF haplotype was evident. The mutation was subsequently identified also in a single patient from Southern Italy, with significant bleeding history and similar FVIII/VWF levels.
Conclusions: De novo mutations are important to be identified by VWF gene sequencing since the typical autosomal dominant inheritance is not evident in the family and the phenotype is not in keeping with a true recessive disorder. This also is relevant to predict the risk of additional affected offspring in the same family.

PO 426

The first successful treatment of trauma in von Willebrand disease with a specific von Willebrand Factor Concentrate (VWF) in Paysandú, Uruguay – Treatment of fractured unstable lumbar vertebrae

Chalkling AG, Pias SN and Perera F

Hospital Escuela del Litoral, Paysandu, Uruguay

Background: Achieving hemostasis in von Willebrand Disease (VWD) presents a challenge as not all concentrates used for haemophilia A correct the bleeding defect in these patients. The development and approval for the market of specific VWF concentrates represents an important advance.
Aims: We report a case of a female patient, 16 years old, with Type 1 VWD defined, diagnosed in 2002 following multiple episodes of epistaxis and gingival bleeding. Two brothers had Type 1 VWD, one of whom died in a traffic accident.
Methods: Presentation: Trauma with maximum impact on the lumbar region of the back, following a fall of 1.5 metres, while under the influence of inhaled substances. A 20 × 20 by 10 cm height mass at the back of the lumbar spine was detected. Pain was reported around paravertebral muscle masses. Abdominal and right flank hypogastrium pain was elicited without peritoneal tap. Investigation by CT scan revealed unstable fracture of L1 lumbar vertebra at the right lamina, pedicle and facet joint. There were no hematomas in the abdomen pelvic region, and ultrasound revealed no free intra-abdominal fluid. Investigations: Hemostasis Tests: APTT: 34.6 s, Prothrombin time 11.9 s, fibrinogen 372. A 4 mg/dl. Platelet adhesiveness: 26% (normal range 25–75); FVIII coagulant activity 113% (normal range 60–150%), von Willebrand Factor 30% (normal range 50–150%) von Willebrand antigen 41% (normal range 58–132%). Treatment: A specialist Transfusion Medicine consultation was performed 2 days after admission. Haematological investigations (Table).
Factor therapy: Commercial Factor VIII concentrate (Immunate®, Octapharma) loading dose 1000 IU I/V bolus, followed by commercial von Willebrand Factor concetrate (Wilate®, Octapharma) 900 IU loading dose followed by 450 IU intravenously every 12 h for 6 days.
Results: Bleeding continued until the initiation of substitution therapy, after which the patient was stabile (Table). The hematoma was resolved and plaster immobilization with a thoracolumbar brace was possible, stabilizing the lumbar vertebrae and preventing further damage. All objective clinical and preclinical criteria indicated complete remission after initiation of replacement therapy. Excellent response and tolerance to the treatment was observed.
Conclusion: Use of a specific VWF concentrate allowed treatment and resolution of this complex case. The provision of such products is an essential part of modern care for VWD. The importance of assessing the patient in a comprehensive and interdisciplinary treatment to achieve timely, safe and effective resolution was evident. Rapid communication between the admitting area and the specialist service is essential for optimal and cost-effective care.

PO 427

Severe periodical menorrhagia, corpus luteum rupture, haemoperitoneum with acute abdomen, laparoscopic ovariectomy, WILFACTIN® substitutive therapy in young female with type IIA Von Willebrand disease

Cultrera D, Cipolla A and Di Raimondo F

Haemophilia Regional Reference Centre, Catania, Italy

Von Willebrand disease (vWD) is the most common hereditary bleeding disorder affecting both males and females. It arises from quantitative or qualitative defects of von Willebrand factor and causes mucocutaneous and visceral haemorrhages, as well as rarely hemartroses.
The aim of treatment is to correct the dual defect of hemostasis caused by the abnormal/reduced vWF and the concomitant deficiency of Factor VIII. In the females, especially in those in fertile age, the menorrhagia, the severe anaemia and haemoperitoneum remain of big concern. So, the individual treatments is often difficult.
We here report the case of a young female, aged 25 years, HBV, HCV and HIV negative, affected by type IIA of von Willebrand disease; the parents are cousins.
The patient had heavy menorrhagias, treated for long time with plasma products containing vWF, started at the onset of bleeding, tranexamic acid, iron oral therapy, with sufficient control of the bleeding.
In December 2010, she was hospitalized for an excessive bleeding, with severe anaemia (hemoglobin 5 g/dl), due to the rupture of a corpus luteum, subsequent haemoperitoneum with acute abdomen.
Surgical removal of one ovary, RBC packed units ($n = 4$), antifibrinolytic agents and replacement therapy with plasma products containing vWF at the dosage of 40 IU/Kg b.w. every 8 h were carried out.
Then, she was discharged with iron therapy and oral contraceptives. Despite the therapy, she had excessive bleeding during the menstrual cycles, severe iron deficiency anaemia, with a poor quality of life.
Then we decided to try therapy with Wilfactin©, a highly purified plasma vWF concentrate containing very little FVIII, at the dosage of 40 IU/Kg b.w./day for 3 days, administered during menstrual cycle, with a remarkably reduction of this, from 8 to 10 days to 4–5, with a good response to the therapy, without collateral effects and normalization of the values of hemoglobin. The patient had no need to continue iron therapy, with an excellent outcome. Now the patient has normal value of hemoglobin and her quality of life is good.
We conclude that Wilfactin® may be considered for short-term prophylaxis in elective surgery or for long-term secondary prophylaxis in women with dangerous menorrhagia.

PO 428

Management of severe coronary artery disease in a patient with type Vicenza von Willebrand disease

De Bon E, Barbar S, Di Pasquale I, Casonato A and Bertomoro A
2nd Chair of Internal Medicine, Universtity of Padua, Padova, Italy

Background: Von Willebrand disease (VWD) is a congenital bleeding disorder caused by von Willebrand factor (VWF) deficiency or abnormalities. Although high levels of VWF are referred to play an important role in the onset of atherothrombosis, a lifelong hypocoagulable state does not seem to protect VWD patients against atherosclerosis. As previously reported, moreover, long-term prophylaxis with FVIII/VWF could increase the thrombotic risk due to excessive circulating FVIII levels. The literature on cardiovascular disease management in VWD patients is limited and recommendations on the type and duration of antithrombotic therapy for such patients are unavailable.
Case report: A 69-year-old diabetic male with type Vicenza VWD presented with a recent worsening of a known stable angina. Basal blood tests showed factor VIII (FVIII:C) levels of 34% (normal range 60–160%), von Willebrand factor antigen (VWF:Ag) of 17.8% (normal range 60–160%), and von Willebrand factor ristocetin cofactor (VWF:RCo) of 16.6% (normal range 60–130%). He had a past history of several muco-cutaneous bleeding episodes, chemotherapy for a nasal non-Hodgkin lymphoma, a surgically-treated testicular lymphoma, and HCV-related hepatocellular carcinoma treated with transarterial chemoembolization (TACE). He had also undergone coronary artery by-pass surgery 9 years earlier for severe coronary artery disease (CAD).
After admission, coronary angiography via radial artery puncture demonstrated severe and extensive CAD. During procedure unfractionated heparin (1000 IU) was administered intra-catheter. Prophylaxis with FVIII/VWF concentrates (40 IU/kg) was administered before and for 3 days after the endovascular procedure. No endovascular or surgical treatment for CAD was proposed.
Considering the high cardiovascular risk and worsening coronary status, clopidogrel was administered for secondary anti-platelet prophylaxis. Since the patient had never taken antiplatelet drugs before, and considering his lifelong bleeding history, we planned a long-term prophylaxis with VWF concentrates. To avoid excessive FVIII concentrations and the correlated risks of arterial and venous thrombosis, we preferred a highly-purified plasma-derived VWF concentrate (Wilfactin®, LFB). The patient received 60 UI/kg twice weekly to maintain VWF:Ag and VWF:RCo above 25–30% and FVIII below 80–100%. Anti-hemorrhagic prophylaxis, in association with antiplatelet treatment, was given for 7 months. No bleeding or thrombotic complications were observed during a further 7-month follow-up.
Conclusions: The appropriate antithrombotic management of VWD patients presenting with coronary syndromes is still unclear. Our experience suggests that antiplatelet drugs might be used in association with VWF concentrates to reduce the bleeding risk. Administering highly-purified VWF concentrates might be helpful, as anti-hemorrhagic prophylaxis, in type 2 VWD patients at high thrombotic/cardiovascular risk, in order to avoid excessively high concentrations of circulating FVIII.

PO 429

Dental invasive procedures in von willebrand disease (VWD) outpatients treated with high purity VWF/FVIII complex concentrate: experience of a single center

De Padua V[1], Santoro C[2], Gaglioti D[1], Bosco R[1], Riva F[1], Baldacci E[2], Mercanti C[2], Parlanti L[2] and Mazzucconi MG[2]
[1]George Eastman Hospital Rome; [2]Hematology Sapienza University of Rome, Rome, Italy

Background: Dental procedures in Von Willebrand Disease (VWD) patients are associated with a risk of bleeding during and after surgery. Replacement prophylactic therapy, and local measures, reduce the risk of complications in this kind of surgeries. VWF/FVIII concentrate is the treatment of choice in VWD type 3 and type 2b, but is also indicated in other VWD subtypes when there is no response or contraindication to Desmopressin. Aim. To describe the dental procedures performed in a group of VWD outpatients utilizing systemic prophylactic therapy with a high purity VWF/FVIII and local hemostatic control measures.
Methods: During 6 years, in our Dental Department, we performed 23 dental procedures on eight patients (4M, 4F; median age 63 years, range 49–78) affected by VWD: 2 type 1, 3 type 2b, 3 type 3. All patients were treated with a high purity VWF/FVIII concentrate. All the surgeries were performed under local and loco-regional anesthesia. Local hemostasis was ensured applying gelatine packing, fibrin glue, absorbable suture, 15-min compression with tranexamic acid saturated gauze. In the post-operative period patients were treated with antibiotics. Tranexamic acid mouthwashes (three times a day for 3 days) were prescribed; acetaminophen was used as the only pain-relief treatment.
VWD type 1. One patient has undergone 3 roots extractions and one other, 2. They have been treated with high purity VWF/FVIII concentrate according to the subsequent scheme: 1 h before surgery (t_0), 60 IU/Kg; from the 12th to 48th h (t_{12h} and t_{48h}) after surgery, 30 IU/Kg every 12 h; from the 3rd to 7th post-operative day, 30 IU/Kg/day.
VWD type 2b. One patient has undergone 5 roots extractions according to the subsequent scheme: VWF/FVIII 50 IU/Kg t_0; $t_{12\ h}$à$t_{60\ h}$ 25 IU/Kg, every twelve h, then 25 IU/Kg every 24 h, until 7th post-operatory day. One other patient has undergone 1 tooth extraction while treated with VWF/FVIII 50 IU/Kg t_0, t_{24}. The last one has undergone 1 extraction, 1 scaling and root planning, 1 excisional biopsy under the administration of VWF/FVIII 30 IU/Kg t_0; then he continued treatment with tranexamic acid orally, at a dosage of 40 mg/kg/day until 7th post-operatory day. VWD type 3. One patient has undergone 2 wisdom teeth extractions according to the subsequent scheme: VWF/FVIII 50 IU/Kg t_0; $t_{12\ h}$à$t_{48\ h,}$ 30 IU/Kg every twelve h, then tranexamic acid orally, 40 mg/kg/day until 7th post-operatory day. One other patient has undergone 3 roots extractions, 2 dental extractions and 1 wisdom tooth extraction under treatment with VWF/FVIII 60 IU/Kg t_0; $t_{12\ h}$à$t_{48\ h}$ 50 IU/Kg every twelve h, then 30 IU/Kg/day until 7th post-operatory. The last one has undergone 1 scaling and root planning while treated with VWF/FVIII 50 IU/Kg t_0, t_{24}. We didn't observe any hemorrhagic or local abscesses. All patients completed the post-surgery home-treatment.
Conclusions: A tailored prophylactic treatment with high purity VWF/FVIII concentrate ensures a good hemostasis in VWD patients undergoing dental procedures. Multidisciplinary approach allow to manage coagulopathic patients without bleeding complications; home-treatment limits patient discomfort and reduces management cost.

PO 430

Successful percutaneous coronary intervention in a patient with von Willebrand disease

Ettorre CP, Malcangi G, Scarafile R, Iandolo V and Marino R
Unviversity Hospital, Bari, Italy

Background: The prolonged life expectancy in coagulopathic patients has increased the risk of age-related morbidites, such as cardiovascular disease. There are no standard treatment guidelines for coronary artery disease in patients with von Willebrand disease (vWD), especially in the field of coronary intervention. We describe a successful percutaneous coronary intervention (PCI) in a patient with vWD.
Case Report: The patient is a 63 year-old man with type I vWD and several cardiovascular risk factors (obesity, hypertension, dislipidaemia, diabetes mellitus). He was hospitalized for unstable angina and a coronary angiography was planned. He was treated with a factor von Willebrand (vWF) concentrate with low factor VIII (FVIII) content (Wilfactin®, LFB) infused the day before the procedure at the dose of 40 IU/kg and with the same dosage one h prior the angiography. The

procedure was performed by radial venipuncture and evidenced a critical coronary disease whose indication was a surgical revascularization, refused by the patient. Alternatively, he underwent a PCI with implantation of a bare metal stent in the middle portion of the left ascending coronary artery. The angioplasty was performed one h after the infusion of 40 IU/Kg of Wilfactin®. Furthermore, according to the standard practice, the patient received a preloading dose of clopidogrel (300 mg) and during the procedure he was treated with 70 IU/Kg of unfractionated heparin and 250 mg of acetylsalicylic acid. The PCI was uneventful and bleeding complications were not observed. After the procedure he continued the dual antiplatelet therapy (clopidogrel 75 mg/die and aspirin 100 mg/die) for 2 months and in this period he received a prophylactic treatment with Wilfactin® at the dose of 40 IU/kg twice a week, without presenting any haemorragic or thrombotic event. With clopidogrel discontinuation he stopped Wilfactin® prophylaxis, carrying on long-term aspirin treatment (100 mg/die).

Conclusion: Little data are available regarding the management of coronary artery disease in vWD patients. In our case Wilfactin® showed a good efficacy and safety profile in providing an adequate hemostatic cover during the PCI. A vWF concentrate with low FVIII content may be more suitable in vWD patients with cardiovascular risk factors, because it ensures the haemostasis avoiding persistently high FVIII plasma levels, which could represent an additional thromboembolic risk factor.

PO 431

Acquired von Willebrand syndrome secondary to a functional defect of von Willebrand factor

Galvez KM, Combariza JF and Gomez M

Hospital Pablo Tobón Uribe, Medellín, Colombia

Background: The acquired von Willebrand syndrome (AVWS) is a bleeding disorder that is frequently unrecognized or is misdiagnosed as von Willebrand disease.

Aims: To describe a case of a patient with Acquired von Willebrand syndrome.

Methods: Case report.

Results: Female patient, who from her 12 years began to have episodes of gingival brushing associated with joint pain in knees and ankles. The PTT was above the reference range and the initial study for coagulation disorders showed deficiency of factor XII associated with positive antinuclear antibodies (1:160 speckled pattern) and C3 low, no other conclusive criteria for systemic lupus erythematosus (SLE) or for antiphospholipid syndrome. One year later she started her menstrual cycles although the bleeding was not abnormal, she presented exacerbation of abdominal pain, diagnosed with dysmenorrhea associated with polycystic ovary syndrome. New studies evidenced the persistence of prolonged PTT, ANAS positive 1:320 homogeneous pattern, decreased complement C4 fraction and deficiency of coagulation factor XII. Four years later she starts to have episodes of metrorrhagia, with iron deficiency anemia motive why she start with drospirenone/ethinyl estradiol regulating the cycles and bleeding. Two years later she consulted the emergency department with acute abdomen, finding hemoperitoneum without a clear cause, new immunological profile revealed ANAS 1:1320 homogeneous pattern, all other tests were negative. She was transfused with fresh frozen plasma presenting allergic reaction. One year later she consults due to metrorrhagia, bruising and right hip pain with functional limitations, hemarthrosis was discarded by MRI. Given the evidence of hemorrhagic manifestations with prolonged PTT is was considered that it was not the clinical behavior of a deficiency of factor XII. Mixing test is performed and PTT was corrected with plasma, indicating deficiency of factor. Paraclinical input is sought: platelet aggregation curve was normal with ADP, collagen, epinephrine and ristocetin, von Willebrand factor 52%, ristocetin cofactor 31.9%, clotting factor VIII 62.8%, clotting factor IX 61%, inhibitors against factor VIII and IX negative. The patient continued with metrorrhagia and spontaneous ecchymosis increase. Further studies were performed that showed a progressive decrease of ristocetin cofactor activity (16%). She was valued by rheumatology, anticromatinm antibodies were negative. Given the findings of bleeding and some symptoms of connective tissue disease diagnosis was proposed as an acquired von Willebrand disease mediated by autoantibodies, the treatment was defined by low doses of prednisone (20 mg/day) associated with hydroxychloroquine 200 mg/day, which results in the disappearance of spontaneous ecchymosis, the remission of musculoskeletal symptoms, normalizing menstruation and the absence so far of new bleeding episodes.

Summary/Conclusion: This case is interesting because it is a prolonged TTP patient suggestive of an acquired bleeding disorder. Initially it raised the possibility of deficiency of factor XII, but the patient always presented bleeding manifestations WITH prolonged PTT which indicated that there was another clotting defect, hemophilia A and B acquired were ruled out and finally it was documented progressive decrease ristocetin cofactor activity, which is an unusual presentation of an acquired von willebrand syndrome.

PO 432

Bleeding score and fibrinolysis after DDAVP in possible type 1 VWD patients

Woods AI[1], Sánchez-Luceros A[1], Blanco AN[2], Meschengieser S[2] and Lazzari MA[1]

[1]IMEX-CONICET-ANM; [2]National Academy of Medicine, CABA, Argentina

Background: VWD is rarely associated with spontaneous bleeding, but may result in a possibly severe bleeding after a haemostatic challenge such as trauma, delivery or surgery. Nevertheless, incomplete VWD penetrance and low specificity of the bleeding symptoms make type 1 VWD a diagnostic challenge, especially in the subjects with low VWF (30–50 IU/dl) and mild bleeding symptoms who are currently diagnosed as 'low VWF' or 'possible' type 1 VWD.

DDAVP is the main treatment in most of VWD pts, although the enhanced response of fibrinolytic could add a bleeding risk factor in these pts. In addition of the VWF, DDAVP also produces the release of fibrinolytic activators from the endothelial cells.

Fibrinolytic activity is evaluated by euglobulins lysis time (ELT).

Aims: Our purpose was to evaluate the changes in plasmatic fibrinolytic activity induced by DDAVP infusion, and to correlate these changes with the bleeding score (BSS), in 471 possible type 1 VWD adult pts (358 females, 113 males).

Methods: BSS was calculated. Blood samples were drawn before (B), and after 1 (1 h) and 2 (2 h) the DDAVP infusion (i.v. 0.3 μg/kg). ELT was done in each sample.

Pts were grouped according to gender and the BSS being < 5 and ≥ 5 for females, and < 3 and ≥ 3 for males. Difference (DIF) between ELT-1 h and 2 h vs. before was calculated.

Results: Females: BSS < 5 ($n = 276$): ELT-B = 190.6 ± 91.6 min; 1 h =73.3 ± 34.8 min; DIF = 3.08 ± 1.6 min; 2 h = 93.1 ± 46.4 min; DIF = 2.3 ± 0.9.

BSS ≥ 5 ($n = 84$): ELT-B = 177.7 ± 65.7 min ($P = 0.23$); 1 h = 63.9 ± 28.5 min ($P = 0.025$); DIF = 3.5 ± 1.5 min ($P = 0.03$); 2 h = 85.1 ± 29.6 min ($P = 0.137$); DIF = 2.3 ± 0.7 ($P = 1$).

Males: BSS < 3 ($n = 95$): ELT-B = 177.1 ± 72.5 min; 1 h = 78.6 ± 44.9 min; DIF = 2.7 ± 1.3 min; 2 h = 89.4 ± 46.6 min; DIF = 2.3 ± 1.4.

BSS ≥ 3 ($n = 18$): ELT-B = 168.9 ± 67.5 min ($P = 0.661$); 1 h = 67.5 ± 39.1 min ($P = 0.329$); DIF = 3.1 ± 1.9 min ($P = 0.238$); 2 h = 89.3 ± 43.2 min (0.993); DIF = 2.0 ± 0.8 ($P = 0.38$).

Conclusions: In females with a BSS ≥ 5 there was a significantly higher fibrinolytic activity in the first h post DDAVP. In contrast, there were no differences in males. Given these results, it is possible to consider that some enhanced fibrinolytic activity associated with pathophysiological stress situations, could be influencing the severity of the clinical

profile observed in possible type 1 VWD patients. Gender-related differences in endothelial response to stimuli such as stress or drugs (DDAVP) could explain both the differences found in the fibrinolytic activity, and the clinical expression of VWD in women.

PO 433

Changes in von Willebrand parameters during the menstrual Cycle

Halimeh S, Rott H and Kappert G
GZRR, Duisburg, Germany

Introduction: Von Willebrand disease is most common bleeding disorder with a prevalence of 1–2% of the population. Nevertheless to diagnose a von Willebrand Syndrom Typ 1 is still a challenge. In a newer publication (1) 30 studies about the haemostatic variables during the menstrual cycle were compared. Eleven studies were focused on the von Willebrand parameters but only in one study they observed these parameters in patients with von Willebrand disease. We like to investigate if there are cyclic variations in women with menorrhagia which can lead to a diagnosis of a coagulation disorder.
Samples and Methods: We conducted a laboratory workup in 94 women sent to our lab for menorrhagia. The following tests were conducted: Blood count, VWF:RCo, VWF:Ag, VWF:CB, Fibrinogen (Clauss), activities of FII, FV, FVII, FVIII (clotting and chromogenic), FIX, FX, FXI, FXII, FXIII during the menstrual cycle on predefined time points (day 1–6, day 7–11, day 12–18, day 19–23, day 24–28).
Results: In 47 (50%) patients a von Willebrand disease could be detected, 41% hat other coagulation disorders like p. e. factor-VII-deficieny and factor-XIII-deficiency. In 8.5% no coagulation disorder could be found.
In patients with von Willebrand disease we found cyclic variations especially in the VWF:Ag ($P = 0.026$). They showed the lowest level during the ovulation. The same was found for VWF:RCo and F VIII but without significance.
Conclusion: There are cyclic variations in von Willebrand parameters. To investigate women on predefined time points during the menstrual cycle can be useful to diagnose a von Willebrand disease particularly in mild cases in which no other suspicious bleeding symptoms exists.
Literature: Knol H.M., Kemperman R.F.J., Kluin-Nelemans C., Mulder A.B., Meijer K., Haemostatic variables during normal menstrual cycle, Thrombosis and Haemostasis 107.1/2012.

PO 434

Feno- and genotyping von Willebrand disease type 2A patient because of spontaneous tonsilliar haemorrhage

Harsfalvi J[1], Udvardy ML[2], Kallai J[2], Kerenyi A[2], Szegedi I[2], Marjan E[3] and Kiss C[2]
[1]University Debrecen, Medical and Health Science Center; [2]Medical and Health Science Centre, University Debrecen, Debrecen; [3]Szabolcs-Szatmar-Bereg County Hospital, Nyiregyhaza, Hungary

Background: A 14-year-old female patient was admitted to local haemophilia treatment center due to repeated bleeding from the tonsils. Spontaneous tonsillar haemorrhage could not have been controlled by increasing dose of von Willebrand factor (VWF) – FVIII concentrate.
Aim: In order to precise diagnosis and treatment, the patient has been transferred to our hospital.
Methods: Platelet function testing: Bleeding time, PFA-100; aggregation; VWF level and activity measurement using VWF:Ag, VWF:RCo, VWF:CB assays, VWF multimer analysis by SDS-agarose electrophoresis; genetic analysis by direct sequencing of exon 28 (primers were designed at the basis of Penas et al. 2005).
Results: Diagnosis was confirmed in our laboratory as type 2A VW disease (VWD): PFA-100 closure times were > 300s, VWF:Ag = 18–35%, VWF:RCo = 13%, VWF:CB = 3–15%, FVIII = 33%, RIPA test revealed no aggregation for 1.2 mg/mL, nor for 0.6 mg/mL ristocetin and lack of high molecular weight multimers (HMW) was shown by SDS-agarose electrophoresis. DDAVP increased the amount of the secreted VWF; still no HMW multimers were found. Platelet suspension did not result in any change in bleeding tendency. HMW multimers appeared in patient plasma after intravenous administration of FVIII concentrate and platelet count increased from 316 to 336; however, this treatment did not decrease PFA-100 closure time, or bleeding time. Detailed platelet aggregation and secretion analysis revealed a 36; 39 and 44% decrease in ATP secretion elicited by ADP, adrenalin and collagen, respectively. Intravenous test dose of VWF-FVIII concentrate (2000 IU), platelets (4 U) and rFVIIa (90 μg/kgbw) resulted in a decrease in bleeding time from 14.5 to 9.0 min. Thus, the patient was given a combination of the above factors what was accompanied by the stop of tonsillar bleeding and afterwards tonsillectomy was performed without any complication. Molecular genetic analysis revealed mutation type 2A in exon 28; nucleotide change: 4628C>T, amino acid substitution: S1543F. Two more siblings have the same mutation, with the same bleeding disorder. A 3692 A>G polymorphism was detected in the three children of the family with the VWD and in the one healthy sibling too.
Summary/Conclusion: This report suggests that in surgeries like tonsillectomy, prophylactically administered rFVIIa together with VWF-FVIII and platelet supplementation seems effective to avoid bleeding in type 2A VWD patient with mild secretion defect. We provide three further cases with 4628C>T mutation to the two listed in the ISTH-SSC VWFdb and four more to the 3692 A>G polymorphism data.

PO 435

Treatment of a high thrombosis risk von Willebrand disease type 3 patient with high-purity von Willebrand factor during last trimester, cesarean delivery and post partum – a Case Report

Holme PA
Oslo University Hospital, Rikshospitalet, Oslo, Norway

Background: Patients with von Willebrand disease (VWD) type 3 may have increased risk of venous thrombosis during surgery while using von Willebrand factor (VWF)/Factor VIII (FVIII) replacement therapy due to an elevated concentration of factor VIII. Patients with previous venous thromboembolic events may benefit from high-purity VWF substitution treatment containing very low levels of FVIII. This case report describes the treatment and clinical features of a high thrombosis risk VWD type 3 patient receiving replacement therapy with high-purity VWF during last trimester, cesarean delivery and puerperium of her first child. To enable rapid adjustments of VWF activity levels during the cesarean procedure, an approach with a loading dose followed by continuous infusions (CI) was selected.
Case presentation: A VWD type 3 patient with pronounced bleeding tendency and previous venous thrombosis after dental surgery while using a FVIII containing VWF product was given prophylactic treatment with a high-purity VWF through the last trimester, cesarean delivery and puerperium. One bolus infusion (4000 IU) was administered before start of surgery, followed by CI (1500–2000 IU/24 h) during delivery until 5 days post partum. Prophylactic therapy of 1000 IU daily as bolus infusions was started 4 months before planned delivery and was continued after the end of the CI. Tranexamic acid 1 g × 3 was started at day of delivery and continued for 15 days. Low molecular heparin (Dalteparin 2500 IE × 1 s) was given from day 1–5.
Before start of surgery VWF antigen (VWF:Ag) was 58%, VWF activity (VWF:RCo) was 24% and FVIII activity (FVIII:C) was 81%. At start of surgery VWF:Ag was 211%, VWF:RCo was 77% and FVIII:

C was 79%. During the whole procedure and until 5 days post partum, VWF:RCo was kept > 50%. FVIII:C increased to a maximum level of 139% at day 3 post partum, and gradually decreased to 90% on day 7 post partum. A good haemostasis was achieved using the substitution therapy, and no signs of thrombosis were observed.
Conclusion: Treatment with high-purity VWF during last trimester, cesarean delivery and puerperium successfully controlled any bleeds in the patient. There was no indication of any thromboembolic events.

PO 436

Automated ristocetin cofactor assay on STA-R®

Mathieu O, Dunois C, Guimbard D, Beaupere D, Poncet L, Juif V and Contant G
Stago, Gennevilliers, France

Background: von Willebrand disease (VWD) is the most inherited bleeding disorder, caused by either a quantitative or qualitative deficiency of von Willebrand factor protein (VWF). The ristocetin cofactor assay (VWF:RCo) is mandatory for the diagnosis and the monitoring of patients with VWD. Quantitative analysis of VWF:RCo in human plasma can be determined by the agglutination on an aggregometer of formalin-fixed platelets via the GPIb-V-IX receptor with VWF patient plasma and ristocetin. Since this method is time consuming, requests an experimented operator and is poorly reproducible (within and between-assay), automation of VWF:RCo assay can be helpful. Moreover, it tends to improve these drawbacks.
Aim: Automation of VWF:RCo assay on STA-R® (Diagnostica STAGO, Asnières, France) and its evaluation in VWD diagnosis.
Methods: The ABP Ristocetin co-factor assay kit (American Biochemical & Pharmaceutical Ltd., Epsom, UK) was automated using immunoturbidimetric method at 540 nm. The concentrations of platelets and ristocetin were optimized to improve the assay sensitivity at low level. Moreover the software was changed to discriminate the absence and presence of agglutination using kinetic curves. The reconstitution of ABP platelets was modified. Results of normal and VWD plasmas with automated assay were compared to those obtained with the reference aggregometric method.
Results: Order 3 polynomial regression was used for calibration with a coefficient of correlation > 0.950 and a range from 0.10 to 0.60 IU/mL (from 0.10 to 1.80 IU/mL with redilution). Reproducibility within and between-assay was improved through automation on STA-R®: 5% and 8% CV respectively, threshold 0.27 IU/mL. The ratio calculation (VWF:RCo/VWF Ag) using automated assay allowed VWD typing in agreement with the reference method.
Conclusion: The automated VWF:RCo assay using ABP-RCof kit showed good performances and offers a greater sensitivity at low levels compared to Chronolog aggregometric method. It is easy to improve the VWF:RCo measurement in clinical laboratory.

PO 437

Case study: rare laboratory presentation of type IIB von Willebrands disease

Needham J[1], Lewis H[1], Rangarajan S[1], De Vos J[2] and Mitchell M[3]
[1]Hampshire Hospitals NHS Foundation Trust, Basingstoke; [2]The Royal Surrey County Hospital NHS Foundation Trust, Guildford; [3]Guys & St Thomas' Hospital, London, UK

Background: An adult female patient was referred to her local haematology clinic requiring a surgical procedure with a historical definitive diagnosis of von Willebrands disease (VWD) possibly Type IIB. Original investigations had been performed overseas and clinical documentation detailing results and diagnosis were unavailable. She had a bleeding phenotype going back to early childhood associated with nose bleeds, post trauma and surgical procedures on three occasions. At the last of these procedures she was treated with DDAVP and Haemate P. Since then the diagnosis of VWD has been questioned.
Aims: To perform diagnostic investigations to clarify the presence or absence of a congenital bleeding disorder in this female patient.
Methods: Samples were collected for initial diagnostic laboratory investigations for a suspected congenital bleeding disorder. Analysis performed included prothrombin time (PT), activated partial thromboplastin time (APTT), fibrinogen and platelet function screening (PFA), factors VIIIC (FVIIIC), XI and VII activity, von Willebrand factor (VWF) activity (VWF:RCo), VWF antigen (VWF:Ag) and collagen binding assay (VWF:CB), full blood count (FBC) and liver function tests (LFT's). Further investigations were subsequently performed on freshly collected samples including repeat VWD screening, VII activity, ristocetin induced platelet agglutination (RIPA) and VWF and VII genetics studies.
Results: There was no evidence to support a diagnosis of VWD from initial investigations. PT = 15.1 s (s) and APTT = 39.2 s which were both mildly prolonged with a normal fibrinogen (2.6 g/L). Factor XI = 59.1 IU/dL, FVIIIC = 97.8 IU/dL, VWF:Ag = 100.2 IU/dL, VWF:RCo = 90.7 IU/dL and VWF:CB = 117.0 IU/dL were all within normal range. PFA screening was normal with closure time COLL/EPI = 99s and COLL/ADP = 72s. Factor VII was measured due to prolonged PT and found reduced at 37.7 IU/dL. FBC indices showed evidence of mild iron deficiency and LFT's were normal. These findings raised the question of possible vitamin K deficiency. Investigations were repeated on fresh citrate samples with consistent results, FVIIIC = 88.8 IU/dL, VWF:Ag = 96.1 IU/dL, VWF:RCo = 92.9 IU/dL and FVII = 40.3 IU/dL. RIPA performed at ristocetin concentrations of 1.25 and 0.5 mg/ml demonstrated a hyper-agglutination response to low dose ristocetin. Genetic studies identified a c.3797C>T mutation on exon 28 VWF gene which replaces proline with leucine and is associated with VWD type IIB and c.1304G>A mutation on exon 9 factor VII gene which is associated with mild FVII deficiency.
Summary/Conclusions: A comprehensive repertoire of specific laboratory diagnostic assays routinely performed to identify VWD unexpectedly failed to detect the VWF abnormality in this patient. This case highlights the importance of the clinical history in considering and identifying patients were further investigation may be warranted to elucidate a rare bleeding disorder when an initial extensive diagnostic assessment is normal. It illustrates the pivotal role of platelet and genetics studies which are not always readily available in the confirmation of type IIB VWD diagnosis in this patient.

PO 438

Von Willebrand disease a common inherited bleeding disorder after haemophilia A in Pakistan

Patel H[1], Naz A[1], Shamsi T[1], Muhammad N[1], Saqlain N[2], Ahmed N[2], Imran A[3], Tarique S[3], Amanat S[4] and Raziq F[5]
[1]National Institute of Blood Disease and Bone Marrow Transplantation Center, Karachi; [2]Children Hospital; [3]Chughtai Lab, Lahore; [4]Pakistan Atomic Energy Comission, Islamabad; [5]Hayatabad Medical Complex, Peshawar, Pakistan

Background: Von Willebrand disease is one of the common autosomal recessive inherited bleeding disorders globally. It may be due to quantitative or qualitative defect of Von Willebrand factor secondary to mutation in Von Willebrand factor gene located on chromosome 12. The current study was carried out in patients with a history of spontaneous bleeding with primary objective to determine the frequency of hemophilia A, B and Von Willebrand disease in patients with bleeding disorders and with secondary objective to categorize Von Willebrand disease into various its types.
Material and Method: This study was carried out from January 2010 to December 2012 in NIBD (Karachi), Children Hospital & Chughtai Lab (Lahore), PAEC (Islamabad) and Hayatabad Medical Complex (Peshawar) after approval of institutional review board. Patients with

history of spontaneous bleeding were selected, blood samples were collected and tested for Platelets counts, PT, APTT, Bleeding Time, Factor VIII, Factor IX, Von Willebrand factor & Ristocetin cofactor after written consent from the patients or relatives..

Results: A total of 470 patients were evaluated with inherited bleeding problems, among them 165 (35.1%) had Haemophilia 'A', 28 (06%) Haemophilia 'B' & 114 (24.3%) were diagnosed as Von Willebrand disease. There were 63 (55.26%) males & 51 (44.74%) females with the mean age of 10.32 ± 7.81 years. Out of 114 patients of VWD, 5 (4.4%) were categorized as Type 1 (with mean APTT 51.64 ± 25.62 s, F-VIII 27.4 ± 9.44%, VWF 23.2 ± 7.46% & Ricof 14.73 ± 19.39%), 3 (2.6%) as Type 2 (with mean APTT of 37.36 ± 5.35 s, F-VIII 62.66 ± 13.01%, VWF 37.66 ± 4.5% & Ricof 20.3 ± 13.62%) & 106 (92.9%) patients were diagnosed as Type-3 (with mean APTT 61.51 ± 8.63 s, F-VIII 3.99 ± 3.14%, VWF 3.48 ± 5.56% & Ricof 2.89 ± 3.39%). The patients were categorized into various types of VWD according to Nichols WL et al., 2008.

Conclusion: Our study has found VWD as 2nd most common inherited bleeding disorder in Pakistan. For accurate & precise diagnosis not only well equipped laboratory is required but there is also a need of awareness campaign among the treating physicians & diagnostic workshops should be arranged for healthcare professionals early diagnosis and management of these patients.

PO 439

Update on laboratory findings in a prospective cohort of childbearing women with bleeding history

Sánchez Luceros A, Meschengieser S, Woods AI, Bermejo IE, Alberto MF, Blanco AN and Lazzari MA

National Academy of Medicine, Buenos Aires, Argentina

Background: Menstruation and childbirth affect excessively women with bleeding disorders. Previously (ISTH Congress 2011), we described that the most frequent disorder in women with bleeding complaints was low von Willebrand factor level.

Aims: To investigate the prevalence of hemostatic and platelet functional disorders we studied a prospective cohort of childbearing women with bleeding complaints.

Patients and Methods: Three-hundred women (mean age 30 years, range 10–50, 54% blood group O) were included. Gynecological and obstetric history (menorrhage defined by PBAC), as well as other bleeding symptoms were registered. Bleeding was defined as major if it was associated with either a decrease in the hemoglobin level of at least 2 g/dL or the need for transfusion of 2 or more units of red cells or hospitalization or surgical procedure. Laboratory parameters: platelet count, bleeding time (BT), PT, aPTT, fibrinogen, factor XIII, euglobulin lysis time, FVIII:C, VWF:Ag, VWF:RCo. Platelet aggregation and ATP release were done as platelet functional studies.

Results: Sixty-nine percent of women had moderate bleeding that required medical intervention, and 61 patients (20.3%) had a major bleeding. The frequency of symptoms was: 87% muco-cutaneous; 68% menorrhage; 5% hemorrhagic ovarian follicle; 51/118 bleeding after delivery. The diagnosis were: 16 mild thrombocytopenia; possible VWD type 1: 37 (2 associated to storage pool disease-SPD); VWD type 1: 26; VWD type 2: 9; Normandy phenotype: 8; Abnormal platelet function: 15; Immune Thrombocytopenia: 2; abnormal ELT: 7; Factor deficiencies: 7.

Discussion: In 300 consecutive women at childbearing age with bleeding symptoms, 41.7% had an hemostatic and/or platelet disorder. VWF abnormalities (62.9%) were the most frequent findings. Platelet function, factor levels and ELT should be studied as well in every patient.

PO 440

De novo mutation in von willebrand disease type III in two siblings of surinamese origin

Simson SG

Academic Hospital Paramaribo, Paramaribo, Suriname

Introduction: Von Willebrand Disease (vWD) is a bleeding disorder caused by inherited defects in the concentration, structure or function of Von Willebrand Factor (vWF). VWD is an under diagnosed disease in Suriname, a country with approximately 500,000 residents. The prevalence of vWD is 1 in every 100 cases but only 1 of 10,000 cases has clinical significance. We recently started a systematic analysis to identify the incidences of bleeding disorders in Suriname. So far we have identified only one family, which we suspect is affected by vWD. Two female members showed to have an increased bleeding phenotype, abnormal Ivy bleeding time and prolonged APTT. PT and fibrinogen levels were normal. The screening tests of the mother were normal. No other family members were included.

Methods: vWF confirmation assays and vWF genotyping were performed to confirm the diagnosis in both siblings and their mother.

Results: Both sisters had factor VIII activity levels of 1%. VWF ristocetin cofactor activity (vWRiCoF) levels were below the cut off levels (< 5%) and vWF antigen (vWF: Ag) levels 1–2%. The mother had 45% factor VIII activity, 38% vWRiCoF and 44% of vWF: Ag levels. Genotypic analysis showed that mother is heterozygous for a small deletion in exon 32 (c.551delG) of the vWF gene resulting in a frame shift and premature stop. The two sisters were carrying the mothers small deletion as well as a nonsense mutation in exon 5 (c.477C>A; p.Cys159X). Both mutations have not been described in vWD databases.

Conclusion: These results show that the two sisters have vWD type 3 due to a compound heterozygous vWF genotype. Their mother is a heterozygous carrier of type 3 vWD. Clinically she will be categorized as type I vWD, but with an autosomal recessive inheritance pattern and not autosomal dominant as seen for other vWD type I patients.

PO 441

Clinical presentation and laboratory findings of Von Willebrand Disease in a tertiary center in Saudi Arabia

Tarek O, Al Hinai K, Al Saleh M, Amal A, Hazzaa A and Almusa A

KFSHRC, Riyadh, Saudi Arabia

Background: Von Willebrand Disease (VWD) is the most common inherited bleeding disorder affecting up to 1% of the population. It is characterized by mutations that lead to an impairment in the synthesis or function of Von Willebrand factor (VWF).

Aims: To identify the incidence of VWD in tested samples in our institute.

Methods: We conducted a retrospective review of all investigated samples for VWD antigen and activity from 2006 to 2011. Out of 100 patients only 60 patients had complete data and were analyzed. There were 28% males & 71.6% females with mean age 20 years range (6–47 year). Information about the following laboratory values were collected including, PT, PTT, platelet count, PFA 100, factor VIII activity, VWF:RCo, VWF:CB, VWF:Ag, & blood group. Clinical data for bleeding were collected and analyzed.

Results: Out of the 60 patients, 15 (27.7%) were having mucous membrane bleed, 14 patients (25.9%) were having ecchymosis & mucus membrane bleed, 9 patients (16.7%) were having only ecchymosis, 5 patients (9.26%) were having genitourinary bleed, 1 patient (1.85%) was having GIT bleed & 10 patients (18.5%) were having other type of bleeds not included in the data collection.

The nature of bleeding was spontaneous in 28 patients (60.8%).it was spontaneous & post trauma in 13 patients (28.3%), post surgery in 3 patients (6.53%), spontaneous & post surgery in 1 patient (2.17%) & post trauma in 1 patient (2.17%),26 patients (48.1%) were having

positive family history, 17 patients (31.5%) were having negative family history and in 11 patients (20.4%) family history was not available. PT & PTT were found normal in 57 (95%) of patients & prolonged in 3 patients (5%) Platelet count was normal in 46 patients (77.9%), high in 12 patients (20.3%), & low in 1 patient (1.69%). PFA was found to be abnormal in 36 patients (78.2%) & normal in 10 patients (21.7%). According to laboratory results and after correction for ABO blood group we hah classified the patients to, 29 (48.3%) were having type I VWD, 24 (40%) were having type III, 4 patients were classified as type II A (6.7%),2 patients (3.3%) having type IIB & 1 patient (1.67%) has type IIN.

Conclusion: Majority 48% of our patients were type 1 and type 3 were 40%.The clinical presentation varies depend on the type of VWD. PFA was found to be the screening test of choice. The high incidence of type III likely to be due to referral bias and probably due to racial difference.

PO 442

Operative management and outcomes in patients with von willebrand disease

Zulfikar B[1], Koc B[2], Ak G[3], Dikici F[4], Karaman I[5], Atalar A[4] and Bezgal F[6]

[1]Cerrahpasa Medical Faculty and Oncology Institute, Istanbul University; [2]Cerrahpasa Medical Faculty, Pediatric Hematology Department, Istanbul University; [3]Dentistry Faculty, Istanbul Univercity; [4]Orthopedics and Traumatology Department, Istanbul Medical Faculty, Istanbul Univercity,; [5]Urology Clinic, Haydarpasa State Hospital; [6]The Haemophilia Society of Turkey, Istanbul, Turkey

Background: Surgery in patients with von Willebrand Disease can present a range of challenges to physicians.

Aims: To determine the perioperative management and outcome of patients with von-Willebrand disease during surgical procedures.

Methods: Data pertaining to surgeries from 2003 to 2012 at our center were retrospectively analysed. All operations, except one appendectomy, were elective and a plan for management of hemostasis was prepared for each patient. This study approved by medical ethic committee.

Results: During this period 31 surgeries were performed in 22 patients with vWD (6 with type 1, 4 with type 2 and 12 with type 3). The surgeries were divided three cathegories: major, minor and dental procedures. Ten major, 12 minor and 9 dental procedures were performed. Major surgeries were 2 orthopedical (resection of radius head, bilateral hip prothesis), 2 urological (both were hypospadias surgeries), 1 urogynecological surgeries (hysterectomy and transobrurator tape), 2 seasons sex change operation (including bilateral orchiectomy, penectomy, vulva/vaginal construction, vaginoplasty, bilateral breast implantation, partial resection of the thyroid cartilage, rhinoplasty), 1 paratyroidectomy, 1 appendectomy and 1 adeno-tonsillectomy. Minor procedure were mostly orthopedical (5 radioactive synovectomy, 1 knee cast and 1 cyst excision from elbow), others were 3 circumcisions, 1 endoscopy and 1 testis biopsy. The patients median age was 21 (4–47), 14 males and 8 females. All patients were treated with intravenous bolus factor replacement therapy pre- and post-operatively and antifibrinolytics. DDAVP were used only half of the type 2 patients. No severe life threating bleeding and thromboembolic event occured in any of the patients. Only 2 patients had mild bleeding after surgery (hysterectomy and hypospadias surgery) and those 2 paitenst were consanguineous. Factor replacement was continued a for 3 months in one patient who underwent bilateral hip prothesis, no bleeding was seen.

Conclusion: Establishing haemostasis for surgical procedures in patients with inherited bleeding disorders is challenging. Providers are often hesitant to undertake surgeries in patients with bleeding disorders out of fear of bleeding complications. However our results show a good outcome in surgery of patients with vWD with a good hemostasis plan and adequate factor replacement therapy. Bleeding remains a problem in a subset of patients and requires ongoing haematological involvement and oversight.

PO 443

Resistance to Anti-platelet therapy in Saudi patients with coronary heart disease

Abdelgadir A, Al Shimairi M and Buyomi NM

Coagulation Laboratory, Physiology Department and Coronary Care Unit, Colllege of Medicine and King Khalid Uiversity Hospital, Riyadh, Saudi Arabia

Background: It has repeatedly shown that in a significant number of patients on anti-platelet therapy, no therapeutic benefit could be gained whether by the laboratory detection of platelet function or the prevention of further cardiorovascular events, so-called *resistance to anti-platelet therapy*. Extensive coverage in the literature on *resistance to anti-platelet therapy*, comes predominantly from developed countries and very scanty information, if any, comes from developing countries.

Aims: To document the prevalence of *aspirin* and *clopidogrel* resistance in Saudi patient with coronary heart disease and to probe the possible mechanism(s) responsible for aspirin and *clopidogrel* resistance.

Materials and Methods: A 238 patients with CHD were enrolled from the outpatient clinic and wards of King Khalid University Hospital Riyadh.

The following platelet function tests were undertaken:

Agonist-induced platelet aggregation: was undertaken in platelet rich plasma in response to arachidonic acid (as a test of aspirin response) and ADP (to test for clopidogrel response).

PFA100 Closure time using both the collagen/epinephrine and the collagen/ADP cartridges.

Results: The prevalence of resistance to *aspirin* (as reflected by the residual response to arachidonic acid-induce platelet aggregation) was detected in 12.6% (30 out of 238 patients). As for resistance to *clopidogrel* (as reflected specifically, by the residual response to ADP-induce platelet aggregation) it was detected in 45 out of 179 (25.1%) patients.

PFA100 closure times: Detection of closure times within the limits of the normal (Laboratory Reference) range was taken to indicate lack of response (or resistance) to anti-platelet therapy. Non-responders were 31 out of 101 patients (30.7%) as detected by the collagen/epinephrine cartridge closure time and in 33% (35 out of 106) patients using the collagen/ADP closure times.

There was no significant effect of diabetes mellitus, smoking, dyslipedidaemia, or consumption of non-steroidal anti-inflammatory drugs (NSAIDs) and the detection of resistance to antiplatelet therapy.

All Patients were followed up for no less than 6 months for outcome, recurrence of angina or MI, re-occlusion of stents or death. A total of 38 episodes were recorded and with significant difference between patients with or without resistance to antiplatelet therapy.

Conclusion: The prevalence to antiplatelet therapy among Saudi CHD patients is comparable with similar figures from most published studies. We feel strongly for the routine use of laboratory testing of platelet function at least as a pharmacological evidence to support the efficacy of administration of antiplatelet drugs.

PO 444

Frequencies of CYP2C19 in mexican-mestizo patients with coronary or cerebral atherosclerosis, and their association with high on-treatment platelet reactivity to adenosine diphosphate

Cortina de la Rosa E[1], Merlin González E[1], Villegas Torres B[2] and Izaguirre Avila RP[1]

[1]*Instituto Nacional de Cardiologia Ignacio Chavez;* [2]*Instituto Nacional de Medicina Genómica, Mexico City, Mexico*

Background: There exists a wide variability of individual response to clopidogrel, dependent on CYP2C19 polymorphisms as well as intrinsic and extrinsic platelet factors. Clopidogrel resistance has been related to an adverse evolution in patients with coronary artery disease.

Aims: Obtain the prevalence of CYP2C19 polymorphisms in Mexican mestizos patients and its relationship with clopidogrel platelet response.

Methods: One hundred and sixty cardiovascular patients and 11 stroke patients were analyzed for CYP2C19 alleles *1, *2, *3 and *17, that were determined by allelic discrimination assay with Taqman probes (Applied Biosystems) and TaqMan GT Master Mix (Applied Biosystems) in a 7900HT Fast Real-Time PCR System thermal cycler (Applied Biosystems). Of them, 83 were tested for clopidogrel resistance by 10 microM ADP-induced platelet aggregation according to North American Consensus Guidelines for medical laboratories; high-on-treatment residual platelet reactivity bas when maximal platelet aggregation > 60%. CYP2C19 polymorphism was expressed as ultrarapid-, normal-, rapid-, normal/intermediate, intermediate and poor metabolizers.

Results: Allelic frequencies were 9.6%, 0% and 11.7% for CYP2C9*2, *3 and *17 respectively. Genotypes were expressed as normal (CYP2C19 *1/*1), intermediate (CYP2C19 *1/*2), normal/intermediate (CYP2C19 *2/*17), rapid (CYP2C19 *1/*17), ultrarapid (CYP2C19 *17/*17) or poor metabolizer (CYP2C19 *2/*2). Frequencies of CYP2C19 genotypes were: CYP2C19*1/*1: 62.6%; CYP2C19*1/*17: 19.9%; CYP2C19*1/*2: 12.3%; CYP2C19*2/*17: 2.3%; CYP2C19*2/*2: 2.3% and CYP2C19*17/*17: 0.6%. Of 83 patients with platelet aggregation, 54.2% were responsive and 45.8% were resistant to clopidogrel. Genotypes in clopidogrel resistant patients were: 46.8% for CYP2C19*1/*1, 18.8% for CYP2C19*1/*17, 66.6% for CYP2C19*1/*2, 0% for CYP2C19*17/*17, 66.6% for CYP2C19*2/*17 and 75% for CYP2C19*2/*2. In addition, patients were divided into two groups: Group A (n = 64; 77.1%): normal, rapid and ultrarapid metabolizers, and Group B (n = 19; 22.9%): intermediate, normal/intermediate and poor metabolizers. Responsiveness vs. resistance to clopidogrel was 60.9% vs. 39.1% and 31.6% vs. 68.4% respectively. Clopidogrel resistance was more associated with unfavorable genotypes for metabolism (CYP2C19 *1/*2, *2/*17 and *2/*2) than with favorable genotypes (CYP2C19 *1/*1, *1/*17 and *17/*17), OR = 3.38 (CI 95%: 1.13–10.05). Maximal platelet aggregation in each genotype group, expressed in median and quartiles (p25-p75) was: CYP2C19*1/*1: 56.5% (27.3–72.1%); CYP2C19*1/*17: 49.1% (44.2–58.4%): CYP2C19*17/*17: 38.0%; CYP2C19*1/*2: 62.9% (52.8–74.9%); CYP2C19*2/*2: 83.4% (64.1–90.2%); CYP2C19*2/*17: 73.2% (43.1–84.9%).

Conclusion: Prevalence of CYP2C19 in Mexican mestizos patients is similar to other populations. Clopidogrel resistance is a complex *in vitro* phenomenon that is not explained by CYP2C19 polymorphisms alone, like inflammation mediators or acute phase proteins that were not studied in these patients.

PO 445

Comparative effectiveness of the verifynow P2Y12 Test and light transmittance aggregometry for detecting the antiplatelet effect of clopidogrel

Dahlen JR[1] and Serebruany VL[2]

[1]*Accumetrics, San Diego;* [2]*HeartDrug Research, Baltimore, USA*

Background: The VerifyNow P2Y12 Test is a rapid, point-of-care platelet function test that has been extensively validated as a tool for measuring the antiplatelet effect of P2Y12 receptor inhibitors. The VN P2Y12 Test reports results as P2Y12 Reaction Units (PRU) and device-reported percent inhibition of platelet reactivity (%I), based on using thrombin receptor-induced platelet aggregation as a substitute for a baseline, P2Y12 inhibitor naïve PRU result. The PRU result is highly specific for P2Y12 receptor blockade due to the effect of a P2Y12 inhibitor, and is more specific than light transmittance aggregometry (LTA) due to the presence of PGE1 in the assay, which minimizes the effect of the platelet P2Y1 receptor. The present analysis evaluates the comparative effectiveness of the VN P2Y12 PRU and%I results and LTA (%AGG) for the detection of a P2Y12 inhibitor effect, measured as reduced platelet reactivity to ADP. The sensitivity of detecting the antiplatelet effect of a P2Y12 inhibitor can be affected by 1) the time since the last dose, 2) the potency of the P2Y12 inhibitor therapy, and 3) inter-individual variability in the response to the drug. Factors such as genetics, concomitant disease, antecedent medication, and compliance can all influence the individual response to antiplatelet therapy. The ability to specifically detect the antiplatelet effect of P2Y12 inhibitors is important whenever the physician wishes to identify the presence of an antiplatelet effect in their assessment of the patient.

Aims: The objectives for this study were to: (1) compare the discriminatory ability of each method for detecting the P2Y12 inhibitor effect, and (2) determine the optimal cutoff for each test from ROC analysis.

Methods: Participants eligible for the study had to (1) have a clinical indication to receive a P2Y12 inhibitor, (2) be taking aspirin at least 2 days prior to enrollment, and (3) have at least two risk factors for developing vascular disease: family history of vascular disease; sedentary lifestyle; diabetes mellitus; hypertension; morbid obesity; known history of hypercholesterolemia; postmenopausal women; and smoking. VN P2Y12 and LTA measurements were performed from blood samples collected prior to clopidogrel ingestion and either 24 h after ingestion of ≥ 300 mg clopidogrel loading dose or 7 days after starting a 75 mg/day clopidogrel maintenance. ROC curve analysis, sensitivity and specificity calculations were based on the ability to correctly identify the presence of a P2Y12 inhibitor.

Results: The area under the ROC curve for VN P2Y12 PRU and%I results was significantly greater than%AGG (0.95 vs. 0.90, P = 0.0067; 0.98 vs. 0.90, P < 0.0001 respectively). The optimal cutoff for detecting the presence of a P2Y12 inhibitor was VN P2Y12 Test PRU < 208,%I > 18%, and%AGG < 62%. PRU and%I had greater sensitivity and specificity than%AGG at these cutoffs.

Summary/Conclusion: The VN P2Y12 Test is superior to LTA for detecting the presence of a P2Y12 inhibitor, with significantly greater specificity. VN P2Y12 is suitable for use in clinical settings where it is necessary to identify a measurable effect of a platelet P2Y12 inhibitor.

PO 446

An optimal approach to selecting the appropriate cutoff for platelet function tests

Dahlen JR[1] and Brar S[2]

[1]*Accumetrics, San Diego;* [2]*Kaiser Permanente, Los Angeles, USA*

Background: Various platelet function tests (PFT) have been described for their ability to identify patients at increased risk for future cardiovascular events. The association between on-treatment platelet reactivity and incidence of cardiovascular events is largely attributed to the

level of pharmacodynamic effect of the antiplatelet medication. The optimal cutoff for describing the prognostic utility of PFT has been frequently determined through ROC analysis and selection of the cutoff with the highest J statistic. This approach has resulted in variability in the reported 'optimal' cutoff.

Aims: The objective of this study was to evaluate the variability in 'optimal' cutoff selection based on ROC curve analysis of a prognostic evaluation (Px) dataset compared to a diagnostic evaluation (Dx) dataset.

Methods: A dataset comprised of naïve and on-treatment PRU measurements from 147 subjects was used for the Dx dataset. ROC analysis was used to characterize the ability of the PRU result to distinguish on-treatment samples from naïve samples after pooling the naïve and on-treatment PRU results. A dataset comprised of on-treatment PRU measurements form 3059 subjects was used for the Px dataset. ROC analysis was used to characterize the ability of the PRU result to distinguish subjects that had a future cardiovascular event from those that remained event-free during long-term followup. The J statistic was determined for each cutoff according to the formula J = sensitivity+specificity-1, and the standard deviation (SD) of the J statistic was calculated for each cutoff. A 2 × SD range was used to describe the bounds of the J statistic. Uncertainty in cutoff selection for each dataset was described by determining the range of PRU cutoffs where the upper bound of the J statistic was greater than the J statistic for the optimal cutoff. To neutralize the effect of differences in sample size and the associated differences in average SD, the uncertainty analyses was repeated using a fixed variability of 0.05 in the J statistic at the optimal cutoff, representing a 5% absolute difference in the combination of sensitivity and specificity.

Results: The J statistic range for the Px dataset was 0–0.192, compared to a 0–0.769 range for the Dx dataset. The range of PRU cutoffs with a J statistic upper bound greater than the 'optimal' cutoff J statistic was 160–271 for the Px dataset compared to 182–266 for the Dx dataset. When imposing a fixed variability of 0.05 units to the J statistic, the range of PRU cutoffs with a J statistic upper bound greater than the 'optimal' cutoff J statistic was 167–261 for the Px dataset compared to 196–260 for the Dx dataset.

Summary/Conclusion: The use of datasets evaluating prognostic performance introduces greater uncertainty in optimal cutoff selection compared to datasets evaluating diagnostic performance. This uncertainty is largely attributed to differences in the range of the J statistic, which is typically much lower for datasets evaluating prognostic performance. Cutoff selection for PFT should be performed based on diagnostic performance for detecting the drug effect and the diagnostic cutoff should be confirmed on the basis of prognostic performance.

PO 447

Urinary levels of 11-dehydro-TxB2 are not an accurate marker of inhibition of platelet thromboxane A2 production by aspirin

Femia EA[1], Cavalca V[2], Pugliano M[1], Razzari C[1], Squellerio I[2], Porro B[2], Podda GM[1], Lombardi F[1], Tremoli E[2] and Cattaneo M[1]
[1]Università degli Studi di Milano; [2]Centro Cardiologico Fondazione Monzino, Milan, Italy

Background: Aspirin is used in the prevention of coronary artery disease (CAD) and other clinical manifestations of atherothrombosis. It inhibits the synthesis of the platelet agonist thromboxane A_2 (TxA_2) from arachidonic acid, by acetylating the platelet cyclooxygenase-1 (COX-1). Some studies suggested that incomplete inhibition of platelet TxA_2 biosynthesis by aspirin is associated with heightened cardiovascular risk, based on the finding that high urinary levels of the TxA_2 metabolite, 11-dehydro-TxB_2, are associated with increased risk for cardiovascular events. However, urinary 11-dehydro-TxB_2 reflects systemic TxA_2 formation, which not exclusively occurs in platelets. About 30% of urinary 11-dehydro-TxB_2 derives from extra-platelet sources and this fraction increases in inflammatory conditions. Inflammatory cells produce thromboxane A_2 via COX-2, which is mimimally affected by the low doses of aspirin that are used to prevent CAD. Therefore, urinary 11-dehydro-TxB_2 is not an accurate parameter for monitoring the effects of aspirin on platelets. Because atherothrombosis is an inflammatory disease, high urinary levels of 11-dehydro-TxB_2 may reflect an increased generation of COX-2 dependent eicosanoids by monocytes/macrophages in severely inflamed atherosclerotic plaques, which are at high risk of thrombotic complications. If this hypothesis were true, urinary levels of 11-dehydro-TxB_2 should correlate with urinary levels of 8-isoPGF2α, a product of the free radical-mediated oxidation of arachidonic acid, which induces inflammatory vascular responses that are involved in the pathogenesis of atherosclerosis.

Aims: To test whether, in aspirin-treated subjects, the urinary levels of 11-dehydro-TxB_2 correlate with the degree of inhibition of platelet COX-1 (reflected by the levels of serum TxB_2) and/or with the urinary levels of isoprostane 8-isoPGF2α.

Methods: We measured the levels of serum TxB_2, urinary 11-dehydro-TxB_2 and 8-isoPGF2α 24 h after the last dose of aspirin in 50 patients with CAD and diabetes mellitus (CAD-DM), 50 patients with CAD on chronic treatment with aspirin (100 mg od), and in 25 healthy subjects who had been on aspirin treatment (100 mg od) for 4 days.

Urinary 8-isoPGF2α levels were higher in CAD and CAD-DM patients, compared to healthy controls; a similar trend was observed for urinary 11-dehydro-TxB_2 levels, but differences did not reach statistical significance. There was no difference in serum TxB_2 across the 3 groups of subjects. There was no correlation between urinary 11-dehydro-TxB_2 and serum TxB_2 levels in each study group and in all subjects considered together ($r = 0.04$, $P = 0.68$). In contrast, there was a statistically significant correlation between urinary 11-dehydro-TxB_2 and 8-isoPGF2α levels in each study group and in all subjects considered together ($r = 0.4$, $P < 0.0001$). Conclusion. The lack of correlation between urinary 11-dehydro-TxB_2 and serum TxB_2 in subjects on aspirin treatment is compatible with our hypothesis that urinary 11-dehydro-TxB_2 levels are not an accurate marker of inibition of platelet COX-1 by aspirin. The positive correlation between urinary 11-dehydro-TxB_2 and isoPGF2α levels in subjects on aspirin treatment supports our hypothesis that urinary 11-dehydro-TxB_2, in subjects whose platelet COX-1 has been inhibited by aspirin, reflects the production of arachidonic acid metabolites by inflammatory cells, which are implicated in the pathogenesis and progression of atherosclerotic lesions.

PO 448

Usefulness of light transmission aggregometry to optimize aspirin regimen in patients with left ventricular assist devices

Fiore M, James C, Boiteux M-Ch, Mouton C, Picard F, Calderon J and Barandon L
CHU de Bordeaux, PESSAC, France

Background: Left ventricular assist devices (LVADs) are mechanical blood pumps used for the treatment of severe heart failure (e.g., as a bridge to heart transplantation, myocardial recovery, or as long term destination therapy). Foreign surfaces of LVADs altere rheologic conditions and blood stasis within the chambers of the native heart induce activation of coagulation, requiring adequate anticoagulation to prevent thromboembolic events. Because platelet function is generally assumed to play a key role in these deleterious complications, antiplatelet therapy is considered crucial for such patients. However, they are also exposed to increase bleeding tendencies due to impaired platelet function and/or acquired von Willebrand disease in relation to high shear stress. Therefore, monitoring of platelet function and aspirin response is necessary to manage postimplantation LVADs bleeding risks in those patients.

Aims: We evaluated platelet function and aspirin response in the early, intermediate, and late phase after LVAD implantation.
Methods: We measured induced platelet aggregation to different agonists (ADP, collagen, arachidonic acid, ristocetin and TRAP) using an APACT-4004 aggregometer in 18 patients on LVAD support. Aspirin therapy was administered for 24–48 h after device placement when platelet functions were considered almost normal. Then, aspirin regimen was progressively increased until arachidonic acid-triggered platelet aggregation dropped to levels below 20%.
Results: Eighteen patients, 34–74 years old, with acute or end-stage heart failure were included in this study. Seven of the patients underwent LVAD placement under emergency conditions, and 11 were electively scheduled for surgery. Patients were closely monitored with light transmission aggregometry (LTA) to optimize the dose of aspirin. In the early phase after implantation, initial platelet functions were almost normal in all patients. Using the cut-off of 20% LTA response to arachidonic acid (AA), an aspirin dose of at least 160 mg/day was progressively required in 78% of the patients and a dose of at least 300 mg/day in 39% of the patients. In postoperative period, ristocetin-induced platelet agglutination was impaired in three patients and this condition was associated with a lack of high molecular weight VWF multimers, confirming an acquired von Willebrand disorder which led us to optimize the dose of aspirin. Using this strategy, four patients suffered from major bleeding complications, but among them, only one received 300 mg of aspirin daily. One patient had a cerebral thromboembolic event leading to death, although he received an aspirin dose of 500 mg/day.
Conclusion: We successfully used LTA to optimize the dose of aspirin in 18 patients supported with LVADs and showed that 39% of them required high dose of aspirin to reduce the maximum AA-induced platelet aggregation less than 20%. This strategy allowed us to avoid major thrombotic complications that can often be fatal in such patients. However, whether these patients are resistant to aspirin still remains unclear and needs to be further explored.

PO 449
Antithrombotic activity of synthetic compound LASSBio-752

Frattani S
UFRJ, Niterói, Brazil

Background: Cardiovascular disease is the leading cause for mortality and morbidity in the world.
Aims: Searching for new compounds that have potential antithrombotic activity, the synthesis of a new series of N-acylhydrazones was recently described (Lima *et al*., *Eur. J. Med. Chem*. 2008).
Methods: In this work we test the compound LASSBio-752 in thrombosis models in rat. In a thrombosis model that combines stasis and hypercoagulability the control group received tissue thromboplastin doses of 3 mg/kg and the mean thrombus weight was 11.2 ± 0.1 mg (n = 8).
Results: Orally administration (O.V.) one h before of LASSbio-752 (100 μM/kg) decreased thrombus weight by 37 ± 0.2%. The antithrombotic action this compound (100 μM/kg) showed a time-dependent pattern, showing 87.5 ± 2.1% of inhibition after 24 h of administration. When tested in the arterial thrombosis model of the compound also showed inhibitory effect, reducing the time of vascular occlusion. From the interval of 1 h there is already an extension in time of total occlusion was 34 ± 2.4 min and the intervals between 6 and 15 h of administration there was no occlusion of the artery. The occlusion begins to be observed in 24 h, where the occlusion time is 23.8 ± 2.3 min, close to the time control 17.6 ± 2.0 min. In the model of induced bleeding was observed that the effect of bleeding was not too intense for any of the intervals tested (1–48 h).
Conclusion: Up to now our results indicate that compound LASSBio-752 is potential candidates for utilization in the treatment of cardiovascular diseases.

PO 450
First European performance evaluation of the VerifyNow II System

Godschalk TC[1], Bergmeijer TOT[2], Dahlen JR[3], Kühbauch M[3], Hackeng CM[4] and Ten Berg JM[2]
[1]St. Antonius Hospital; [2]Department of Cardiology, St. Antonius Hospital, Nieuwegein, The Netherlands; [3]Accumetrics, San Diego, California, USA; [4]St. Antonius Hospital, Dept. of Clinical Chemistry, Nieuwegein, The Netherlands

Background: The VerifyNow System has been well-characterized for its ability to provide accurate and rapid information about the antiplatelet effect of aspirin and P2Y12 inhibitors such as clopidogrel, prasugrel and ticagrelor. The results from the VerifyNow Aspirin Test and VerifyNow P2Y12 Test have been clinically validated to identify patients at increased risk for thrombosis and bleeding on the basis of their platelet reactivity. The VerifyNow II System is a next-generation test system that uses the same reagents as the VerifyNow System, but incorporates several new features to improve the user experience, including the ability to use various commonly-used blood collection tubes and a reduced sample wait time prior to performing measurements of response to aspirin therapy.
Aims: The objectives for this study were (1) to show equivalence between the VerifyNow II System results and the VerifyNow System results, (2) to demonstrate the suitability of alternative blood collection tubes, and (3) to evaluate the blood sample wait time prior to performing the VerifyNow II Aspirin Test.
Methods: A total of 23 subjects receiving treatment with a P2Y12 inhibitor and aspirin were enrolled. All testing was performed according to the manufacturer's instructions. Results obtained from the VerifyNow II Aspirin and P2Y12 Tests were compared to results from the same samples tested with the VerifyNow Aspirin and P2Y12 Tests. Evaluation of alternative blood collection tubes was performed using the VerifyNow System-recommended Greiner Bio-One partial fill Vacuette tube compared to the standard BD Vacutainer blood collection tube with 1.8 cc and 4.5 cc fill volume. All blood collection tubes contained 3.2% sodium citrate. The sample wait time prior to VerifyNow II Aspirin testing was evaluated by comparing VerifyNow II Aspirin measurements performed after a 30 min waiting period (as required with the VerifyNow Aspirin Test) to measurements performed after a 10–15 min waiting period. Data were analyzed using Deming regression and Lin's concordance correlation coefficient.
Results: PRU,% inhibition, and ARU results obtained with the VerifyNow II System were equivalent to the VerifyNow P2Y12 System, with Lin's concordance correlation coefficients of 0.98, 0.96, and 0.96, respectively. VerifyNow II System PRU,% inhibition, and ARU results obtained with standard blood collection tubes were equivalent to partial-fill blood collection tubes, with Lin's concordance correlation coefficients of 0.97, 0.94, and 0.98, respectively. There was no difference between 1.8 cc and 4.5 cc fill volumes for the standard blood collection tubes. VerifyNow II Aspirin results obtained after a 10–15 min sample wait time were equivalent to results obtained after a 30 min wait time (Lin's r = 0.95).
Summary/Conclusion: The results of this investigation confirm that the VerifyNow II System produces results that are equivalent to the original VerifyNow System, with the added benefits of allowing use of standard blood collection tubes and a reduced sample wait time prior to VerifyNow II Aspirin testing.

PO 451

Effects of platelet reactivity on long-term clinical outcomes and bleeding events in Japanese patients receiving aspirin therapy

Horiuchi H[1], Yamane K[2], Kita T[2] and Kimura T[2]

[1]Institute of Development, Aging and Cancer, Sendai; [2]Graduate School of Medicine, Kyoto University, Kyoto, Japan

Background: Aspirin is a widely-used for prevention of cardiovascular diseases while it is also known to increase bleeding events. It is controversial whether a low response to aspirin is associated with poor prognosis or not.
Aims: The aim of this study was to evaluate the impact of the antiplatelet activity of aspirin on cardiovascular and bleeding events in Japanese patients.
Methods: In the study the University ethical committee approved, we analyzed the clinical course of 239 Japanese patients undergoing antiplatelet therapy with aspirin alone for 5 years in a prospective observational study where all participants provided written informed consents. Their residual platelet reactivity was examined at enrollment and after 2 years by the optical aggregometer and whole blood aggregometer with screen filtration methods using collagen as an agonist. The co-primary endpoints were the occurrence of major adverse cardiac and cerebrovascular events (MACCEs) and bleeding events.
Results: The results revealed that the annual incidence of MACCEs and major bleeding events was 3.7% and 0.48%, respectively. With a cut-off value of platelet reactivity measured by the optical aggregometer at enrollment, 67 patients (28%) were classified as low-responders. Low response to aspirin was not associated with increase of MACCEs, while it was clearly associated with increased MACCEs in patients less than 70 years old (low-responders 36.9% vs. responders 14.8%, log rank $P = 0.008$). On the other hand, low responders determined at enrollment by the whole blood aggregometer (27%) did not show increased risks. Major bleeding occurred in 5 patients, who were all responders although the difference was not statistically significant ($P = 0.07$).
Summary: Thus, low response to aspirin was not associated with increase of long-term MACCEs, while it increased MACCEs in patients less than 70 years old; however, it tended to decrease major bleeding events in Japanese patients.

PO 452

Coagulation markers and platelet reactivity after dual antiplatelet therapy in patient with acute myocardial infarction treated with primary percutaneos coronary inervention

Kocica T[1], Antonijevic MN[2] and Davidovic L[1]

[1]Vascular and Endovascular Surgery Clinic; [2]Clinic of cardiology, Belgrade, Serbia

Background: Intracoronary thrombosis is almost a synonym for acute coronary syndrome. An impaired response to antiplatelet therapy with aspirin and clopidogrel has been associated with major adverse cardiovascular events (MACE) in patients with acute myocardial infarction. Elevated levels of coagulation markers, especially fibrinogen and von Willebrand factor increase platelet reactivity and predispose arterial thrombosis.
Aims: We tried to establish a correlation between low response to aspirin and clopidogrel measured by impedance aggregometry and level of blood coagulation markers (aPTT, PT, INR, fibrinogen, FVII, FVIII, vWF, FXII, AT-III, FXII, plasminogen, PAI).
Methods: Between November 2010 and October 2011, patients with acute myocardial infarction submitted to primary percutaneous coronary intervention were enrolled in this prospective study. Patients were consecutively recruited from the Coronary Unit at Clinical Centre of Serbia. A total of 126 patients fulfilled inclusion criteria and their diagnostic and clinical parameters were collected and analyzed. On the basis of platelet functional analysis, patients were divided in two groups: those with good and others with low response to dual antiplatelet therapy.
Results: Of 126 patients, good clopidogrel response was found in 66 (52.4%), while weak clopidogrel response was present in 60 (47.6%) patients. Good aspirin response was recorded in 108 (85.7%) patients, while weak aspirin response was found in 18 (14.3%) patients. Those with weak response to dual antiplatelet therapy and high platelet activity had significantly higher levels of fibrinogen and vWF, in comparison to patients with sufficiently inhibited platelet function. Chances to suffer MACE were significantly higher among weak responders. In patients with MACE, significantly elevated fibrinogen levels and highly significantly elevated vWF levels were recorded.
Summery/Conclusion: Weak responders to dual antiplatelet therapy had elevated levels of fibrinogen and vWF. Weak responders to dual antiplatelet therapy and high residual plaelet activity were significantly correlated with risk of MACE.

PO 453

Non-invasive method for study aggregation properties of the platelet, leukocyte, erythrocyte and hemostasis state

Kuznik B[1], Fine I[2], Maksimova O[1], Kustovskaya E[1], Martynova E[1], Rodnina O[1] and Khasanova N[1]

[1]Chita state medical academy, Chita, Russia; [2]ELFI-TECH LTD, Rehovot, Israel

Aims: The aim of our research is the study the aggregation activity of blood cells using non-invasive method of speckle-analysis.
Summary. Non-invasive method for an assessment the thrombocyte and leukocyte-thrombocyte complexes activity and some other parameters of the haemostasis is proposed. This method is based on the analysis of the speckle pattern behavior that is originated by the coherent light that is scattered from the skin surface.
A significant correlation between the measured optical indexes and spontaneous, ADP-, adrenalin and collagen induced platelet aggregation as well as with the leukocyte-erythrocyte and platelet-erythrocyte aggregates, fibrinogen, soluble fibrin-monomer complex, and some other related parameters was found.
The obtained results indicate that the newly proposed non-invasive method might be usable for an assessment of a tendency of the intravascular clotting.

PO 454

Comparison of P2Y12-receptor blockade in cardiovascular disease patients undergoing antiplatelet therapy by Innovance PFA P2Y assay and light transmission aggregometry using ADP agonist

Margetic S, Getaldic B, Vuga I and Vrkic N

Medical School University Hospital, Zagreb, Croatia

Background: In the recent years platelet function testing has expanded to include the assessment of the effectiveness of antiplatelet therapy in both research and clinical settings. Light transimission aggregometry (LTA) is still regarded as the gold standard for platelet function testing, despite its technical limitations. Development of point-of-care platelet function analyzers, such as Platelet Function Analyzer (PFA-100 system, Siemens, Germany) has allowed simpler and rapid assessment of platelet function using whole blood sample and thus presenting the potential for widespread clinical use. The recently available P2Y cartridge (Innovance PFA P2Y) of the PFA-100 system is specifi-

cally designed for monitoring clopidogrel therapy by measuring ADP-induced platelet aggregation.

Aim: The aim of this study was to evaluate the PFA-100 P2Y assay by measuring on-treatment platelet reactivity in parallel by LTA method using ADP agonist. We aimed to establish the agreement between results assessed by the two methods.

Methods: Twenty (7 females, 13 males) stable cardiovascular patients under antiplatelet therapy were included in the study. Fifteen patients were treated with clopidogrel alone (75 mg/day) and the remaining five patients were on acetylsalicylic acid (ASA, aspirin, 100 mg/day) alone. Clopidogrel-induced inhibition of platelet aggregation was assessed by PFA-100 P2Y assay and by LTA method using ADP agonist on Behring Coagulation Timer (Siemens, Germany). The PFA-100 P2Y is an assay in which citrated whole blood is aspirated through disposable cartridge containing ADP thus measuring the antiplatelet effect of clopidogrel due to P2Y12-receptor blockade. Platelet aggregation is determined by the time taken for the occlusion of blood flow. The cut-off value for PFA P2Y was defined at 106 s according to the manufacturer¢s recommendations and cut-off for LTA using 20 μM ADP was defined as value < 60% according to the literature data.

Results: The clopidogrel treatment target value for PFA P2Y (> 106s) was achieved in all 15 patients on clopidogrel therapy, while ADP-induced LTA found 14 of 15 patients on clopidogrel to be responsive (< 60%). Using cut-off values of 60% (LTA) and 106s (PFA P2Y), the aggrement between the two methods was 19/20 (0.95), while 1 of 20 (0.05) results showed discrepancy. The only discordant result showed reduced platelet aggregation by P2Y (> 300s) and LTA ADP-induced aggregation of 64%. All five patients on ASA therapy alone had P2Y values below 106s.

Conclusions: Comparison of the results obtained by the two methods has shown very good agreement. Sensitivity of PFA P2Y assay in detecting responsiveness to clopidogrel was comparable to LTA method using ADP agonist. The results suggest PFA P2Y assay to be suitable for detection of P2Y12-receptor blockade and monitoring the antiplatelet effect of clopidogrel. Cut-off value (> 106s) given by manufacturer can be considered as suitable for the defining the responsiveness to clopidogrel. The results in patients on ASA therapy alone showed that this therapy has no effect on the PFA P2Y assay. Compared with the LTA method, PFA P2Y assay is much easier to perform, requires smaller amount of whole blood sample and results are accessible in a shorter period of time.

PO 455

Identification patients less sensible to Aspirin treatment through arachidonic acid stimulated platelet marker

Pulcinelli FM[1], Temperilli F[1], Rina A[1], Massimi I[1], Montemari AL[1], Maria Luisa G[1] and Cardillo MT[2]

[1]University of Rome La Sapienza; [2]Cattolica University of Rome, Rome, Italy

Background: Arachidonic Acid (AA) induced platelet aggregation > 20% is currently used to identify patient less sensible to aspirin treatment.

Frelinger et al. (Circulation 2009) demonstrated that residual COX-1 function measured by serum TXB2 assay correlates with subsequent major adverse cardiovascular events, but not with AA-stimulated platelet markers.

Aims: In this study, we investigated if platelet aggregation induced by Arachidonic Acid is useful to identify patients less sensible to aspirin treatment.

Methods: We assessed a retrospective study in which serum TXB2 and platelet aggregation (Born's method) induced by Arachidonic Acid 0.5 mg/ml were analysed in 116 patients receiving a daily dose of apirin (100 mg/die > 1 mount) and in 27 patients receiving aspirin on alternate days, on prescription by doctor.

Moreover, it was measured AA induced TXB2 formation in 42 patients of our population.

Results: We assessed cut off for residual platelet COX-1 function TXB2 > 3.1 ng/ml according to Frelinger (Circulation 2009). While, we used TXB2 > 100 ng/ml to estimate patients non compliant to therapy.

According to TXB2 values, we divided our population into three groups: (1) TXB2 < 3.1 ng/ml (n = 83); (2) TXB2 > 3.1 ng/ml < 100 ng/ml (n = 28); 3) TXB2 > 100 ng/ml (n = 5).

In the first group (Tx < 3.1 ng/ml), patients having platelet aggregation induced by Arachidonic Acid > 20% were 8 (tot = 83) In the second group (Tx > 3.1 < 100 ng/ml), patients having platelet aggregation induced by Arachidonic Acid > 20% were 2 (tot = 28); none of the patients in both groups showed platelet aggregation induced by Arachidonic Acid > 30%.

In the third group, patients having platelet aggregation induced by Arachidonic Acid > 20% < 30% was1 and 4 patients were > 30%. All such patients were found non compliant, as plasma salicylates were absent.

Moreover, we divided 27 patients receiving aspirin on alternate days into two soubgroup:

patients receiving aspirin the day before performing platelet aggregation (n = 12).

patients who didn't receive aspirin the day before performing platelet aggregation (n = 15).

The patients who showed platelet aggregation induced by Arachidonic Acid > 20% were similar in both groups (8% and 13% respectively).

In 42 patients out of our daily aspirin assumption population, we performed both AA induced TXB2 formation and serum TXB2 assays. The results obtained showed a good correlation (r = 0.8258) between the two methods.

Conclusions: Platelet aggregation induced by Arachidonic Acid > 20% isn't sensibile enough to identify patients less sensible to aspirin treatment. Moreover, we found good correlation AA induced TXB2 formation and serum TXB2. AA induced TXB2 formation may be a useful test to identify patients less sensible to aspirin treatmnet when it isn't possible to treat blood for 1 h at 37 °C immediately after collection.

PO 456

Platelet – dependent thrombin generation assay provides new insights into the monitoring of antiplatelet therapy effectiveness

Smirnova O[1], Namestnikov Y[1], Berezovskaya G[2], Klokova E[2], Karpenko M[2], Golovina O[1], Matvienko O[1] and Papayan L[1]

[1]Russian Research Institute of Hematology and Transfusiology; [2]Almazov Federal Heart, Blood and Endocrinology Centre, St - Petersburg, Russia

Background: Patients underwent percutaneous coronary interventions have an increased risk of recurrent ischemic events. Using of antiplatelet agents can reduce the occurrence of clinically relevant stent thrombosis. But the individual assessment of the treatment effect is still complicated. Thrombin generation test (TGT) in platelet-rich plasma (PRP) reflects contact pathway activation and may be useful as a global method to assess the procoagulant potential of platelets and its changes induced by antiplatelet agents.

Aims: The aim of our study was to evaluate a possibility of using TGT for the assessment of efficacy of antiplatelet therapy.

Methods: Venous blood was obtained from 25 patients after the successful coronary stent placement. All of them were given clopidogrel and aspirin (75 and 150 mg per day, accordingly). The control group comprised 29 healthy volunteers. TGT was performed in fresh PRP with the platelet count adjusted to 150 × 10^9/L by dilution with autologous platelet poor plasma. Thrombin generation was measured in a Fluoroscan Ascent® fluorometer at 1 pM tissue factor concentration

using dedicated software. The following parameters were analyzed: lag time of thrombin generation (LT, min), endogenous thrombin potential (ETP, nM/min), maximum concentration of thrombin (Peak, nM), time to reach the peak (TTP, min), velocity index (VI = Peak/[TTP – LT], nM/min). Statistical analysis of the results was performed by non-parametric methods using the median (Me), 95% confidence interval (95% CI) and Mann–Whitney *U* test (Statistica 6.0).

Methods: There were no differences in ETP and LT parameters between patients and controls (1854,0 (1781,7–2001,6) vs. 1911,0 (1865,9–2043,8) for ETP and 17,8 (16,1–20,0) vs. 14,6 (14,1–17,9) for LT). The estimation of Peak, TTP and VI in patients vs. controls showed the statistically significant ($P < 0.003$) decreasing of Peak, 112,7 (103,1–122,1) vs. 138,5 (123,6–143,6), and VI, 7,6 (6,4–8,8) vs. 12,1 (10,9–13,7), and prolongation of TTP, 33,3 (30,8–35,5) vs. 26,8 (25,2–29,3).

Summary: Thrombin generation measurement in fresh PRP can be suggested for the monitoring of antiplatelet therapy effectiveness. Nevertheless more research is required.

PO 457

Possibilities to assess compliance with low-dose aspirin treatment using a highly sensitive assay for salicylic acid in plasma?

Stålesen R, Spectre G, Östensson CG, Ander C, Hedman E, Beck O and Hjemdahl P

Karolinska Institute, Stockholm, Sweden

Background: Aspirin, i.e., acetylsalicylic acid (ASA), is a widely used antiplatelet drug at low dosages (75–325 mg daily) but is also used at higher doses for its analgesic and antiinflammatory effects. ASA irreversibly inhibits platelet cyclooxygenase and the antiplatelet effect persists 7–10 days. After administration of ASA, it is rapidly hydrolyzed to salicylic acid (SA) which has a longer persistence in plasma. Compliance is an important factor for treatment results and an objective measure of compliance with low-dose ASA treatment would be valuable.

Aim: To establish a highly sensitive method to determine low concentrations of SA in plasma after administration of low-dose ASA for possible use to monitor compliance.

Methods: Citrated plasma samples from 43 patients included in two different studies were used. In the first study, each patient ($N = 25$) took three dosages of ASA (75 mg OD, 75 mg BID and 320 mg OD) for at least 2 weeks in a randomized order. After each treatment period, samples were collected 12 (BID) or 24 (OD) h after the last intake of ASA. In the second study treatment with ASA was not allowed which provided samples from non-ASA treated patients.

For the analysis, 90 μL of patient plasma, standards (0–5000 ng/mL) or quality control samples were aliquoted and 10 μL of internal standard (salicylic acid-d_6; Isotec) was added. After precipitation using MeCN with 0.1% formic acid the tubes were centrifuged (16000 × *g*, 10 min). Supernatants were evaporated under nitrogen and resuspended in MeCN:formic acid 1:1 for analysis using Waters Aquity Quattro Premier XE UPLC and an Aquity BEH SHIELD, Waters column, 1.7 μm 50 × 2.1 mm.

Results: The median (interquartile ranges) concentrations of SA were 1.24 (0.44–4.95) ng/mL in non-ASA treated patients. In patients taking ASA the plasma SA concentrations were 7.84 (4.95–9.63) ng/mL with 75 mg OD, 24.22 (14.41–38.56) ng/mL with 320 mg OD, and 71.56 (44.55–109.51) ng/mL with 75 mg BID. Thus, there was a dose- and time-dependent persistence of SA in plasma during ASA treatment. However, there were overlaps between the dosages, and, most importantly, also an overlap between samples from ASA treated and non-ASA treated patients. Occasional unexpectedly high levels may be due to non-compliance with instructions to take the last dose of ASA 12 or 24 h before sampling.

Conclusion: Low levels of SA can be detected in patients treated with low-dose ASA 12–24 h after intake of the last dose of ASA. However, SA levels above 5 ng/mL could be detected also in non-ASA treated patients. This may be related to uncontrolled intake of ASA and/or the presence of SA in nutrients or from endogenous sources. Thus, salicylate analyses in plasma may be helpful to detect compliance during low-dose ASA treatment but measurements do not seem to be reliable at the lowest end of the concentration spectrum. Further improvement of the analytical technique and better understanding of possible sources of SA may provide a useful method for the monitoring of compliance with ASA treatment.

PO 458

Anti-platelet aggregation activity observed in Honkaku shochu

Sumi H[1], Fujii S[1], Tokudome S[1], Yoshida E[1], Yatagai C[1], Naito S[1] and Maruyama M[2]

[1]*Kurashiki University of Science and the Arts, Kurashiki;*
[2]*University of Miyazaki, Miyazaki, Japan*

Background: We have previously reported that the intake of various types of alcoholic beverages (Sumi *et al*., H., *Alcohol & Alcoholism*,23, 33, 1988; Sumi *et al*., *Jpn. J. Alcohol & Drug Dependence*, 33, 263, 1998) brings about changes in the coagulation and fibrinolytic system, and that drinking *Honkaku shochu* (distilled through a pot still) results in promotion of fibrinolysis in blood for a rather long period. In another report, we demonstrated that the distillation fractions of *shochu* have the effect on cells to release t-PA (tissue plasminogen activator) and that the *shochu* aroma is effective in inhibiting platelet aggregation (Sumi *et al*., 21st ISFP, p.18, Brighton, UK, 2012).

Aims: We have now conducted a comparative study of the effects of various types of Japanese *Honkaku shochu*on platelet aggregation. The results are reported here as new information.

Methods: *Honkaku shochu* is classified by the laws of Japan into 2 types: *shochu* and *awamori*. For the tests, 7 types of *awamori* and 24 types of *shochu* were purchased as specimens, and then diluted by deionized water to achieve an ethanol concentration of 25%.

The platelet aggregation rate was then measured with an aggregometer (PAT-4A). Inhibition rate against platelet aggregation of each aromatic component specimen in the dilution series was calculated and the 50% inhibition value (IC_{50}) was determined.

Results: Approximately half of the *Honkaku shochu* tested exhibited anti-platelet aggregation activity. Under typical concentration conditions of 25% ethanol concentration, direct inhibition against aggregation was observed to be 20.5% on average. The *shochu* specimens exhibiting the strongest inhibitive activity against aggregation were made from such raw materials as brown sugar (S-1), sweet potatoes (S-11), rice (S-6), and barley (S-12). It is presumed that the activity does not difference on the raw materials. Aspirin is a well kwon anti-platelet agent. A-6 and S-11 showed the strongest effects, the inhibitive capacity has an equivalent value to 50–200 mM Aspirin.

Summary/Conclusion: A total of 31 types of *Honkaku shochu* were tested, and it was found that 4 out of 7 types of *awamori* and 12 out of 24 types of *shochu* inhibited the aggregation induced by the use of ADP or collagen. It is believed that the inhibitive capacity observed is not the effect of the materials used in producing *Honkaku shochu*, such as sweet potatoes, rice and barley, but rather the result of the fermentative production process. We foresee that if inhibitive effects against platelet aggregation can be achieved by merely smelling the given material instead of eating it, then these types of material could prove to be functional materials in a completely new category not thought of before.

PO 459

The effect of clopidogrel with and without aspirin on hemostatic system activation *in vivo* in man

Traby K, Kollars M, Kaider A, Eichinger S and Kyrle PA
Medical University of Vienna, Vienna, Austria

Background: Dual anti-platelet inhibition with clopidogrel (C) and aspirin (A) is a cornerstone in the management of patients with acute coronary syndrome, but confers a considerable risk of bleeding.
Measurement of platelet and coagulation activation indicators in blood emerging from a local injury site of the microvasculature made to determine bleeding time (called 'shed blood') is a method to investigate hemostatic system activation under close to *in vivo* conditions.
Aim: To investigate if combining C and A has a more pronounced inhibitory effect on hemostatic system activation *in vivo* than C alone.
Methods: In a prospective, randomized, double-blind, placebo controlled study, 44 healthy male volunteers (26 years, range 19–43) were treated with C (loading dose 600 mg, maintenance dose 150 mg/d) and A (100 mg/d) or C (same dose) and placebo for 7 days. Shed blood was obtained at baseline, 2 h and 7 days. ß-thromboglobulin (TG) and thromboxane B2 (TxB2) (reflecting platelet activation) as well as D-Dimer (dd) and prothrombin fragment 1.2 (f1.2) (reflecting coagulation activation) were measured by ELISA. The number of microparticles (MP) was determined by flow cytometry. The sample size was calculated to detect a 20% difference in the main outcome variable (TG) with an alpha of 0.05 and a power of 80%. To test the differences between the treatment groups, two sample *t*-tests were performed. Repeated measures ANOVA was applied for comparisons considering repeated measurements in time. The study was approved by the local ethics committee and informed consent was obtained from all volunteers.
Results: Compared to baseline, both CA and C caused a decrease in TG at 2 h [from 3.3 ± 1.6 to 1.7 ± 0.8 ($P < 0.001$) and from 3.0 ± 1.8 to 1.8 ± 1.4 mg/L ($P < 0.001$), respectively) and at 7 days [from 3.3 ± 1.6 to 1.8 ± 1.2 ($P < 0.001$) and from 3.0 ± 1.8 to 2.1 ± 1.7 mg/L ($P < 0.001$), respectively)]. At all time points, no difference in the concentration of TG was found between CA and C. CA (and to a lesser extend C, data not shown) inhibited TxB2 formation: by 80% at 2 h and by 96% at 7 days. Compared to baseline, CA and C caused a decrease in dd at 2 h [from 0.45 ± 0.55 to 0.22 ± 0.08 ($P = 0.05$) and from 0.39 ± 0.29 to 0.22 ± 0.10 mg/L ($P = 0.02$), respectively] but not at 7 days [0.45 ± 0.55 vs. 0.29 ± 0.37 ($P = 0.3$) and 0.39 ± 0.29 vs. 0.45 ± 0.64 mg/L ($P = 0.7$)]. At all time points, no difference in dd was found between CA and C. Neither CA nor C had an effect on f1.2 or MP counts.
Conclusion: In healthy volunteers, both CA and C inhibited microvascular hemostatic system activation. No difference in platelet and coagulation inhibition was found between subjects treated with CA or C indicating that combining C and A does not result in a more pronounced inhibitory effect on hemostatic system activation *in vivo* than C alone.

PO 460

Sulforaphane induces ubiquitination of p85 and PDK1 and inhibits phosphatidylinositol 3-kinase signaling in human platelets

Wu CC, Chuang W-Y, Kung PH and Kuo CY
Kaohsiung Medical University, Kaohsiung City, Taiwan

Sulforaphane, a dietary isothiocyanate found in cruciferous vegetables, has been shown to exert beneficial effects in animal models of cardiovascular diseases. In the present study, we show that sulforaphane inhibited human platelet aggregation caused by different receptor agonists, including collagen, U46619 (a thromboxane A_2 mimic), protease-activated receptor 1 agonist peptide (PAR1-AP), and an ADP $P2Y_{12}$ receptor agonist. In exploring the underlying mechanism, we found that sulforaphane specifically prevented phosphatidylinositol 3-kinase (PI3K)/Akt signaling, without markedly affecting other signaling pathways. The inhibition of the PI3K/Akt pathway by sulforaphane may result from causing ubiquitination of two important components, i.e. PI3K p85 subunit and PDK1, in this pathway. The ubiquitination of p85 and PDK1 can lead to impaired function or protein degradation. In conclusion, we have demonstrated that sulforaphane can prevent platelet aggregation, which may explain its protective effect in cardiovascular diseases; our data also support that the inhibition of the PI3K/Akt pathway by sulforaphane contributes it antiplatelet effects.

PO 461

Could von Willebrand's disease be overlooked in women using combined oral contraceptives?

Larsen JB, Bor MV and Hvas AM
Aarhus University Hospital, Aarhus N, Denmark

Background: Von Willebrand's disease is the most common inherited bleeding disorder. It is caused by a quantitative or qualitative deficiency of von Willebrand factor, a plasma protein involved in primary haemostasis. A common symptom of von Willebrand's disease in women is menorrhagia. For this reason, many women suspected of having von Willebrand's disease are treated with combined oral contraceptives (COCs) and are receiving COC treatment at the time of investigation. Few studies have examined the effect of COCs on von Willebrand factor plasma levels, and results are conflicting. However, if COCs can cause an increase in plasma level of von Willebrand factor, this could interfere with test results, and the disease could be masked in women receiving treatment with COCs.
Aim: The aim of the study is to investigate whether COCs induce an increase in von Willebrand factor plasma levels.
Methods: A clinical longitudinal study is conducted with two groups (each $n = 30$) of healthy participants; A) women wishing to begin p-pill treatment and B) women not receiving p-pill treatment (control group). A baseline blood sample is taken at the time of inclusion, after which the participants in group A begin COC treatment. Blood samples are obtained again 3 and 6 months after baseline. Von Willebrand factor plasma levels at baseline and at 3 and 6 months are compared within the group, and potential differences in von Willebrand factor levels before and after p-pill treatment are compared with the control group.
The following analyses, which are all routinely employed in the diagnosing of von Willebrand's disease, are carried out: von Willebrand factor (vWF) antigen and vWF activity employing immunoturbimetric assays, vWF ristocetin cofactor assay, vWF collagen binding assay (ELISA), and factor VIII Clot.
Results: The project is currently still in the recruitment phase, but we will be able to present preliminary results at the time of the conference.
Summary/Conclusion: The study examines the effect of combined oral contraceptives (COCs) on von Willebrand factor plasma levels in healthy women. Our results will hopefully help in improving the diagnosing of von Willebrand's disease in women treated with COCs.

PO 462

Association of methionine synthase and thymidylate synthase genetic polymorphisms with idiopathic recurrent pregnancy loss

Kim NK, Kim JO, Young Joo J, Lee BE, Choi DH, Lee WS, Kim JH and Oh D
CHa University, Seongnam, South-Korea

Background: One-carbon metabolism is important for maintaining pregnancy and the enzymes codified by these genes are relevant in this metabolic pathway.

Objective: To investigate the association between one-carbon metabolism and recurrent pregnancy loss (RPL), we examined polymorphisms in four genes: methionine synthase (*MTR*); methionine synthase reductase (*MTRR*); methylenetetrahydrofolate dehydrogenase 1 (*MTHFD1*); and thymidylate synthase (*TS*).
Methods: A cohort of 353 RPL patients (3.09 ± 1.65 pregnancy losses) and 226 controls. Genotyping was assessed by polymerase chain reaction-restriction fragment length polymorphism assay.
Results: The *MTR* 2756AA polymorphism was associated with RPL. Gene-gene interaction analysis revealed that the frequency of the *MTR* 2756A-*TS* 6 bp allele combination was significantly higher in RPL.
Summary: Based on these results, we propose that the *MTR* 2756AA genotype and *MTR* 2756A-*TS* 6 bp allele combination are possible predisposing factors for RPL development in Korean women.

PO 463

Association study of Paraoxonase-1 gene polymorphisms and Homocysteine Levels in Patients with Ischemic Strokes

Kim NK, Kim JO, Young Joo J and Oh D
CHa University, Seongnam, South-Korea

Background: Paraoxonase-1 (PON1), a high-density lipoprotein (HDL) associated enzyme, is involved in the lipid metabolism and detoxification of insecticides and pesticides.
Aims: The aims of this study were to evaluate the role of Paraoxonase-1 gene polymorphisms in patients susceptible to ischemic stroke, and to determine the relationship between PON1 gene polymorphisms and plasma total homocysteine (tHcy) levels.
Methods: Five hundred and eighty-seven patients with ischemic stroke and 476 controls were genotyped for the PO01L55M, Q192R polymorphisms. The PON1 L55M and Q192R genotypes were determined by the polymerase chain reaction-restriction fragment length polymorphism method. Logistic regression analyses, adjusting for multiple comparisons, were used to determine the association between the minor allele of each of the polymorphisms and the risk of ischemic stroke.
Results: The LL and LM+MM genotype frequencies of the L55M polymorphism were significantly different between the stroke and control group. When stratified by the size of the occluded vessel, the PON1 Q192R polymorphism was associated with patients with multiple small-artery occlusions. When the patients were divided into 3 groups according to the tHcy level, the sum of the control groups and ischemic stroke patient groups, age and gender were found to be significantly associated with an elevated tHcy level. Moreover, the folate level was decreased upon increasing tHcy levels.
Summary/Conclusion: In accordance with these studies, our study indicated that PON1 polymorphisms should be considered as risk factor for ischemic stroke in Koreans.

PO 464

Effects of hypertonic saline hydroxyethyl starch solution on heatstroke-induced damage in a rat model

Kuen Bor C, Wu-Tien H, Tsai-Hsiu Y, Hsin-Mao T and Chia-Chyuan L
Chia Nan University of Pharmacy & Science, Tainan City, Taiwan

Hypertonic saline hydroxyethyl starch solutions have been used for 'small volume resuscitation' in patients with peripheral arterial stenosis, hemorrhagic shock, cerebral and cardiac ischemia. In rats, heat stress leads to arterial hypotension, microvascular injury, thrombosis, inflammation, hypoxia, hypercoagulable state and brain and heart dysfunction. The aim of the present study was to determine whether Hypertonic saline hydroxyethyl starch solution could improve the heatstroke-induced microvascular injury, thrombosis, inflammation, circulatory shock, cerebral ischemia, and hypercoagulable state. When the untreated rats underwent heat stress, the heatstroke rats displayed cerebrovascular dysfunction (evidenced by hypotension, hypoxia, and ischemia), higher levels of thrombomodulin, interleukin-1, activated partial thromboplastin time, prothrombin time, D-dimer, and decreased platelet count and protein C (heatstroke-induced disseminated intravascular coagulation was assessed by plasma markers). However, the heatstroke-induced hypotension, cerebral ischemia, activated inflammation, microvascular injury, thrombosis, and hypercoagulable state can be significantly reduced by hypertonic saline hydroxyethyl starch solution. Our results suggest that hypertonic saline hydroxyethyl starch solution can be used as a beneficial agent for heatstroke. In particular, hypertonic saline hydroxyethyl starch solution may ameliorate the situation of microvascular injury, thrombosis, inflammation, and hypercoagulable state in heatstroke.

PO 465

Children's playbook validation for cardiovascular disease prevention

Lima L, Oliveira Ferreira M, Henrique Vieira Oliveira S, Antonio Oliveira G, Euzébio Domingues F, Oliveira Junior JR, Tarbes M and Rezende Castilho P
Federal University of Vicosa, Viçosa, Brazil

Background: The playbook uses the influence of early childhood education in the remodeling of the family habits to prevent cardiovascular disease (CVD).
Aims: The aim of this study was the validation of an infant playbook to be used in cardiovascular health education of children, suggest actions seeking education in order to promote the empowerment of the child population in health issues and citizenship.
Methods: We created a first version of the playbook using a roadmap aimed at children and manuals drawings that could be colored by children. This version was assessed by 4 cardiologists, 4 pediatricians and 4 childhood education professionals through a structured questionnaire. From the contribution of professionals, we created a second version evaluated for 40 children aged between 5 and 10 years. The third version of the playbook was made after the relevant corrections pointed out by children, plus the suitability of the information, illustrations and language.
Results: The first version of the playbook was well accepted by most professionals, 83.3% of the participants found the information correct and appropriate for children. Seventy-five percent strongly agreed with the quality and content in this material. The second version got 80.8% in the field understand, 100% attractiveness, 92.3% of children interacted with the material (coloring or doodling), and 100% of children have responded that claim to help your family to improve habits. The analysis of the material by pediatricians allowed the inclusion of an illustration demonstrating the importance of blood pressure measurement in children from 3 years.
Conclusion: The method used in the validation of the children's playbook contributed to the betterment of itself and wide acceptance of the target audience. The third version of the playbook may act in interface education/health seeking to form a culture of prevention of CVD in the family. However, the final version of the material depends on its use and further studies, which may suggest the need for changes in the script and drawings, to achieve the target of an increasingly effective.

Coagulation factor VII gene polymorphisms and cardiovascular diseases in Iran

Cohan N

Hematology Research Center, Shiraz, Iran

Background: The association between coagulation factor VII (FVII) gene polymorphisms and FVII level, activity, and cardiovascular diseases (CVD) has been reported in several studies.

Aim: Determine whether two FVII gene polymorphisms including: −401 G>T and HVR4 influence risk of CVD in Iranian population.

Methods: A total of 110 patients with cardiovascular disease that confirmed by angiography (57 male and 53 female, mean age 55.4 ± 10.8 years old) and 110 age and sex match controls (54 male and 46 female, mean age 53.8 ± 9.7) without cardiovascular disease (confirmed by angiography) were genotyped for these two polymorphisms.

Results: Although TT genotype of −401G>T polymorphism was at a higher frequency among control group compared to patients (18.1% vs. 16.3%), the difference was not statistically significant ($P > 0.05$). Also Carriers of the H7-allele (H7H7) were at a higher frequency among control group in compare with patients group (23.6% vs. 21.8%) but it was not statistically significant too ($P > 0.05$).

Conclusion: We could not found any association between −401 G>T and HVR4 polymorphisms of coagulation FVII and CVD in Iranian population, but future studies with larger study groups are recommended for more evaluation of these associations.

PO 467

Compound folate deficiency, elevated homocysteine and pseudo-homozygosity for MTHFR677T as predisposing factors in TIA: a case study

Cutler J[1], Sobczynska-Malefora A[1], Holmes P[2], Howard R[2] and Rahman Y[2]

[1]GSTS Pathology, London, UK; [2]Guys and St Thomas' NHS Trust, London, UK

We present a patient with multiple transient ischaemic attacks due to intracranial stenosis. Folate deficiency, high homocysteine with associated heritable variation in the *MTHFR* gene were the only identified risk factors which contributed to the atherosclerosis.

A 21 year old male of African extraction presented with a 3 month history of intermittent, transient neurological events, which required admission for clinical investigation. Apart from a history of cerebral vascular events in a maternal aunt he had no significant personal or family history, was previously healthy and not on any medication. An MRI scan showed an area of restricted diffusion in keeping with an infarct, and an angiogram demonstrated an intracranial stenosis in the internal carotid artery, consistent with atherosclerosis. A full range of laboratory investigations were performed and a highly elevated homocysteine of 95.3 μM (reference limit < 15) was detected. Further analysis revealed that both plasma folate and 5-MTHF were reduced, and his plasma methionine was at the lower end of the normal range. This raised the suspicion of a remethylation defect of homocysteine to methionine. The patient was treated with folic acid supplementation for 3 months, and his plasma homocysteine responded, falling to 12.9 μM.

Molecular analysis of a small panel of thrombotic risk factors showed him not to carry either the FVL or PT20210 polymorphisms. He was shown to be heterozygous for the common MTHFR 677C/T variant which in this state is neither a thrombotic risk factor nor sufficient cause of the elevated homocysteine levels. Analysis of the entire coding region of the *MTHFR* gene was undertaken to investigate the proposed re-methylation defect and heterozygosity for a c.3G>C nucleotide substitution was identified. Although this base change predicts the replacement of the initiating Methionine at codon 1 with an Isoleucine, it is probable that loss of p.Met1results in the lack of translation from this allele. Protein analysis would be required to confirm this. It is proposed that the loss of p. Met1, coupled with folate deficiency, may be significant for the remethylation process in this patient, and may contribute to the neurological event and narrowing of his cerebral arteries. If the c.3G>C variant is proven to be on the alternate allele to the *MTHFR* 677T polymorphism, the consequence of this would be pseudo-homozygosity for *MTHFR* 677T. Homozygosity for this polymorphism is associated with an increased thermolability of the MTHFR enzyme, with a reduction in enzyme activity of approximately 50%. It is associated with mildly elevated total homocysteine with an increased risk of cardiovascular events. It is probable that the combination of pronounced dietary folate deficiency, an *MTHFR* 'null allele' and the 677T variant is sufficient to explain both the moderate hyperhomocysteinaemia and the clinical presentation in this patient. This case highlights the need to investigate other possible mutations in the *MTHFR* gene, particularly in the absence of homozygous MTHFR 677C/T status in pre-mature cardiovascular events.

PO 468

Individuals with coronary artery disease at a young age and features of the metabolic syndrome have an increased prothrombotic potential

Kok MG[1], Meijers JC[2] and Pinto S-J[3]

[1]Academic Medical Center, Amsterdam, AMSTERDAM, The Netherlands; [2]Academic Medical Center Amsterdam, Amsterdam, The Netherlands; [3]Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands

Background: The relation between coagulation and atherosclerosis has been extensively described. However, most literature on this issue shows conflicting results. Surprisingly, hypercoagulability is most pronounced in young patients with coronary artery disease (CAD).It is known that obesity and hereby induced metabolic syndrome (MS), a risk factor for CAD, are related to a higher incidence of thromboembolic events. We hypothesized that individualswith CAD at a young age and features of MS have an increased prothtombotic potential. Weanalyzed this by measuring the endogenous thrombin potential (ETP) in patients with CADbefore the age of 51 in men and 56 in women and compared them to their healthy first-degreerelatives. Furthermore, we studied whether the presence of the MS in these CAD patientsfurther increased the prothrombotic potential.

Methodology and Principal Findings: We included 118 patients with CAD at a young age and 50 healthy first-degree relatives. Anadjusted general linear model (GLM) showed that there is a positive association between thepeak thrombin levels and the presence of CAD at a young age (B = 9.4; $P < 0.05$). Based onthe NCEP guidelines we divided our patient group in CAD patients with and without MS, andcompared them to healthy first-degree relatives without MS. The adjusted GLM showed thatCAD patients with MS have increased ETP levels, both in comparison with healthy firstdegree relatives (B = 13.0; $P < 0.05$) and with CAD patients without MS (B = 12.9; $P < 0.05$).There was no difference in ETP levels between CAD patients without MS and healthy firstdegreerelatives (B = 0.1; P = ns).

Conclusion: This study shows that individuals with CAD at a young age have an increased prothromboticstate. Furthermore, we show that the increased prohrombotic state in the young CAD patientsis associated with the presence of the metabolic syndrome.

PO 469

Prevalence of risk factors for cardiovascular disease in Thai rural elderly

Komanasin N, Neamsum N, Weerachai A, Mongkolwongroj P, Puntumetakul M and Settasatian N

Faculty of Associated Medical Sciences, Khon Kaen University, Khon Kaen, Thailand

Background: The number of elderly people in the society is steadily increasing, and age is considered as an important risk factor for cardiovascular disease. Investigation of the prevalence of risk factors for cardiovascular disease in the elderly may be a guide to their worthy life and community.
Aim: This study aimed to investigate the prevalence of risk factors for CAD in the elderly in the rural area of Thailand.
Methods: The study was based on data from the academic service project concerning a health check up for the elderly at Ban Non Muang, Khon Kaen Province, all of whom were aged 60 years and above. The data of risk factors for cardiovascular disease were collected from questionnaire responses whilst the physical data of subjects were directly measured. Venous blood was taken from the subjects for laboratory analysis. A total of 177 subjects (79 males and 98 females) with the mean age of 62.9 years were recruited. According to their ages, the subjects were classified into three groups: 60–69, 70–79, and > 80 years.
Results: Weight and body mass index were statistically significantly different among age groups ($P = 0.02$ and < 0.001 respectively) which was in corresponding to a rising the nutritional screening initiative (NSI) value. The prevalence of risk factors for CAD in the subjects was evaluated and found that the most common risk was metabolic syndrome (60.5%) with the higher prevalent in females than in males (71.4 vs. 45.6%, $P < 0.001$). However, the prevalence was not statistically significantly different among age groups. Dyslipidemia (49.7%) and hypertension (48.9%) were also highly prevalent in the study population. The highest prevalence of hypertension was found in the male elderly which was higher than those in females (87.5 vs. 35.7%, $P = 0.039$).
Conclusion: The results of this study serve as the useful information for further preventive planning of cardiovascular disease in the elderly at the rural area of Thailand.

PO 470

Immunization With A Peptide Containing Two Epitopes Derived From Chlamydia Pneumoniae (Cpn) Significantly Reduces Atherosclerotic Lesion In Apobtm2SgyLdlrtm1Her/J Mice Infected With The Cpn Bacteria

Lu X[1], Xia M[1], Chen D[2], Endresz V[3], Faludi I[3], Szabo A[3], Gonczol E[4], Mundkur L[1] and Kakkar V[1]

[1]Thrombosis Research Institute, London, UK; [2]King's College London, London, UK; [3]University of Szeged, Szeged, Hungary; [4]National Center for Epidemiology, Budapest, Hungary

Background: *Chlamydia pneumoniae* (*Cpn*) is an important human pathogen that causes atypical pneumonia and is associated with various chronic inflammatory diseases such as atherosclerosis, a major cause of cardiovascular disease and death in the Western world. However, the theoretical role of *Cpn* in acceleration of atherosclerosis is still controversial.
Aim: To investigate the antigenic effect of a peptide containing two epitopes of *Chlamydia pneumoniae* (*Cpn*) on atherosclerotic lesion formation in mice infected with *Cpn*.
Methods: Six-week-old Apob^{tm2Sgy}Ldlr^{tm1Her}/J mice were immunized using a repetitive immunization multiple-sites strategy with KLH-conjugated peptides derived from the major outer membrane protein and the putative outer membrane protein 5 of *Cpn*. Mice were fed a high-fat diet and infected with *Cpn* twice during the 10-week diet period. Lesions were evaluated histologically; local and systemic immune responses were analyzed by immunohistochemistry of aorta samples and cytokine levels in plasma samples and splenocyte supernatants were measured.
Results: Mice immunized with the combined *Cpn* peptide showed a greater reduction in lesion size compared to mice immunized with either epitope alone [54.7% vs. 39.8% or 41.72%] and was also associated with a significant decrease in lesion area in descending aortas compared with those in controls (88.9% for combined Cpn peptide, 81.9% for MOMP peptide and 75.7% for Omp5, respectively). This effect was associated with a shift in the cellular composition of plaques towards decreased inflammatory cell and increased regulatory T-cell content and increased production of anti-inflammatory cytokines and decreased secretion of proinflammatory cytokines demonstrated in plasma and in supernatant of stimulated spleen cells.
Conclusions: Atherosclerotic lesion formation may be promoted by *Cpn* infection in the presence of a high-fat diet, and reduced by immunization with the combined *Cpn* peptide. The combined peptide has more potential than either epitope alone in reducing atherosclerotic lesion formation.

PO 471

Association of serum gamma-glutamyl transferase (GGT) and other markers with extent of coronary artery disease in angiographically proven patients and its potential use as risk indicator

Sangeeta M, Sharma A, Madan G, Kakkar VV and Vangala RK

Thrombosis Research Institute, Bangalore, India

Background: Accumulating evidence from epidemiological studies suggests that higher serum GGT is associated with incident cardiovascular disease (CVD), its risk and related death.
Aims: In this study we have assessed the levels of GGT and other biomarkers association to the extent of coronary artery disease (CAD) in angiographically proven patients and their use in risk assessment.
Methods: Four hundred and eighteen age and gender matched subjects (187 CAD affected and 231 unaffected) were selected for a case control study from ongoing Indian Atherosclerosis Research Study (IARS). The information regarding inclusion, exclusion criteria and process of sample collection, and data storage have been published (Indian Heart J, 2010;6:286–95). All the blood samples were collected after overnight fasting of 12–14 h. GGT, matrix metalloproaease-9 (MMP9), oxLDL and myeloperoxidase were measured in the serum samples using ELISA assays. The Gensini scoring system was utilized in the evaluation of CAD severity and was calculated for each patient from the coronary angiography report by assigning a severity score to each coronary stenosis. Reduction in the lumen diameter of the affected arteries were evaluated (reductions of < 50%, 50–70%, 71–90% and > 90% were given Gensini scores of 1, 2, 4 and 8 respectively). Each principal vascular segment was assigned a multiplier in accordance with the functional significance of the myocardial area supplied by that segment: the left main coronary artery×5; proximal segment of left anterior descending coronary artery (LAD)×2.5; proximal segment of circumflex artery×2.5; mid-segment of the LAD×1.5; right coronary artery, distal segment of LAD, posterolateral artery and the obtuse marginal artery×1; and others×0.5.The logistic regression model development was performed using SPSS software version 17.
Results: The mean GGT levels were not significantly different between CAD affected (35.6 U/L) and unaffected (35.1 U/L, *P*-value = 0.81), however after adjustment with levels of MMP9 the difference was significant (affected = 39.9 U/L and unaffected = 30.3 U/L, *P*-value = 0.006). The mean GGT levels were found to be correlating with the extent of disease in arteries such as left main coronary artery, diagonal and obtuse marginal artery. In the Logistic Regression model

for risk assessment, GGT gave an odds ratio of 1.08 (95% CI 0.6–1.91, *P*-value = 0.79) which improved to 3.73 (95% CI 1.28–10.87, *P*-value = 0.02) upon addition of MMP9 and to 4.21 (95% CI 1.3–13.46, *P*-value = 0.02) with lipids (HDL, LDL, Tryglycerides and total cholesterol) for the fourth quartile in comparison to first. The C-statistics analysis show that the Area Under the Curve for GGT alone was 0.514 (95%CI 0.46–0.57, *P*-value = 0.64) increased to 0.762 (95%CI 0.68–0.84, *P*-value = 4.93×10^{-8}) with MMP9 and lipids.

Conclusions: Our study suggests that serum GGT levels in association with MMP9 levels and lipids correlate to the severity of the CAD. However the significance of predicting recurrent disease and death requires larger study and long term follow up.

PO 472

The hemostatic system status in chronic generalized periodontitis in the elderly people with coronary heart disease

Malezhik L, Pinelis Y and Malezhik M

Chita State Medical Academy, Chita, Russia

Matter of Current: Chronic generalized periodontitis (CGP) takes its features by concomitant atherosclerosis and disseminated intravascular clotting in elderly people. Local changes in the mouth worsen the thrombogenic status on a background of systemic hypercoagulability. Data on profound changes in the hemostatic system in comorbidity of periodontal and ischemic processes in the cardiovascular system are presented in this study.

Purpose: To evaluate the thrombogenic potential of blood and saliva in chronic generalized periodontitis in elderly people with coronary heart disease.

Materials and Methods: Ninety-six patients with generalized periodontitis of moderate severity were examined. They were admitted to Transbaikalia Hospital for War Veterans on the clinical manifestations of coronary heart disease (CHD) with the diagnosis of stable angina pectoris of I-II functional class, CGP of II-A stage, hypertension of 1- 2 stages.

All patients were administered a local anti-inflammatory therapy for chronic periodontitis for 10 days. Additionally cardiovascular therapy of CHD clinical manifestations was performed. Analysis of blood and oral fluid (mixed saliva) was made, taken in the first days of admission and after it. Hemostasis was estimated in the blood on the following parameters: prothrombin time, thrombin time, fibrinogen, fibrin monomer complexes, euglobulin fibrinolysis by the methods described in the classic manuals.

Procoagulant and fibrinolytic activity of saliva was determined by adding of 0.1 ml centrifuged saliva into the plasma of the same individual with the subsequent registration of the time of its coagulation and fibrinolysis.

The control group consisted of 25 elderly people correlating major group in age, sex, degree of CAD, cardiovascular ongoing therapy, but without obvious signs of periodontal inflammation.

Methods: The obtained data suggested that the procoagulant activity of saliva in patients in relapse was higher than in healthy ones. Prothrombin time, thrombin time was accelerated by adding saliva to the blood plasma of the same patients. Clot lysis was slowed due to the presence of fibrinolysis inhibitors in saliva.

Procoagulant activity was decreased in saliva after comprehensive treatment of periodontal disease but inhibited fibrinolysis was remained.

Hypercoagulation was observed in the blood of patients. Induced coagulation was accompanied by the increase of fibrinogen, inhibition of fibrinolysis and a high concentration of fibrin monomer complexes, which were considered the markers of thrombinemia.

he degree of hypercoagulability was reduced after the treatment. Fibrinolysis was stimulated, but did not reach the control level. Concentrations of fibrinogen and fibrin monomer complex were remained high. It meant that the threat of DIS syndrome was remained. The level of fibrin and depressed fibrinolysis was remained high.

Conclusions: Hypercoagulability was developed in the blood of elderly patients ill with chronic generalized periodontitis and coronary artery disease. In saliva procoagulant activity was increased and fibrinolytic activity was decreased. Basic therapy of CGP did not cause the essential correction of hemostasis.

PO 473

Mucosal Tolerance to Multiple Peptides Ameliorates Atherosclerosis in Rabbits

A Mundkur L, Biradar S, Rao N, Sheena P, Ponnusamy T, Vrushali D, Lu X and Kakkar V

Thrombosis Research Institute, Bangalore, India

Background: Atherosclerosis occurs naturally in humans, few primates, and pigs. Rabbits are very sensitive to cholesterol-rich diets and develop an atherosclerotic condition closely resembling human lesions. This rabbit model is highly reproducible with minimal inter and intra laboratory variation between animals. Mucosal route of antigen administration is an attractive method for inducing antigen-specific peripheral tolerance, the efficiency of which is dependent on the type and dose of antigen. Treatment with high and low dose of antigen results T cells anergy and expansion of antigen-specific Treg cells respectively, while intermediate dosed are not effective in inducing tolerance. We have earlier established the efficacy of a recombinant multi antigenic construct in inducing oral tolerance and preventing development of atherosclerosis in mice model.

Aim: The objectives of the present study was to induce oral tolerance to recombinant multi antigenic construct, expressing the epitopes from apolipoprotein B 100 (ApoB), heat shock protein (HSP60) and Chlamydia pneumonia outer membrane protein (Cpn) in normocholesterolimic rabbits and to evaluate the protective effect of tolerance in preventing development of atherosclerosis.

Methods: Four different doses of multi antigenic construct were given by oral route to New Zealand white rabbits in order to determine the dose required to induce tolerance. Optimum dose for inducing tolerance was determined by reduction in systemic T cell response, secretion of the anti-inflammatory cytokines, and suppression of antibody response. Protective effect of tolerance was studied with the optimum dose of recombinant antigen in groups of New Zealand white rabbits with appropriate controls. Rabbits were given a feed containing 0.5% cholesterol for 16 weeks to induce development of atherosclerosis. Quantification of atherosclerotic lesions was carried out in the aortic sinus sections stained with Elastic van Geison (EVG). Lipid content was analyzed by Oil-Red-O staining. Immunohistochemical analysis were carried out by indirect immunofluorescence.

Results: Rabbits were given five doses of recombinant antigen ranging from 5 to 320 ug per dose to determine the optimum dose. Based on the systemic T cell response, Treg activity and antibody levels to peptides, 80 μg/dose was found to be the optimum dose to induce tolerance in rabbits. During 16 weeks of cholesterol rich diet feed, the total serum lipid content increased in control as well as the treated animals. Tolerance to recombinant antigen resulted in increase in the number of Treg cells in peripheral lymphoid organs with antigen specific functional activity. Development of atherosclerosis was reduced by by 51.3% in rabbit aortic sinus and descending aorta following oral tolerance. Total lesional area in the aortic sinus reduced from 28.78 ± 2.83% in control to 14.78 ± 1.66% in tolerized mice. Protection against atherosclerosis was associated with reduction in lipid accumulation as seen by oil -red O staining, infiltration of inflammatory cells and changes in the expression of cytokines and chemokines in the developing lesion.

Conclusions: Our results suggest that oral administration of multi antigenic construct expressing ApoB, HSP60 and Cpn peptides induces peptide specific tolerance which can prevent early atherosclerotic plaque development of in a rabbit model of diet induced atherosclerosis.

PO 474

A genetic risk score for coronary artery disease in Asian Indians

Shanker J, Arvind P, Nair J, Sathyamurthy Y, Ravindran V, Setty P, Jambunathan S and Kakkar V

Thrombosis Research Institute, India, Bangalore, India

Background: Recent discoveries of single-nucleotide polymorphisms (SNPs) showing modest association with coronary artery disease (CAD) have spurred the development of genetic risk prediction models.

Aims: We sought to identify genetic markers of CAD in a representative cohort of Asian Indians and to build a genetic risk score for significant discrimination of CAD in combination with the traditional risk factors.

Methods: An initial panel of 61 variants from 42 genes selected from published genome-wide association studies and internal discovery were genotyped by Taqman assay in 500 CAD patients and 500 matched controls in the 1st stage of a two-stage process. The cohort was selected from the ongoing Indian Atherosclerosis Research Study (IARS)*. Significant SNPs were independently validated in Stage II in 534 cases and 534 matched controls and confirmed in the combined cohort. The main outcome measure was the association of specific SNPs with CAD and the combined ability of significant SNPs to discriminate CAD based on 'c' index.

Results: In Stage I, nine SNPs showed significant association with CAD. In Stage II, seven of the nine SNPs showed persistent association and belonged to two distinct loci: 9p21.3 CAD locus (rs10757278, rs2383206, rs10757274, rs1333049, rs4977574) and *CELSR2-PSRC1-SORT1* cholesterol locus (rs646776, rs599839) with strong linkage disequilibrium among the variants. Two representative SNPs, rs2383206 and rs646776, one from each cluster, carrying high allelic odds ratio, constituted the pilot genetic risk score (GRS). Weighted GRS model ($P = 7.88 \times 10^{-10}$) performed better than unweighted additive model ($P = 1.66 \times 10^{-9}$). Subjects in top weighted GRS quartile showed higher risk of CAD than the bottom quartile (OR 2.59, 1.77–3.80; $P = 1.09 \times 10^{-6}$), after adjusting for potential confounders. Prediction model that included 2 SNPs and conventional risk factors enhanced CAD discrimination (c index 0.787, 0.768–0.807) than conventional risk factors (c index 0.779) or SNPs alone (c index 0.574) ($P = 0.018$).

Summary/Conclusion: A pilot 2-SNP GRS shows 2.6-fold higher risk of CAD in Asian Indians, with modest discrimination, offering scope for further improvement with the addition of newer genetic variants.

* The rationale and design of IARS has been published in *Indian Heart journal* 2010,62:286–95.

PO 475

Non-invasive surrogate markers of coronary artery disease in Asian Indians

Shanker J[1], Govind S[2], Bhasker D[1], Vaz P[1], Ravindran V[1], Kumar V[1] and Kakkar V[1]

[1]*Thrombosis Research Institute;* [2]*Narayana Hrudayalaya, Bangalore, India*

Background: A close correlation has been reported between endothelial dysfunction in the coronary and peripheral circulation. Carotid intima media thickness (CIMT), measured by B-mode ultrasound, is one such marker which is expensive and requires trained personnel to perform the test. On the other hand, pulse wave velocity (PWV), arterial stiffness index (ASI) and ankle brachial index (ABI) markers reflect the extent of atherosclerotic disease in the peripheral arteries and can be measured by Periscope, an oscillometry based monitoring and PC based acquisition and analysis system. This tool is cost-effective, easy to perform and ideal for performing large scale screening of cardiovascular disease in the population..

Aims: We studied the association of CIMT and peripheral vascular resistance markers in an unselected cohort of angiographically proven CAD patients and their unaffected family members, assessed the correlation between the different surrogate markers and tested their ability to discriminate CAD independently as well as in combination with the classical risk factors.

Methods: CIMT was measured by B-mode ultrasound in 380 (64 CAD affected and 316 unaffected) subjects while, ankle and brachial PWV, ASI and ABI were measured using Periscope in 710 (125 CAD affected, 585 unaffected) subjects participating in the ongoing Indian Atherosclerosis Research Study. The incremental value of clinical indices in discriminating CAD beyond the established risk factors was assessed though analysis of area under the ROC curve (A[ROC]).

Results: Both mean CIMT (0.68 ± 0.022 mm vs. 0.52 ± 0.010 mm) and max CIMT (0.84 ± 0.026 mm vs. 0.66 ± 0.012 mm ($P < 0.0001$) were higher in CAD affected as compared to unaffected subjects. Further, CAD patients showed higher PWV (1737.18 ± 51.89 m/s vs. 1465.84 ± 18.26 m/s) ($P < 0.0001$) and ASI (41.36 ± 15.92 mmHg vs. 37.56 ± 13.48 mmHg) ($P = 0.018$) as compared to the unaffected subjects. Subjects in the top tertile of mean IMT showed 20-fold increased risk of CAD (OR 20.42, 6.13–68.04 ($P < 0.0001$) before and 6-fold higher risk (6.02, 1.46–24.80 ($P = 0.013$) after adjusting for potential confounders. Similar comparisons yielded 7-fold increased risk of CAD (OR 7.25, 95% CI 3.87–13.60 ($P < 0.0001$) for PWV; however, statistical significance was lost following covariate adjustment. Males showed higher levels of CIMT and PWV than females. There was robust correlation between mean and maximum IMT ($r = -0.92$, $P < 0.0001$) and between PWV and ASI ($r = 0.13$–0.31, $P < 0.001$). Modest correlation was also observed between CIMT and ASI ($r = 0.14$, $P = 0.01$). Contrary to published reports, ABI did not show significant association with CAD in our study. Mean CIMT was higher in the presence of plaque and lower in CAD patients on statins. The risk prediction model that combined the classical risk factors, IMT and Periscope markers yielded the highest c index (AUC 0.906, 95% CI 0.880–0.932) than any of the markers alone, with 34% reclassification in the intermediate risk group.

Summary/Conclusion: Both CIMT and Periscope markers show significant association with CAD, suggesting that they can complement the established risk factors in predicting the risk of CAD in Asian Indians.

PO 476

Non-invasive assessment of extent of atherosclerotic disease, CVD risk factors and atherothrombotic biomarkers in Asian Indians

Shanker J[1], Govind S[2], Bhasker D[1], Vaz P[1], Ravindran V[1], Kumar V[1] and Kakkar V[1]

[1]*Thrombosis Research Institute;* [2]*Narayana Hrudayalaya, Bangalore, India*

Modest correlation was also observed between CIMT and ASI ($r = 0.14$, $P = 0.01$). Contrary to published reports, ABI did not show significant association with CAD in our study. Mean CIMT was higher in the presence of plaque and lower in CAD patients on statins. The risk prediction model that combined the classical risk factors, IMT and Periscope markers yielded the highest c index (AUC 0.906, 95% CI 0.880–0.932) than any of the markers alone, with 34% reclassification in the intermediate risk group.

Summary/Conclusion: Both CIMT and Periscope markers show significant association with CAD, suggesting that they can complement the established risk factors in predicting the risk of CAD in Asian Indians.

* The rationale and design of IARS has been published in *Indian Heart journal* 2010,62:286–95.

PO 477

Association of periodontal disease, extent of peripheral vascular changes, oral pathogens and risk of coronary artery disease in Asian Indians

Shanker J, Setty P, Arvind P, Nair J, Bhasker D and Kakkar V

Thrombosis Research Institute, India, Bangalore, India

Background: There is growing evidence from published studies to support a close association between oral health and cardiovascular disease. Periodontal disease induces early vascular changes in peripheral circulation, while several obligate oral pathogens have been detected in both sub gingival plaques and atheromatous plaque specimens.

Aims: The association of Periodontal disease with the extent of peripheral vascular disease and the association of two oral pathogens with oral and Coronary Artery Disease (CAD) were tested in two subsets of Asian Indians.

Methods: Individuals with either Gingivitis ($N = 575$) or Periodontitis ($N = 312$) were identified based on standard clinical criteria from the dental out-patient unit from a semi-urban charitable hospital in Bangalore. These subjects were then assessed for the extent of peripheral vascular disease using non-invasive oscillometry based Periscope, which measures pulse wave velocity (PWV), arterial stiffness index (ASI) and ankle brachial index (ABI).

Further, saliva samples were collected from 56 Periodontitis and 29 Gingivitis cases along with 51 angiographically proven CAD patients who were recruited from a Cardiac specialty hospital in Bangalore and analyzed for presence of Porphyromonas gingivalis (Pg) and Aggregatibacter actinomycetemcomitans (Aa). Salivary DNA was extracted by in-house method and relative quantitation (RQ) of Pg and Aa were determined by Taqman assay by amplifying pathogen-specific gene targets, 16srRNA and IktA, respectively, and 16s universal bacterial rRNA as endogenous control.

Results: Periodontitis cases showed greater extent of peripheral arterial disease with higher measures of pulse wave velocity and arterial stiffness index as compared to Gingivitis cases ($P < 0.0001$). Furthermore, there was higher prevalence of Pg in CAD patients based on RQ levels (0.85 ± 0.12) relative to Periodontitis (0.32 ± 0.04) or Gingivitis (0.13 ± 0.03) ($P < 0.0001$) cases, after correcting for expression of endogenous control, age and gender. Top RQ quartile of Pg was associated with nearly 8-fold higher risk for CAD as compared to the bottom quartile, after adjusting for potential confounders (OR 7.85, 95% CI:1.77–34.83). Subjects with Periodontitis showed higher prevalence of diabetes and hypertension compared to Gingivitis while Pg expression was also elevated in the presence of these classical cardiovascular risk factors. In variance with other published reports, Aa was detected only in three individuals in this study.

Summary/Conclusion: Our findings of strong association of Periodontitis with peripheral vascular changes and the association of Porphyromonas gingivalis with higher risk of CAD in this Asian Indian cohort provides new opportunities for reducing cardiovascular burden by spreading awareness of oral hygiene in the population.

PO 478

A comprehensive genetic analysis of the 9p21.3 CAD risk locus in Asian Indians

Shanker J, Arvind P, Jambunathan S, Nair J, Setty P and Kakkar V

Thrombosis Research Institute, Bangalore, India

Background: The 9p21.3 region, commonly referred to as the '*9p21.3 CAD risk interval*', encompasses multiple genetic variants in tight linkage disequilibrium, and is considered to be the best replicated genetic region for coronary artery disease (CAD).

Aims: We aimed to study the association of common variants in the 9p21.3 locus with incident CAD, analyze the expression profile of putative candidate genes and ANRIL, a non-coding RNA and their splice variants, supported by *in vitro* functional studies on Human Aortic smooth muscle cells (HuAoSMCs).

Method: A cohort of 1034 cases with positive family history of cardiovascular disease and 1034 age and gender matched controls were selected from the ongoing Indian Atherosclerosis Research Study (IARS) for the genetic association study, while an independent cohort of 100 cases with family history and 100 healthy controls, without family history of cardiovascular disease were included for the gene expression study. Five 9p21.3 common variants, rs10757278, rs10757274, rs2383206, rs1333049 and rs4977574, were genotyped by TaqMan allelic discrimination assay. Relative expression of following candidate genes and splice variants were measured by Taqman assay – *C9orf5, MTAP 1*, *MTAP 2*, *P16INK4a*, *P14ARF* (*CDKN2A*), *p15INK4b* (*CDKN2B*) and three splice variants of *ANRIL*, a non coding RNA – *NR_003529, NR_003529 + DQ485454 and EU741058*. Absolute copies of *DQ485454* were determined by subtracting copies of *NR_003529* from *NR_003529 + DQ485454*. Mechanism of regulation of ANRIL splice variants and neighboring genes in the 9p21.3 locus was determined by transfecting HuAoSMCs with siRNA that target either exon 1–2 or exon 18–19 of ANRIL.

Results: All five variants showed significant independent association with CAD. rs2383206 showed the highest individual association with CAD (OR 2.02, 95% CI 1.56 −2.62, $P < 0.0001$) and an adjusted OR of 2.55 (1.33–2.88) ($P = 0.004$) when combined with rs10757278. Analysis of area under the RIOC curve (A[ROC]) revealed that the risk prediction model that included conventional risk factors (CRFs), rs2383206 and rs10757278 showed a higher 'C' index (0.790, 95% CI 0.770 −0.810) than either CRFs (0.783, 0.763–0.803) or variants (0.561, 0.536–0.586) alone. The *GAAAA* haplotype showed significant protective association against CAD when compared to the common *CGGGG* haplotype (OR 0.45, 95% CI 0.27–0.77, $P = 0.004$). All the five 9p2.1 variants were in strong LD ($r = 0.90$–98). ANRIL splice var-

iant, *DQ485454,* showed higher expression while *CDKN2A* and *CDKN2B* showed lower expression in cases relative to controls. Subjects carrying the *GG* genotype showed higher expression of *EU741058* and lower expression of *P16INK4a* as compared to those with *AA* genotype. This pattern was consistent across all five variants. The AoSMCs transfected with siRNA specific for exon 18–19 but not exon 1–2 showed lower expression of full-length *ANRIL* (*NR_003529*) and p15INK4b, implying that the activity of this tumor suppressor gene is regulated through epigenetic mechanism via ANRIL.

Summary/Conclusion: This study provides further evidence on the importance of the 9p21.3 variants for risk of CAD in Asian Indians. The risk alleles in this locus appear to modulate expression of ANRIL, which in turn regulate the activity of adjacent tumor suppressor genes through epigenetic mechanisms.

PO 479

The polymorphism Sst? in APOC3 gene is not associated with abnormal lipid profile in Brazilian dyslipidemic children

Silva F, Sousa MO, Carvalho MG, Ferreira CN and Gomes KB

Federal University of Minas Gerais, Belo Horizonte, Brazil

Background: Polymorphisms in Apolipoprotein C3 (APOC3) gene have been associated with increased triglyceride levels, which may favor the development of cardiovascular disease.

Aims: This study aimed to investigate the relationship between SstI polymorphism (alleles C and G) in the APOC3 gene and lipid profile in dyslipidemic children from Brazil.

Methods: The study included 49 dyslipidemic children and 56 healthy children (control group), selected in the Academic Hospital at the Federal University of Minas Gerais, Brazil, after informed consent by their relatives. The study was approved by the ethics committee of the respective university. DNA samples were amplified by PCR followed by digestion with restriction enzyme *SstI* and polyacrylamide gel electrophoresis. Statistical analysis was performed using SPSS v.13.0.

Results: As expected, triglycerides ($P = 0.001$), total cholesterol ($P < 0.001$) and LDL-C ($P < 0.001$) levels were higher in dyslipidemic children compared to control group. There was no significant difference in the frequency of SstI polymorphism between case/control groups: 0.88 for the CC and 0.12 for the CG genotype in the case group, and 0.87 for CC and 0.13 for the CG in the control group ($P = 0.78$, OR = 0.74 and CI = 0.21 to 2.54). The difference in the allele frequency between normolipidemic and dyslipidemic groups was not significant. There was no association between the allele G or C and the triglyceride levels ($P = 0.97$), total cholesterol ($P = 0.59$), LDLc ($P = 0.62$), and HDL cholesterol ($P = 0.66$).

Conclusions: The results suggest that the polymorphism SstI is not associated with abnormal lipid levels in a small set of Brazilian dyslipidemic children, however, it is necessary to evaluate a larger sample group to confirm this finding.

Supported by CNPq, CAPES and FAPEMIG.

PO 480

Improvement of risk assessment with multi-pathway representative markers for coronary artery disease in the indian population

Vangala RK, Madan G, Ravindran V, Sharma A, Shankar J and Kakkar VV

Thrombosis Research Institute, Bangalore, India

Background: Asian Indians exhibit higher risk for developing coronary artery disease (CAD) at a younger age and many risk prediction algorithms underestimate this risk. We assessed multiple biomarkers from different patho-physiological pathways in assessing the risk to CAD in Indian population.

Aims: In this study we evaluated association of markers representative of inflammation (IL6, hsCRP, sPLA2), oxidative stress (Myeloperoxidase), Tumor necrosis factor (TWEAK), renal function (Cystatin C) and macrophage activation (Neopterin) pathways for developing multi-marker risk assessment in Asian Indians.

Methods: Eight hundred and sixteen age and gender matched subjects (408 CAD affected and 408 unaffected) were selected for a case control study from ongoing Indian Atherosclerosis Research Study (IARS). The information regarding inclusion, exclusion criteria and process of sample collection, and data storage have been published (Indian Heart J, 2010;6:286–95). All the blood samples were collected after overnight fasting of 12–14 h. Biomarkers Ilterleukin-6 (IL6), high sensitive C-reactive protein (hsCRP), secretory phospholipoprotein-2 (sPLA2), Myeloperoxidase (MPO), Tumor necrosis factor-like weak inducer of apoptosis (TWEAK), Cystatin-C (Cys-C) and Neopterin were assayed using ELISA kits according to the manufacturer's instructions. Logistic Regression, C-statistics and other statistical analysis were performed using SPSS ver17 software.

Results: A 49.5% of CAD affected subjects were diabetic and 45.8% had hypertension which was almost twice that of the unaffected group. A significant proportion of CAD affected subjects were on Statin (68.9%), Betablockers (60.8%), and Antiplatelet (87%) therapies. Higher levels of four biomarkers (IL6, sPLA2, Myeloperoxidase, Neoptrin) out of the seven were observed in CAD affected subjects in comparison to unaffected. In Logistic Regression models it was observed that individual markers were significantly associated with CAD namely IL6 with odds ratio of 1.74 (95% CI 1.14–2.66, *P*-value = 0.011), Neopterin odds ratio of 1.55 (95% CI 1.02–2.37, *P*-value = 0.041) and MPO odds ratio of 1.71 (95%CI 1.12–2.61, *P*-value = 0.013) for fourth quartile in comparison to first. The adjustment of above models to conventional risk factors did not yield any significant improvement in the odds ratio. However, for IL6, the odds ratio improved to 1.87 (95%CI 1.15–2.97, *P*-value = 0.011) after adjustment with lipids (triglycerides, total cholesterol, LDL and HDL). The C-statistics analysis was performed to understand the contribution of these three biomarkers to risk assessment wherein a combination of IL6, Neopterin and MPO alone gave a AUC of 0.647 (95%CI 0.610–0.685, *P*-value = 0.001) which improved to 0.825 (95%CI 0.797–0.853, *P*-value = 4.43×10^{-53}) with lipids. The net-reclasification analysis suggests that final model of combination of biomarkers reclassify 28 upwardly and 55 downwardly in unaffected and 4 upwardly and 6 downwardly in affected group.

Conclusions: Our data suggests that biomarkers from three different pathways namely, inflammation (IL6), oxidative stress (MPO) and macrophage activation (Neopterin) play a major role in risk assessment. For risk stratification by multimarker analysis, a combination of these three biomarkers add significant value proposition to the standard risk factors.

PO 481

The comparison of efficacy between recombinant activated factor VII (ARYOSEVEN®) and NOVOSEVEN® in patients with congenital factor VII deficiency

Faranoush M[1], Hassan A[2], Toogeh G[3], Karimi M[4], Eshghi P[5], Managchi MR[3], Hamid H[6], Kamyar K[7], Heshmat R[3] and Keykhahi B[8]

[1]Iranian Blood Transfusion Organization; [2]Shahid Beheshti University of Medical Sciences; [3]Tehran University of Medical Sciences, Tehran; [4]Shiraz University of Medical Sciences, Shiraz; [5]Shahid Beheshti University of Medical Sciences, Tehran; [6]Isfahan University of Medical Sciences, Isfahan; [7]AryoGen Biopharma Company, Karaj; [8]Ahvaz University of Medical Sciences, Ahvaz, Iran

Introduction: Recombinant factor VIIa is approved for the treatment of bleeding episodes in congenital factor VII deficiency, hemophilia

A/B with an inhibitor and Glanzmann's thrombasthenia. Factor VII deficiency is an autosomal recessive bleeding disorder. This study is a comparison between the efficacy of a new biosimilar recombinant factor VIIa concentrate (Aryoseven®) and Novoseven® in patients with congenital factor VII deficiency.

Methods: A multicenter double-blind randomized clinical trial was conducted in comprehensive hemophilia care centers in Iran. Inclusion criteria: 1- congenital factor VII deficiency with more than one episode of bleeding per month, 2- age > 2 years. Exclusion criteria: 1- any other coagulation disease, 2- prophylaxis therapy with rFVIIa during the last month, 3- platelet count < 50,000, 4- presence of a neutralizing anti-factor VII antibody.

Consenting patients who met these criteria were randomly assigned to an intervention or a control group. The patients in the intervention group (Group A) received the biosimilar recombinant factor VIIa (AryoSeven) and the patients in the control group (Group B) received Novoseven®. rFVIIa (Novoseven® or AryoSeven) dosage was 30 μg/kg, intravenously, once per week for 4 weeks.

Primary outcome was plasma FVII: C activity IU/dl 20 min after injection, with a level of FVII: C below 30 IU/dl considered a treatment failure. Secondary outcome was self-reported bleeding frequency. FVIIa was measured by STACLOT® VIIa-rTF made by Diagnostica Stago. FVII activity has been checked by recombinant thromboplastin. Sixty-six patients were enrolled and allocated to the two groups by consecutive balanced block randomization tables (fixed block size of 4) per hemophilia center. Group A (35 patients, 53%) received Aryoseven® and group B (31 patients, 47%) received Novoseven®.

Results: The mean age was 21.2 (range: 2–64 years) and 48.5% (32 patients) were male. Median (IQR) plasma level of FVIIa activity in group A and B was 1.6 (1.1–20.0) IU/ml and 6.0 (1.1–27.0) IU/ml before injection. All patients in the two groups had FVIIa concentrations exceeding 30 IU/ml 20 min after rFVIIa injection. There was no difference in increment of FVIIa activity level 20 min after rFVIIa injection between two groups in any of the 4 weeks (for example in week 4: group A: 222.0 (range 192.7–504.3), group B: 216.5 (range 175.4–486.5), $P = 0.481$).

The severity of bleeding was also similar between the two groups, with a similar reduction in bleeding compared with the month prior to treatment (group A -1.5 bleeding events per month, group B -1.53).

Reported side effects were minor (headache, nausea) and occurred in similar frequency in both groups [Group A: 8 (24.2%), Group B: 3 (10.0%)].

Conclusion: AryoSeven® is similar to Novoseven® in post-injection FVIIa activity, as well as in clinical efficacy. The frequency of side-effects was also similar, although the study was underpowered to detect differences in rare complications between the two compounds.

PO 482

New data on the non-invasive method for the study of the haemostatic system

Kuznik B[1], Fine I[2], Maksimova O[1], Kustovskaya E[1] and Khasanova N[1]

[1]Chita state medical academy, Chita, Russia; [2]ELFI-TECH LTD, Rehovot, Israel

Aim: The aim of the study to examine the state of the hemostatic system in health and in various of the disease (coronary heart disease, diabetes mellitus type 1 and 2, hyperthyroidism, etc.) through the analysis of the speckle nature of the scattering of coherent light from the skin surface.

Methods: We, together with the union Elfi-tech Ltd (Israel) developed methods to noninvasively assess the degree of plasma viscosity, kinetics of aggregation of blood cells, cardiovascular system, haemostasis, and endothelial dysfunction. With the proposed method in terms of blood flow and stop it determined the following indicators (both before and after clamping): (1) Perfusion index before clamping (characterizes the intensity of blood flow), (2) The index of blood flow (the product of the velocity on the volume of flowing blood), (3) Index corresponding to the blood flow velocity (relative value), (4) SKF-index, which characterizes the biological age of the vessels, (5) Congestion index – the ratio of blood flow after occlusion of blood flow to occlusion, (6) Diffusion coefficient (DC), the corresponding rate of Brownian motion of red blood cell. Simultaneously the state of the aggregation function corpuscles, blood coagulation, the basic content of natural anticoagulants and fibrinolysis were assessed.

Results: It was established that the index of SKF correlated directly with biological age. After 60 years dependence on age is much less pronounced, which is mainly due to the direct or indirect diseases of the circulatory system, proceeding on a background of atherosclerosis. Patients, especially with endothelial dysfunction, the index was higher than in healthy of the corresponding age.

High correlation relationship between SKF and a DC on one side, and the rate of blood coagulation, platelet aggregation, formation of red blood cell-leukocyte-platelet aggregates, the concentration of SFMC and D-dimer, INR, and protein C.

When receiving antiplatelet (aspirin, trental, clopidogrel, etc.) and especially of indirect anticoagulants (warfarin) SKF index decreases. In the case of resistance to antiplatelet SKF little changed. Therefore, using the proposed non-invasive method for studying the activity of blood coagulation can be controlled receiving of indirect anticoagulants (warfarin), and also to judge the resistance to antiplatelet agents.

When registering speckles, which are the result of the Brownian motion of red blood cells, we developed a new method to determine blood clotting time *in vitro*.

In patients with damage to the cardiovascular system, leading to endothelial dysfunction, SKF index to the action of heat does not change or increases.

Conclusion: The developed methods proved to be highly sensitive and can be introduced in clinical practice to assess the aggregation activity of blood cells, vascular-platelet hemostasis and coagulation, and endothelial dysfunction.

PO 483

Relationship of hla-phenotype with some hemostasis profiles

Nimaeva D and Tsyrendorzhieva V

Chita state medical academy, Chita, Russia

In recent years, there were many studies about a single integrated system of protection that is formed by the immune system, hemostasis and nonspecific resistance of the body. The existence of immune regulation of physiological functions including hemostasis is determined. Hence, assume the existence of associations between HLA-specificities and hemostasis.

Aim: The goal of our study was to discover interrelations between HLA-phenotype of healthy people of Buryat nationality and hemostasis profiles.

Materials and Methods: we examined 53 healthy donors of Buryat nationality who live in Aga Buryat Autonomous District of Russia in the age of 18–34 years, who are not in relation with each other, with an equal sex ratio.

Nationality was established by polling on the direct relatives of at least 2 or 3 previous generations.

Coagulation tests included determination of activated partially thromboplastin time (APTT), prothrombin time and international normalized ratio (INR), thrombin time, activity of protein C, and antithrombin-III, fibrinogen concentration and XIIa-dependent fibrinolysis.

Antigenic identity was defined in the standard two-stage microlymphocytotoxic test (Terasaki PI, Bernoco D., Park MS et al., 1978) 19 antigens of locus A and 38 antigen of I locus B I class were identified.

Statistical analysis of the data included calculation of the degree of incidence of HLA-antigens, genes, haplotype frequencies, values of linkage disequilibrium, the authenticity of differences and genetic distance between populations for HLA-alleles (P. Mattiuz et al., 1970 Brownlee, KA, 1997). indetifying specific indicators of HLA-antigens, that mark the level of a particular parameter, set the average value of hemostasis in subgroups of healthy people, selection based on the presence or absence of each of the investigated HLA-antigens, and compared using T. Student's test.

Results: Those with a phenotype B51 typically have reduced platelets count and shortened prothrombin time. However, carriers of B62 have increased platelets count, accelerated XIIa-dependent fibrinolysis and reduced concentration of fibrinogen. At the same time, carriers of antigens HLA-B40 and B5 have lower concentration of protein C, whereas in those with B7 phenotype is increased. Specific inhibition of fibrinolysis is typical for people with HLA-B40, they also tend to have low fibrinogen.

Marker B12 is associated with prolongation of prothrombin time and decreasing the concentration of antithrombin-III (AT-III). The carriers of A2 have shortened APTT, and those with A23 antigen have it prolonged. For people with HLA-antigens A1, A9, B7, B12, B44 characteristic reduction in the concentration of AT-III.

It was found that the value of prevalence of parameters associated with a particular HLA-antigen of the total number of investigated profiles of hemostasis respective to the frequency of HLA-antigen in the population, being expressed by the index F/A, is the highest for phenotypes A3 and B12. These antigens are found with average or below-average rate, but are associated with the greatest number of the studied parameters.

Conclusion: The data presented shows close relationship between antigens HLA – class 1 with hemostasis, and confirms that the immune system, vascular-platelet hemostasis, blood coagulation and fibrinolysis are in single humoral defense system.

PO 484

Variations of coagulation parameters during orthotopic liver transplantation – single center experience

Novakovic-Anucin SL[1], Gnip S[1], Canak V[1], Radovic P[1], Jurišic D[1], Erdeljan S[2], Miloševic Z[2] and Mitic G[1]

[1]Clinical Centre of Vojvodina, Centre of Laboratory Medicine; [2]Clinical Centre of Vojvodina, Novi Sad, Serbia

Background: During liver transplantation values of coagulation parameters show significant changes, while in the postoperative period a gradual normalization in the function of the coagulation system occurs.

Aims: Aims of the study were to laboratory monitor changes in the coagulation system intraoperatively and postoperatively and to evaluate the dynamics of normalization of the analyzed parameters.

Methods: There were 20 orthotopic transplantations performed at the Clinical Centre of Vojvodina (KCV) in the period from June 2008 to November 2012. The research was conducted on a group which included 20 patients, 6 women and 14 men. In the majority of cases the aetiology was liver cirrhosis caused by viral hepatitis B and C, which was diagnosed in 14 patients in total. Laboratory testing was carried out at the laboratory of the Department of Thrombosis, Haemostasis and Haematology Diagnostics of the KCV. The test samples were taken intraoperatively and postoperatively. The following coagulation parameters were tested: platelet count (PLT), activated partial thromboplastin time (aPTT), prothrombin time (PT), thrombin time (TT), fibrinogen level (FBG), euglobulin clot lysis time (ECLT), D-dimer, antithrombin activity (AT) and anti-Xa level.

Results: During transplantation the most pronounced coagulation system changes were: thrombocytopenia (93 ± 62.3), prolonged aPTT (1.73 ± 0.8), PT (1.58 ± 0.4) and TT (1.94 ± 1.4), hypofibrinogenemia (2.08 ± 0.4), accelerated fibrinolysis (34 ± 23.5), increase of D-dimer values (1261 ± 1167.1) and a decrease of AT activity (60 ± 16.9). The most prominent disturbances during transplantation was verified in anhepatic phase, predominantly high fibrinolytic activity. Further laboratory monitoring after transplantation from postoperative day 1 revealed a progressive normalization in the values of the tested coagulation parameters, reaching physiological levels of all parameters of the coagulation system on the postoperative day 14, except for a sustained high value of D-dimer (2516 ± 1077.6). The level of anti-Xa activity was within the prophylactic range (0.25 ± 0) after the introduction of low-molecular-weight heparin thromboprophylaxis.

Summary/Conclusions: Permanent monitoring of the coagulation system parameters in liver transplantations is very important, as it enables the use of optimal substitution therapy during and after transplantation, as well as an adequate *postoperative prevention of venous thromboembolism.*

PO 485

Implication of post-translational modifications on the function of key haemostatic proteins

Perera S[1], Monagle P[2] and Vera I[1]

[1]Murdoch Childrens Research Institute; [2]The University of Melbourne, Parkville, Vic., Australia

Background: Post-translational modifications (PTMs) such as glycosylation and phosphorylation play an important role in the function of haemostatic proteins and are critical in the setting of disease. Such secondary level changes to haemostatic proteins have wide ranging effects on their ability to interact with other proteins. The PTM of haemostatic proteins and the subsequent impact on protein structure and function, specifically via interaction with other proteins as well as with novel anticoagulants that target specific proteins represents an important area of research.

Aims: To summarize the recently investigated PTMs associated with haemostatic proteins and the implications these modification have on protein function.

Methods: We performed a review of literature published between 2005 to 2008, limited to English and human studies, with the following search terms; post translational modification & haemostatic & protein, Fibrinogen, Factor VIII, tissue factor, von Willebrand Factor (vWF), antithrombin (AT).

Results: The main PTM described with vWF is N-Glycosylation that prevents adhesion of the protein to platelets. This PTM occurs in 13% of the adult population and the prevalence in children is not well documented.

Tissue factor can undergo phosphorylation, which causes a change in the long sugar chain where protein kinases transfer phosphate groups to the hydroxyl side chains. This typically occurs in the setting of protease-activated receptor-2 signaling pathways for coagulation diseases. In adults phosphorylation of TF occurs in 90–95% of hydroxyl side chains with the effect on child TF not well described. This event increases platelet affinity to other coagulation factors and changes signaling pathways.

Factor VIII is commonly sulfated. For normal physiological function of Factor VIII 6 tyrosine residues of the protein need to be sulfated. The degree of sulfation at various sites on the protein has varying implications on the function of Factor VIII.

Antithrombin (AT) function is highly sensitive to PTM and this protein commonly undergoes a polymerization where arginine residues are converted to citrulline. Increased citrullination can lead to increased risk of thrombosis. Adults with rheumatoid arthritis and adenocarcinoma show significantly higher levels of citrullinated AT compared to the healthy population.

Tyrosine residues are the main target for PTM of Fibrinogen by nitration. It is shown that fibrinogen polymerizes faster when tyrosine sites 292 and 422 are nitrated. This PTM amplifies viscoelastic properties of Fibrinogen and carries a prothrombotic risk factor particularly for

patients with Coronary Artery Disease who show a 30% increase in nitrated fibrinogen compared to the healthy population.
Summary/Conclusion: Common haemostatic proteins have recently been shown to be susceptible to PTM by citrullination, sulfation nitration, glycosylation and phosphorylation. These modifications have implications on haemostatic protein function. Future studies are required to compare and contrast the presence of these modifications in child haemostatic proteins and the mechanisms by which they arise in adults.

PO 486
Proteomics of defined platelets

Rezaee F[1], Badlou B[2] and De Vries M[1]
[1]University Medical Center Groningen, Groningen; [2]BB Scientific Advisor, Utrecht, The Netherlands

Background: Platelets play an important role not only in the prime of coagulation but also in the final event of fibrin stabilization. Too much number of platelets in circulation is lead to the clot formation obstructing blood vessels and too low is resulted in the bleeding. Thus a homeostatic regulation of platelets is necessary to prevent unwanted bleeding and blood vessel obstruction via uncontrolled clot formation.
Aim: Since platelets are highly important in wound healing event, we decided to perform a proteomics (nLC-MS/MS) analysis of defined and highly pure platelets. The protein content of platelets helps us to gain more knowledge about the cells without nucleus.
Methods: As first step, the highly pure Platelets were isolated by iodixanol-gradient centrifugation. The protein coverage was subsequently assessed by nLC-MS/MS.
Results: Orbitrap LTQ-XL (LC-MS/MS) analysis detected approximately 110 proteins divided in many functional clusters of proteins such as adhesion molecules, growth factors, coagulation factors (FV, vWF and FXIIIA), immune system and many novel proteins.
Conclusion: A collection of defined and highly pure platelets proved to be essential for correct protein content information of these cells. nLC-MS/MS proved to be a powerful tool for the analysis of proteins synthesized by platelets.

PO 487
A dual role for monocytes in coagulation and fibrinolysis cascades: non-canonical coagulation factor production

Rezaee F[1], Dashty M[1], Akbarkhanzadeh V[2], Zeebregts C[1], Sijbrands E[3], Spek A[4] and Peppelenbosch MP[3]
[1]University Medical Center Groningen, Groningen; [2]Internal Medicine, Amsterdam; [3]Erasmus Medical Center Rotterdam, Rotterdam; [4]Academic Medical Center, Amsterdam, The Netherlands

Background: Coagulation/fibrinolysis system is essential for wound healing after a vascular injury. In canonical haemostasis, synthesis of coagulation factors is exclusively restricted to liver, platelets and the endothelium.
Aim: We decided to challenge this classical interpretation by measuring coagulation factors production in human primary cells.
Methods: The mRNA levels of prothrombinase complex (FV and FX), in tenase complex (FVIII), FVIII-stabilized protein (vWF), fibrin clot stabilizer (FXIIIA) and lyzing (thrombomodulin = TM) were measured in nine different pure human primary cells with and without LPS treatment.
Results: FX mRNA was expressed by fibroblasts, visceral Preadipocytes/adipocytes and hepatocytes, but not macrophages and other cells. All cells express FVIII except endothelial cells. Fibroblasts, endothelial cells and macrophages synthesize TM, but not FV. Since monocytes and platelets express FV and FXIIIA, both cells prime coagulation activation and stabilize the fibrin clot. Vascular-related cells that express FV, FX was not detected and *vice versa*. We called this phenomenon; *FV/FX expression law*. After wound healing, monocytes-released TM possibly destabilizes and lyzed the fibrin clot via 1-FXIIIA-breakdown and 2-activated protein C respectively.
Conclusion: This study provides evidence for the dual role of monocytes in coagulation/fibrinolysis systems. our data suggest that congenital problems in FV production can be rationally treated by allogeneic bone marrow transplantation.

PO 488
Hemostatic alterations in mice model produced by mapanare snake venom (Bothrops isabelae) from Venezuelan Andes

Salazar AM[1], Bouza K[2], Gomez L[2], Rodríguez-Acosta A[2], Salazar E[1], Carvajal Z[1], Gil A[1], Ibarra C[1] and Guerrero B[1]
[1]IVIC; [2]UCV, Caracas, Venezuela

Background: Venom from *Bothrops isabelae*, which belongs to the Viperidae family, contains a complex mixture of components with many biological functions that can act on the haemostatic system. In Venezuela, Bothrops snakes are responsible for more than 80% of all recorded snakebites, being the most important species *Bothrops colombiensis, B. venezuelensis, B. atrox* and *B. isabelae*.
Aim: Evaluate the lethal dose (LD_{50}) in C57BL/6 mice and determinate the hemostatic alterations in this experimental model.
Methods: Lethality of *B. isabelae* crude venom was determined by intraperitoneal (IP) injections into C57BL/6 mice and expressed as LD_{50}, a value that was calculated according to the method of Spearman-Karber (1978). Male mice were injected with a sub-lethal dose of crude venom in 200 μL of sterile saline solution and control mice were injected with 200 μL of sterile saline solution. Blood samples, about 1 mL per mouse, were collected by cardiac puncture under anaesthesia in CO_2 chamber. Hematologic (hemoglobin, hematocrit, leukocyte count, differential leukocyte count and platelets count) and hemostatic parameters (PT -Prothrombin Time, aPTT -activated Partial Thromboplastin Time, TT -Thrombin time, fibrinogen and endogenous fibrinolytic activity) were measured at 48 and 96 h after venom injection.
Results: LD_{50} of *B. isabelae* crude venom was 134 μg/mice (6.7 mg/Kg). In comparison at control mice, the sub-letal dose (50 μg/mice) of crude venom at 48 h after IP injection induced a shorter in aPTTa (20.3 ± 1.3 vs. 25.1 ± 1.4 s) and TT (11.9 ± 0.7 vs. 21.1 ± 0.6 s) ($P < 0.01$), without variation in PT (13.1 ± 0.8 vs. 13.2 ± 0.7 s). Furthermore, there was a decrease in fibrinogen concentration (1.7 ± 0.5 vs. 2.71 ± 0.42 mg/dL) and an increased in the endogenous fibrinolytic activity (144.92 ± 34.35 vs. 40.12 ± 24.01 mm^2), ($P < 0.01$). In hematological parameters was observed that venom induced a decrease in hemoglobin concentration (10.7 ± 0.6 vs. 12.8 ± 0.7 g/dL), hematocrit (31 ± 2 vs. $39 \pm 2\%$), leukocytes (2313 ± 185 vs. 3298 ± 698 mm^3), platelets (285 ± 60 vs. $701 \pm 53 \times 10^9$/L) and increased in lymphocyte percentage (84 ± 3 vs. $65 \pm 11\%$), ($P < 0.01$). At 96 h, all the parameters above were similar to those obtained for the controls, except leukocyte, platelets, hemoglobin and hematocrit.
Conclusions: These findings are related with previous *in vitro* assays of coagulant and fibrinolytic activities induced by *B. isabelae*. In this sense, our study is the first report of the effect in mice on hemostasis by this venom. In addition, our results suggest that C57BL/6 mice represent a useful model to understand the hemostatic alterations induced by snake venoms, allowing a deeper understanding of the action mechanisms for future therapeutic at this level.

PO 489

Anaemic comorbidity is associated with coagulation dysfunction in patients with heart failure

Wang J-S and Chen YW

Chang Gung University, Tao-Yuan, Taiwan

Background: Anaemic comorbidity is associated with an adverse prognosis in the HF population. Anaemia-related malnutrition and vascular inflammation may contribute to coagulation dysfunction.
Aims: This study investigated whether anaemic comorbidity influences plasma procoagulant microparticles (MPs) and MP-mediated thrombin generation (TG) in patients with heart failure (HF).
Methods: According to the WHO criteria for anaemia, 109 HF patients were divided into three groups: non-(N-A, $n = 77$), light-(L-A, $n = 16$), and moderate/several-(M/S-A, $n = 16$) anaemic groups. Dynamic TG, procoagulant MPs, coagulation factors, and peroxide/pro-inflammatory biomarkers in plasma were analysed in these HF patients and 33 normal counterparts (N-C).
Results: All HF groups revealed the reduction of dynamic TG by lengthening lag time, lowering endogenous thrombin potential, and decreasing peak height and rate of TG. M/S-A exacerbated the extent of HF-declined TG, whereas no significant difference in TG between various HF groups occurred following depletion of MPs in plasma. Moreover, N-A, L-A, and M/S-A had lower tissue factor (TF)-rich and phosphatidylserine-exposing MPs that were derived from leukocytes ($CD45^+$), platelets ($CD41a^+$), and erythrocytes ($CD235a^+$), as well as, higher endothelial ($CD144^+$) MPs than N-C. However, M/S-A simultaneously lowered TF activity and tissue factor pathway inhibitor (TFPI) level, which were accompanied by heightened plasma myeloperoxidase and interleukin-6 concentrations, compared to N-A and L-A did. Additionally, both TF activity and TFPI level were negatively correlated with the TG rate in HF patients.
Conclusion: HF decreases blood cell-derived procoagulant MPs, increases vascular endothelial shedding, and reduces dynamic TG in plasma. Furthermore, M/S-A augments HF-declined TG, possibly by depressing TF-related coagulation activity.

PO 490

Counselling by healthcare professional for patients taking oral direct inhibitors as anticoagulant therapy

Baglin CAC

Addenbrookes hospital, Cambridge, UK

Background: The Clinical Leaders of Thrombosis (CLOT) are a specialist interest group made up of approximately 450 multi disciplinary healthcare professionals (HCP) working in the UK who have direct patient contact working in the field of Haemostasis and Thrombosis. They include, nurses, doctors, biomedical scientists and pharmacists in both primary and secondary care. The group's aim is to deliver high quality care to patients by sharing knowledge and experience in order to shape future services and advance the boundaries of healthcare delivery.
Aims: Members of CLOT highlighted the need for written guidance on counselling patients who have been prescribed the newly licensed oral anticoagulant agents. The group felt they have many requests for written guidance on the subject with reference to relevant publications, and want to deliver proactive patient focused care. This group is ideally placed to promote, deliver and review this information.
Methods: At the annual meeting in October 2012 an advancing practice workshop was held. The workshop attendees split into discussion groups looking at national, regional, local and pharmaceutical company recommendations. The recommendations of each were looked at, opinions sort and concerns shared. These were used as the basis for the counselling recommendations given.
Results: As a result the issues to be addressed with this patient group have been identified for use by any HCP. The workshop attendees decided by majority vote that the new anticoagulants should be referred to as oral direct inhibitors (ODI). They identified and agreed what the counselling should consist of. Patients should have an explanation as to the purpose of anticoagulant therapy and how the treatment will work for them. Basic therapy information should be given and counselling should address how to take the medication safely and other medications to avoid, possible side effects of treatment and when to seek further advice and help. It also suggests precautions and risks with this treatment. Finally it gives practical advice on care that needs to be undertaken including laboratory testing, and annual follow up arrangements.
Summary: The CLOT group wants all patients taking ODIs to be given the same safe, unbiased and practical information. They felt that a unified approach with adjustments for local varying arrangements to be the way forward. They intend to continue to review and update this.

PO 491

Subcutaneous injection of enoxaparin in neonates

Goldsmith RE, Nagel K, Paes B and Chan AK

McMaster Children's Hospital, Hamilton, ON, Canada

Background: Enoxaparin, a Low Molecular Weight Heparin (LMWH), is a frequently used anticoagulant in the neonatal population because of reduced adverse effects, ease of administration and reliable pharmacokinetics. The recommended route of administration is by subcutaneous (SC) injection. Through the 1–800-NOCLOTS, a toll-free service established in 1994 to provide consultation to pediatric professionals globally about the management of pediatric thrombosis, the question of the preferred site of SC injection in neonates is often queried.
Objective: To determine if there are any evidence-based guidelines regarding subcutaneous injection of LMWH in neonates.
Methods: Web of Science, PubMed, Medline CINAHL, Cochrane, DARE and OVID databases including relevant published nursing textbooks were searched for articles specific to subcutaneous administration of LMWH in neonates.
Results: A paucity of articles specific to subcutaneous administration of LMWH in neonates exist. We found only one study that examined the absorption of insulin and growth hormone via SC injection, but this did not include neonates. One study was identified on the administration of LMWH to neonates via an indwelling catheter, but the current recommendations are to rotate SC injection sites. One case study supported intravenous administration of LMWH, citing the lack of SC fat in pre-term and low birth weight neonates. A review of nursing textbooks revealed that while SC sites have remained the same for decades, there is no evidence to support the choice of sites except expert opinion.
Conclusion: Currently we rely on expert opinion or local guidelines when administering LMWH by SC Injection during the neonatal period. There are no evidence-based guidelines for the choice of SC site, and the literature regarding optimum sites is based solely on animal data. Several studies have also noted the need for higher loading and maintenance doses of LMWH to achieve target Xa levels during prophylaxis in neonates and this my be influenced by the injection site, the administration procedure or local mass of adipose tissue. A prospective study is needed to determine the best site and angle of SC Injection of LMWH in neonates.

PO 492

Risk of recurrence of venous thromboembolism assessment following discontinuation of initial treatment of anticoagulation

Baglin CAC
Addenbrookes hospital, Cambridge, UK

Background: Specialist nurses working in Haemostasis and Thrombosis have many roles to undertake including delivering proactive patient focused care and to improve the safety and quality of that care within available resources. Clinical leadership should ensure that new evidence based practice is translated into patient care that is safe, effective and person centred.
Aims: To develop a patient focused rather than disease driven approach to care following discontinuation of the recommended initial treatment with anticoagulation after diagnosis of a venous thromboembolism (VTE).
Methods: All patients who commence anticoagulation after diagnosis of a VTE are seen in the anticoagulant clinic. During the clinic visit a care pathway is completed which identifies all patients who have been diagnosed with a first episode of unprovoked VTE. Following national guidelines these patients are advised to have a finite period of anticoagulation. After stopping their initial treatment of anticoagulation these patients are offered an appointment in the nurse led Thrombophilia clinic. This appointment includes a clinical risk assessment which incorporates a Villalta scoring for patients with the post thrombotic syndrome (PTS), appropriate blood testing (including D-dimer) and patient preference discussion. Each patient then has a further clinic appointment, including the Dash scoring system to aid decision making. A treatment plan is agreed based on the patients individual needs.
Results: Since its introduction over 100 patients have followed this pathway. Patients were concerned that following initial treatment with anticoagulation they did not routinely have follow up, or that follow up varied depending on who they spoke to or where they lived. This care pathway has taken pressure off the medical consultants and has become a standardized care pathway in our service delivery. The benefit for patients is a clear route for them to follow and allows closure following discontinuation of treatment after a first episode of VTE.
Summary: This standardized approach allows high quality care to be offered to all patients. We believe we are the first service in the country to introduce a nurse led standardized approach. It is transferable across Trusts, and should be seen as an extension of the role of the clinical nurse specialist in anticoagulation.

PO 493

Treating pregnant women with high dose immunoglobulin (IVIG) in a single skilled center reduce side effects

Bashari D, Avni D, Levinas M and Zadok O
Sheba Medical Center, Ramat Gan, Israel

Background: Fetal neonatal alloimmune thrombocytopenia (FNAIT) is a life threatening bleeding disorder in the fetus/neonate caused by maternal alloantibodies directed against fetal human platelet antigen (HPA) inherited from the father. In 85% of NAIT cases the immuno dominant is HPA 1a. In Caucasians the allele frequencies of HPA-1a and HPA1b are 85% and 15% respectively.
Aim: In order to prevent the delivery of a newborn with intracranial hemorrhage, one of the serious complications of FNAIT, treatment with intravenous immunoglobulin G (IVIG) with or without steroids is currently the standard treatment.
During the last 4 years, our Center treated 24 women with high dose IVIG because of FNAIT. We had the impression that treating those women in a skilled Center and as a group could reduce side effects related to treatment and furthermore, keep them adhered to treatment's schedules.
Method: For studying that, we followed prospectively in the last year four pregnant women treated with IVIG for approximately 21 weeks, 3 of those were treated with IVIG at standard dose of 1 g/kg/week and the remaining one at dose of 1.5 g/kg/week and steroids at dose of 0.5 mg/kg/d initiated at 31 weeks until term. Two of the women received IVIG (Gammagard, Baxter U.S.A) and the other two women were treated initially with Gammagard and then switched to IVIG (Gamunex, Talecreis, U.S.A.) because of Gammagard shortage. Three women complained of mild headache 4–5 h following treatment was finished and which relieved by acetaminophen. Fatigue was another complaint which last for at least 24 h after.
Results: The success of IVIG treatment (higher platelet counts in newborn following treatment) was to some extent related to the fact that the women came regularly to treatments without any rescheduled or postponed treatment. All four women claimed that being treated with IVIG in a group for the same purpose and with the same drug, improved their wellbeing in regard to FNAIT diagnosis and treatment. To the same conclusions came 6 more women that came to our clinic 2 years after given birth.
Conclusion: In summary, we do believe that high dose of IVIG that given by skilled nurses and accompanied by group of women treated for the same purpose could reduce dramatically side effects attributable to the drug and augment success to IVIG treatment.

PO 494

Hemostatic markers and sleep quality among shift work and day work female nurses

Saharov G[1], Nadir Y[1], Keren A[1], Brenner B[1] and Shochat T[2]
[1]Rambam Health Care Campus, Raqefet, Israel; [2]University of Haifa, Haifa, Israel

Background: The haemostatic system has a significant impact on cardiovascular morbidity. Epidemiologic studies indicate an increased risk of cardiovascular diseases amongst shift workers. Such risk may be attributed to circadian misalignment of haemostatic markers and restricted sleep time.
Aims: To reveal some of the underlying mechanisms of cardiovascular morbidity in the shift-work population, we performed a comparison of the profiles of haemostatic markers among healthy shift working vs. daytime working female nurses. It was hypothesized that alterations in the haemostatic system may underlie the increased risk for cardiovascular illness in shift workers. Accordingly it was predicted, that haemostatic markers would be elevated in rotating shift workers compared to regular day workers, and that sleep quality would serve as a mediator in this relationship.
Methods: Thirty shift working and thirty day working female nurses were recruited at Rambam Health-Care Campus (total $n = 60$). For each participant, blood was drawn at 07:00 in the morning for the measurement of six markers of coagulation, including PAI-1, Heparanase procoagulant activity, tissue factor + heparanase complex, protein C, D-dimer and fibrinogen. Sleep quality was assessed by self report (Pittsburgh Sleep Quality Index, PSQI).
Results: PAI-1 levels were significantly higher among shift work nurses compared to day work group (36.6 ng/ml vs. 24.3 ng/ml, $P < 0.05$). In shift workers, Heparanase procoagulant activity was 2-fold and tissue factor + heparanase complex was 1.5-fold compared to day work nurses (both $P < 0.05$). Sleep quality was significantly lower for shift compared to day workers ($P < 0.001$). No group differences were found for Protein C, D-dimer and fibrinogen.
Concusions: PAI-1 and heparanase markers were significantly elevated and sleep quality reduced in shift-work compared to day-work nurses. Such alterations in healthy shift workers point at disturbances in haemostatic system, which may contribute to cardiovascular morbidity in the future.

PO 495

The PLD inhibitor, 5-Fluoro-2-indolyl des-chlorohalopemide, protects from occlusive thrombus formation and ischaemic stroke without impairing haemostasis

Thielmann I[1], Stegner D[1], Kraft P[2], Frohman MA[3], Stoll G[2] and Nieswandt B[1]

[1]University Wuerzburg; [2]Universtity Hospital Wuerzburg, Würzburg, Germany; [3]Stony Brook Universtity, Stony Brook, NY, USA

Background: Phospholipase D (PLD) catalyses the hydrolysis of phosphatidylcholine to phosphatidic acid and choline and is expressed in a wide range of tissues. Recently, we demonstrated that Pld1 is required for GPIb-dependent platelet integrin activation and that Pld1 and Pld2 both contribute to platelet α-granule release. As a consequence, mice deficient in Pld1 or in both PLD isoforms were protected from pathological thrombus formation and ischaemic stroke, whereas haemostasis was not impaired. These findings led to the hypothesis that PLD could serve as target for safe antithrombotic therapy, but *in vivo* evidence in support of this has been lacking.
Aims: We sought to assess whether pharmacologic inhibition of PLD activity with the reversible, small molecule inhibitor 5-Fluoro-2-indolyl des-chlorohalopemide (FIPI) affects haemostasis, thrombosis and thrombo-inflammatory brain infarction in mice.
Methods: Mice received FIPI (3 mg/kg) twice, 12 and 1 h before the experiment, intra peritoneal and were analysed in a tail bleeding assay, arterial thrombosis and the transient middle cerebral artery occlusion (tMCAO, 60 min) model of ischaemic stroke.
Results: In agreement with observations made in Pld1 and Pld1/2-deficient mice, FIPI-treated animals displayed impaired thrombus formation. Upon application of $FeCl_3$ on the carotid artery, 8 of 9 control vessels occluded within 10 min. In contrast, 6 of 9 vessels of FIPI treated mice remained open until the end of the 30 min observation period. Similarly, FIPI treatment resulted in smaller infarct sizes and significantly better motor function and coordination 24 h after tMCAO, and this protective effect was not associated with increased intracerebral haemorrhage. In line with this observation, no differences in bleeding times of control and FIPI-injected mice were observed, demonstrating that PLD inhibition by FIPI does not exert a major effect on normal haemostasis.
Summary/Conclusions: These results provide the first evidence that pharmacologic PLD inhibition might be a safe therapeutic strategy to prevent or treat arterial thrombosis and ischaemic stroke.

PO 496

Brachial artery endothelium-dependent flow-mediated dilation and carotid artery intima-media thickness in the cardiac pacing patients

Janczura M[1], Januszek R[2], Dropinski J[2], Kotula-Horowitz K[2], Lelakowski J[1], Musial J[2] and Domagala TB[2]

[1]The John Paul II Hospital, Krakow; [2]Jagiellonian University School of Medicine, Krakow, Poland

Background: After pacemaker implantation in the patients with brady-tachy syndrome, sick sinus syndrome (SSS) and atrial ventricular block (AVB II, III gr.), the left ventricule (LV) function improved. Flow-mediated dilation (FMD) of brachial artery, being a marker of *in vivo* NO bioavailability, is also predictive of future cardiovascular events. Dynamic changes in the FMD of brachial artery in the cardiac pacemaker recipients still require further in-depth research. Also the carotid artery intima-media thickness (CIMT) is a marker of prevalent and incident cardiovascular disease and is widely used as an indicator of generalized atherosclerotic burden.
Aim: To assess the dynamics of endothelium-dependent FMD and CIMT in the patients with two modes of cardiac pacing.
Methods: The study group comprised 92 cardiac pacing subjects (38 F, mean age 71 ± 7.58 years), divided in line with respective modes of cardiac pacing: Group A (n = 64; mean age 70.20 ± 7.70 years) with physiological (DDD) pacing; Group B (n = 28; mean age 72.70 ± 10.20 years) with non-physiological (VVI) pacing. Cardiac picemakers were implanted due to SSS, AVB (II, III gr.), atrial fibrillation cum bradyarrhythmiae, respectively. Transthoracic echocardiography was performed prior and after pacemaker implantation. LV ejection fraction (LVEF) and LV diastolic function were calculated, and left and right ventricular end-diastolic diameters (LVEDD/RVEDD) were measured. Endothelium-dependent FMD of brachial artery in response to reactive hyperemia and CIMT were non-invasively evaluated by high-resolution ultrasound. Both measurements were taken five times: at baseline, after 7 days, and within 1, 3, and 6 months of pacemaker implantation.
Results: At baseline, both groups differed in: LVEF ($P < 0.001$), LVEDD and RVEDD ($P < 0.0001$). Significant elevation of LVEF ($P < 0.001$), decrease of LVEDD/RVEDD ($P < 0.0001$), decrease of the left and right atrium diameter ($P < 0.0001$) were noted only after DDD pacing. At baseline the mean FMD value was non-significantly higher in Group A subjects (4.05 ± 1.70% vs. 3.76 ± 2.28% for Group A and B, respectively; P = ns). After the pacemaker implantation, the improvement of brachial artery FMD in both groups were observed at 7 days ($P = 0.01$ and $P = 0.04$, for Group A and B, respectively), and the first month ($P = 0.03$ and $P = 0.05$, for Group A and B, respectively), and within 3 ($P = 0.01$ for both Groups) and 6 ($P = 0.003$ and $P = 0.02$, for Group A and B, respectively) following months. The mean value of CIMT were similar in both study groups (0.78 ± 0.14 mm vs. 0.79 ± 0.17 mm; $P = 0.89$) and there were no differences for up to 12 months.
Conclusions: Improvement of endothelial function after pacemaker implantation may indicate an improved integrity of re-modeling and the repaired vascular function in the cardiac pacing patients.

PO 497

Talin and Src protein phosphorylation in hyperractive platelets

Fries DM[1], Debbas V[2], Neiva TJC[3], De Oliveira V[1], Santoro ML[4], Paes Leme AF[5], Rocha TRF[1] and D'Amico EA[1]

[1]Hospital das Clinicas-FMUSP, Sao Paulo; [2]Instituto do Coracao-FMUSP, Sao Paulo; [3]Analises Clinicas-UFSC, Florianopolis; [4]Instituto Butantan, Sao Paulo; [5]Biosciences National Laboratory (LNBio), Campinas, Brazil

Background: Sticky platelet syndrome (SPS) is a disorder distinguished by platelet hyperreactivity in response to physiologic stimuli, in conjunction with clinical arterial or venous thrombotic events, and without coagulation disorders. SPS is associated with transient or permanent vascular occlusions, resulting in acute myocardial infarction, transient ischemic cerebral attacks and strokes, and recurrent venous thromboembolism.
Aim: We aimed here to identify which proteins have an altered association with the outer platelet surface molecules upon thrombin stimulation in SPS patients.
Methods: SPS and normal platelets were activated with thrombin, and then changes in protein expression were analyzed by one-dimensional electrophoresis followed by LC-MS/MS analysis and Western-blotting. This study was approved by the institutional review board, and all individuals gave written consent.
Results: Proteomic analysis of thrombin-activated platelets reveal that talin protein was six-fold more expressed in SPS patients, while Src protein (proto-oncogene tyrosine-protein kinase), was 15-fold more expressed in normal individuals. By Western blotting, the level of talin phosphorylation was 10-fold higher in SPS patients than in normal individuals ($P < 0.05$). Among normal individuals and SPS patients, there was a statistically significant difference on Src expression ($P = 0.02$), however, the activity of Src Y418 was found to be much

higher in patients compared to the protein expression. Analysis of Src phosphorylation in thrombin-stimulated SPS platelets revealed approximately three-fold higher phosphorylation levels in the activating site in Src (pTyr-Src418), with a parallel decline of Src (total) expression, compared to healthy individuals. As we did not observed dephosphorylation of Src Y529 in SPS patients, we conclude that an independent regulatory mechanism, might be involved in Src kinase activation.

Conclusion: A significant increase in tyrosine phosphorylation levels in Src Y418, as well as in talin, suggests that these proteins may play a critical role in controlling integrin activation in SPS patients.

PO 498

Treatment modalities and outcomes in 870 non-surgical bleeds in 184 Glanzmann thrombasthenia (GT) patients. The International Prospective Glanzmann's Thrombasthenia Registry (GTR)

Di Minno G[1], D'Oiron R[2], Zotz R[3] and Poon M-C[4]

[1]Federico II University, Naples, Italy; [2]University Paris XI-Hopital Bicetre, Paris, France; [3]Hemostasis Institute, Dusseldorf, Germany; [4]University of Calgary Foothills Hospital, Calgary, Canada

Background: Standard treatment for GT, a severe autosomal recessive bleeding disorder with defective platelet $\alpha_{IIb}\beta_3$, is platelet transfusion. Recombinant FVIIa (rFVIIa) has been effective in GT with platelet antibodies and/or platelet refractoriness.

Aims: To assess the efficacy of rFVIIa, compared to other systemic hemostatics in GT with or without antibodies and/or refractoriness for surgical prophylaxis.

Methods: Analysis of data from GTR, an international multicenter observational study on the efficacy and safety of rFVIIa and other treatment modalities for bleeding and surgery in GT patients.

Results: From 2004–2011, GTR enrolled 218 patients from 45 sites (15 countries, 4 continents) with 1073 admissions. Out of these, 96 patients (F/M: 52/44 [54%/46%]; age ≥18 year, 69 [72%]) were treated for 204 surgical procedures (minor/major, 167/37 [82%/18%]). Out of 55 patients with known disease type, 48 (87%) had type 1 GT. History of antibodies were reported in 43 patients [45%], refractoriness in 23 [24%], and antibodies + refractoriness in 17 [18%], while 47 [49%] had no antibodies/refractoriness. Treatments analyzed include antifibrinolytics (AF), rFVIIa ± AF (r7), platelets ± AF (P) and rFVIIa + platelets ± AF (r7 + P). The top minor procedures were dental (n = 132, 79%), endoscopy (n = 11, 6.6%) and nasal (n = 8, 4.8%). The top major procedures were GI (n = 9, 24.3%) and orthopedic (n = 9, 24.3%). Most frequent treatment for minor procedures was r7 (n = 120 [72%]); and for major procedures, r7 and r7 + P (13 [35%] each). In GT with no antibodies/refractoriness, r7 was 100% efficacious for both minor (n = 41) and major procedures (n = 7), similar to or better than that for P (minor 11/11 = 100%; major 5/6 = 83%) and r7 + P (minor 4/4 = 100%; major 6/9 = 67%). In GT with antibodies and/or refractoriness, the efficacy of r7 (minor procedures 69/79 = 87%; major 4/6 = 67%) was not inferior to that for P (minor 10/14 = 71%; major 2/2 = 100%) and r7 + P (minor 7/9 = 78%; major 2/4 = 50%). A few patients were treated with AF alone, with an overall efficacy rate of 56% for nine minor procedures, but 100% for three major procedures. rFVIIa was generally given initially at a median of ~90 μg/kg at ~2 h intervals, for both minor (median 2–3 doses) and major (number of doses: higher and variable) procedures. The median (mean ± SD) number of platelet units used in patients with no antibodies and/or refractoriness, was 1 (2 ± 1) for minor and 5 (8 ± 7) for major procedures. In patients with antibodies and/or refractoriness, the median platelet use was higher and variable, up to 60 U for one major procedure. Only one thromboembolic event occurred in an adult female with refractoriness treated with r7 + P for a major procedure. One additional allergic reaction was attributed to platelets.

Summary/Conclusions: (1) The GTR provides the largest experience to date on surgical procedures in GT. (2) GTR results show that the efficacy of rFVIIa ± AF was similar to platelets ± AF and rFVIIa + platelets ± AF in surgical procedures in GT patients, regardless of investigator-reported antibodies/refractoriness status. (3) rFVIIa ± AF was safe for surgical procedures. (4) Platelets were efficacious in GT patients with investigator-reported antibodies and/or refractoriness, but higher doses were reported. (5) The combined use of rFVIIa + platelets could be attributed to the insufficient efficacy of one or the other alone.

PO 499

The significance of TEG and TGA in the evaluation of hemostasis in children with cyanotic and acyanotic congenital heart diseases

Balkan C, Gokce S, Karapinar D, Ulger Z, Karadas N and Kavakli K

Ege University Children's Hospital, Izmir, Turkey

Background: Patients with cyanotic congenital heart disease (CHD) have hemostatic abnormalities, which result in an increased risk of bleeding. The cause is unknown, but recent studies have indicated that an elevated hematocrit, which is present in cyanotic patients, could be an important factor.

Aims: In this study, we aimed to evaluate the hemostatic state of children with cyanotic and acyanotic CHD by using thromboelastography (TEG) and thrombin generation assay (TGA).

Methods: Seventy four patients with CHD (39 acyanotic, 35 cyanotic; ages were between 0 and 18 years) were enrolled in this study. Twenty nine, age matched, healthy children were enrolled as a control group. Hemogram, PT, aPTT, TEG and TGA results were evaluated in all patients before angiography and cardiac surgery.

Results: In the cyanotic group, as expected, hematocrit levels were significantly higher than acyanotic and control groups (P = 0.000). When compared to the acyanotic patients, PT anda PTT results were significantly higher in the cyanotic group (P = 0.011 and P = 0.037 respectively). When TEG parameters were analyzed, TEG-R values were significantly longer in cyanotic patients than acyanotic and control groups (P = 0.000 for both groups). Alpha-angle degree and maximum amplitude (MA) values were significantly lower in cyanotic group than acyanotic (P = 0.001) and control (P = 0,005) groups. When TGA parameters were analyzed, peak thrombin levels were significantly lower in cyanotic group than acyanotic and control groups (P = 0.000, P = 0.000 respectively). When compared to control group, peak thrombin time results were significantly longer in cyanotic and acyanotic groups (P = 0.014, P = 0.028 respectively). Endogenous thrombin production was significantly lower in cyanotic group than acyanotic and control groups (P = 0.000, P = 0.000 respectively).

Conclusion: While it is well known that high hematocrit levels increase the tendency for thrombosis in cyanotic heart disease, TEG and TGA results in our study show that there are also coagulation abnormalities in these patients.

Caspase-8 activation can be triggered in platelets through the intrinsic apoptosis pathway

Mutlu A, Gyulkhandanyan AV, Freedman J and Leytin V

St. Michael's Hospital, Toronto, Canada

Background: Since the seminal report of Vanags et al. (Br J Haematol, 1997), programmed cell death, apoptosis, has been demonstrated not only in nucleated cells, but also in anucleate platelets. While the *intrinsic* (mitochondria-dependent) apoptosis pathway in platelets is well-documented,the role of the *extrinsic* (death ligand-death receptor-dependent) pathway in platelets remains unclear.

Aims: To address this question, in this study, we initiated platelet apoptosis through the intrinsic pathway, using BH3-only mimetic ABT-737 and calcium ionophore A23187, agents that trigger the mitochondrial platelet apoptosis. Our particular interest was to examine whether activation of caspase-8, a caspase 'classically' defined as an initiator caspase of the extrinsic apoptosis pathway, can be induced in platelets treated *in vitro* with ABT-737 and A23187 via the intrinsic pathway.

Methods: Platelets were treated with 30 μM ABT-737, 10 μM A23187 and control diluent buffer for 90 min at 37 °C, and platelet apoptosis was analyzed by flow cytometry using three experimental settings: assays of (i) caspase-9 activation, an initiator caspase of the intrinsic apoptosis pathway, (ii) caspase-8 activation, an initiator caspase of the extrinsic pathway, and (iii) caspase-3 activation, an executioner caspase of apoptosis, each in combination with P-selectin (CD62) exposure on the platelet surface for concomitant determination of platelet activation.

Results: Flow cytometric fluorescence histogram analysis demonstrated that treatment of platelets with ABT-737 and A23187 significantly increased activation of caspase-9 and caspase-3 in comparison to diluent buffer ($P < 0.0001$). Notably, both agents also induced activation of initiator caspase-8 of the extrinsic apoptosis pathway ($P < 0.0001$). Mean levels of activation of all three caspases (9, 8 and 3) were not significantly different ($P > 0.05$), indicating that ABT-737 and A23187 did not trigger an additive or synergistic activation of executioner caspase-3 by initiator caspases-9 and -8. Dual-fluorescence dot-plot analysis of caspase-9, -3 and -8 activation versus CD62 exposure shows that ABT-737-treated platelets are predominantly (63.7–72.7%) apoptotic but not activated, whereas A23187-treated platelets are predominantly both apoptotic and activated (64.3–74.3%).

Conclusions: We demonstrated that apoptosis induced by treatment of platelets with ABT-737 and A23187, which is not triggered by the interaction of death ligands with death receptors, yields caspase-8 activation in platelets without participation of the extrinsic apoptosis pathway. These data indicate that caspase-8 activation does not always represent a marker of the extrinsic pathway of apoptosis. Despite caspase-8 activation in ABT-737- and A23187-stimulated platelets occurring via bypass of the death receptors, the major 'final goal' of the extrinsic pathway, i.e. an activation of initiator caspase-8, is achieved. The mechanism of this death-receptor-independent mitochondria-initiated caspase-8 activation may take place in platelets as described in some types of nucleated cells, which are less dependent on the extrinsic pathway of apoptosis and in which active caspase-9 propagates a cascade of caspase activating reactions, including activation of executioner caspase-3, followed by activation of downstream executioner caspase-6 which, in turn, activates caspase-8. Caspase cascade reactions permit caspase-mediated cross-talk between intrinsic and extrinsic apoptosis pathways in platelets and can broaden the repertoire of caspase-cleaved protein substrates.
